Fig. 3 Sucrose density gradient fractionation of different molecular forms of AChE. Chick muscles were plated at 3×10^5 cells per 60-mm culture dish. On day 3, 6-d embryonic chick spinal cords were dissociated and added ($2–3 \times 10^6$ cells per dish) to the muscle cultures in the presence of 10^{-5} M cytosine arabinoside with or without 50 μM curare. Five days later, three control and three curare-treated cultures were rinsed with Earle's balanced salt solution and the cells were collected by scraping with a Teflon policeman in phosphate-buffered saline containing 0.2 mM EDTA, *p*H 7.4. The cell suspension was centrifuged at 12,000*g* for 5 min and resuspended in 1 M NaCl, 0.5% Triton X-100, 0.05 M Tris-HCl, 0.2 mM EDTA and 1 mg ml^{-1} DNase (Sigma), *p*H 7.3. After 1 h at 0 °C, this suspension was centrifuged at 12,000*g* for 15 min and the supernatant assayed for protein[34] and AChE activity[35]. An aliquot (approximately 400–600 μg per 125 μl) was layered onto a 5–20% linear sucrose gradient and centrifuged in a Spinco SW41 rotor at 205,000*g* for 18 h at 4 °C. Sixty 0.25 ml fractions were collected and assayed for AChE by the radiometric method of Potter[36], as modified by Hall[19]. Three peaks of activity sedimenting at 7S, 11S and 19.5S were evident in the control gradient (left). Activity in the 19.5S peak was reduced at least fourfold by curare treatment (right). This figure shows the maximum 19.5S activity found in curare-treated cultures in five different experiments (platings). Gradient markers were alcohol dehydrogenase (4.8S), catalase (11.3S) and β-galactosidase (16S).

(e.p.p.s), but not impulse-independent miniature endplate potentials. Moreover, AChE did not accumulate in low concentrations (3 μM) of curare, which only reduced the mean e.p.p. by 50%.

Although 3 μM curare did not completely block e.p.p.s, most of the synaptic potentials were subthreshold; few innervated fibres were mechanically active. We therefore examined the role of muscle activity in the induction of synaptic AChE by electrically stimulating individual muscle fibres in the presence of curare. Spinal cord–muscle cultures were grown in 50 μM curare, and $\bar{\tau}_{syn}$ was again determined at previously identified sites of transmitter release. Chronic stimulation in the presence of curare significantly decreased τ_{syn} (Fig. 4). Eight synapses at which $\bar{\tau}_{syn}$ was greater than 2.21 ms were studied before and after stimulation (Table 2). Chronic stimulation in the presence of curare significantly decreased $\bar{\tau}_{syn}$ at seven of these synapses to values typical of fast, AChE-positive sites. One other synapse was fast ($\bar{\tau}_{syn} = 1.54$ ms) before stimulation, and its decay constant did not decrease further.

Influence of dibutyryl cyclic GMP on AChE

During these experiments, we found that low concentrations (25–100 μM) of dibutyryl cyclic GMP can reverse the curare inhibition of AChE accumulation. $\bar{\tau}_{syn}$ was determined at 114 synapses in cultures grown in 50 μM curare with dibutyryl cyclic GMP: 64% were fast and only 3.5% were slow. These percentages are comparable to those obtained with untreated control cultures (Table 1). The effect of dibutyryl cyclic GMP was also evident when AChE was assayed histochemically. Reaction product was present at 70% of identified synapses in cultures of curare plus dibutyryl cyclic GMP. Finally, dibutyryl cyclic GMP reversed the curare inhibition of 19.5S AChE assembly (Fig. 5) without increasing the total AChE activity. In six experiments, the ratio of total AChE (control/dibutyryl cyclic GMP treated) was 1.15±0.25 (mean±s.d.). Dibutyryl cyclic GMP did not 'induce' 19.5S AChE in muscle cells or in spinal cord neurones grown alone. Other agents, including GMP, GTP and dibutyryl cyclic AMP, did not reverse the curare inhibition of synaptic AChE accumulation or assembly of the 19.5S form.

Table 2 Effect of direct muscle stimulation on $\bar{\tau}_{syn}$

Synapse no.	Before	After	% Change
1	2.21±0.70	1.74±0.32	21.3
2	3.09±1.39	1.74±0.39	43.7
3	2.25±0.73	1.35±0.20	40.0
4	3.06±1.04	2.05±0.71	33.0
5	3.19±1.56	1.87±0.49	41.4
6	3.14±0.87	1.75±0.37	44.3
7	2.59±1.15	1.80±0.41	30.5
8	2.42±0.92	2.30±0.65	5.0
9	1.54±0.35	1.51±0.21	1.9

$\bar{\tau}_{syn}$ (±s.d.) was determined from the time constants of decay of at least 20 extracellular potentials recorded at the same synapses in curare-treated cultures before and after direct electrical stimulation of myotubes in the presence of 50 μM curare for 8–12 h at 2–3 Hz and 35–36 °C.

Conclusions

The early accumulation of AChE at newly formed nerve–muscle synapses *in vitro* depends on synaptic transmission. By our physiological and histochemical criteria, the activity of the enzyme is greatly reduced at synapses that form in the presence of curare. Although 19.5S AChE is not restricted to adult chick endplates, it is significant that this form of the enzyme was selectively decreased in curare-blocked cultures.

Of the several events that follow synaptic transmission, muscle activity (electrical and/or mechanical) seems to be the crucial factor, as AChE does accumulate at curare-blocked synapses when innervated myotubes are stimulated directly. Lømo and Slater[23] have also emphasised the role of muscle activity in AChE accumulation at ectopic synapses on adult rat muscle fibres. Weinberg and Hall[24] suggested muscle activity as an explanation for their observation that 16S AChE (and AChE histochemical reaction product) reappears at denervated rat endplates when the denervated muscles are reinnervated at another site. Koenig and Vigny[21] detected 16S AChE in control rat spinal cord–muscle co-cultures but not in inactive cultures grown in the presence of tetrodotoxin[25]. Inadequate muscle activity may explain why no evidence was obtained for AChE activity at nerve–muscle synapses when chick muscle cultures were seeded with a relatively small number of dissociated spinal cord neurones[26]. In this system, innervated myotubes twitch more frequently than uninnervated myotubes, but the overall activity is far less than that observed in innervated myotubes near intact spinal cord explants.

In contrast to the situation with AChE, the clustering of AChRs in the postsynaptic membrane does not depend on activity. Thus, the formation of AChR clusters in the postsynaptic membrane and the accumulation of AChE in the synaptic cleft are not necessariinked. This result does not rule out the possibility that AChE and AChRs are synthesised and transported to the cell surface in a coordinated manner. Muscle activity may simply ensure the anchorage of AChE to the basal lamina of the synaptic cleft.

Muscle activity is probably not the sole determinant of synaptic AChE. Nerve extracts slow the rate of AChE disappearance, measured biochemically, from adult muscle maintained in organ culture[27,28], and saline extracts of central nervous tissue increase total AChE of uninnervated embryonic myotubes in culture[29,30]. Although it is difficult to compare these biochemical estimates of total (intracellular as well as extracellular) AChE with our physiological and histochemical assays, which detect AChE exposed on the cell surface at synapses, our emphasis on the importance of muscle activity is not inconsistent with the notion that synaptic AChE is also regulated by soluble factors supplied by motor nerves. The fact that AChE and AChRs are restricted to sites of transmitter release argues for a local neural influence. Moreover, we have identified AChE-positive and AChE-negative synapses within 500 μm of one another on the same myotube (Fig. 7 in Rubin *et al.*[6]). If both contacts were formed at approximately the same time and if both were exposed to the same degree of muscle activity, some additional factor must be required. Muscle activity may be 'permissive', allowing neuronal factors to exert their effects.

Addition of dibutyryl cyclic GMP to cultures grown in curare mimics the effects of muscle activity on synaptic AChE and on assembly of the 19.5S form of the enzyme. Of interest in this regard is the finding that stimulation of adult skeletal muscle results in an increase in cyclic GMP levels[31]. Neither result demonstrates a necessary connection between activity and cyclic GMP in regulating the appearance of AChE. Perhaps a stronger argument for such a connection could be made if muscle activity and cyclic GMP treatment resulted in phosphorylation of the same muscle proteins.

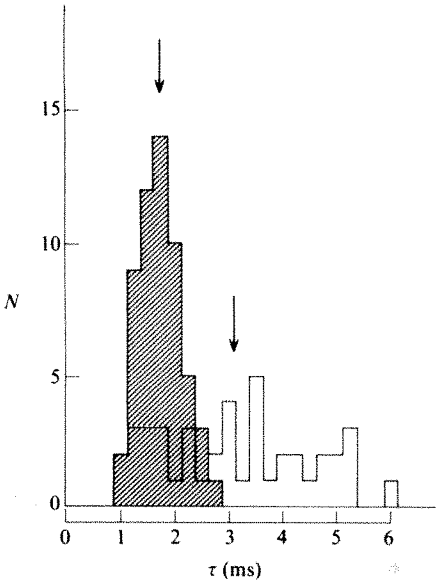

Fig. 4 Chronic muscle stimulation in the presence of curare decreases $\bar{\tau}_{syn}$. This culture was grown in 50 μM curare for 4 d, at which time synaptic current decays (recorded during a brief period of curare washout) at this synapse were prolonged (unshaded histogram). Immediately after the recordings were made, the culture was returned to medium with 50 μM curare, and the innervated myotube was electrically stimulated at 3 Hz for 11 h at 35–36 °C. Immediately after stimulation and curare washout, the same synapse was relocated and a clear decrease in $\bar{\tau}_{syn}$ was observed (shaded histogram). The variance of τ_{syn} was also decreased. All recordings were obtained at 30 °C. Arrows indicate $\bar{\tau}_{syn}$.

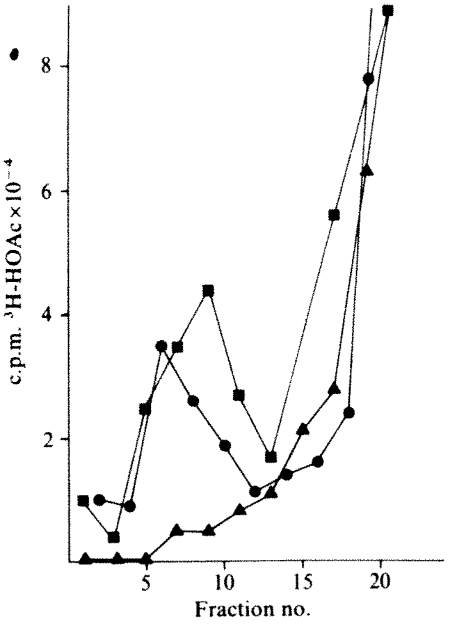

Fig. 5 19.5S AChE appears in spinal cord–muscle cell cultures grown in curare plus dibutyryl cyclic GMP. Cultures were grown without added drugs (●), with 50 μM curare (▲) or with 50 μM curare plus 100 μM dibutyryl cyclic GMP (■). Extracts were prepared and sucrose gradients run, as described in Fig. 3 legend. Only the high-molecular weight region of the gradient is shown. Assembly of 19.5S AChE was nearly completely blocked by curare, but this inhibition was reversed by adding dibutyryl cyclic GMP.

Interactions between the carbohydrate chains of hyaluronate and chondroitin sulphate

E. A. Turley & S. Roth

Department of Biology, Johns Hopkins University, Baltimore, Maryland 21218

Hyaluronic acid-derivatised beads spontaneously agglutinate with chondroitin sulphate-derivatised beads although neither bead type shows any self-agglutination. The interaction between hyaluronate and chondroitin sulphate is specific for these two glycosaminoglycans and appears to occur between their carbohydrate chains.

ALMOST all mammalian cells contain glycosaminoglycans as a part of their coat and extracellular material[1]. All of the glycosaminoglycans so far studied, except hyaluronic acid, are sulphated and covalently linked to protein[1,2]. Hyaluronate, by contrast, is known to bind noncovalently to the protein portion of the proteoglycans[3]. The biological functions of these polymers are poorly understood. Glycosaminoglycans are apparently important structural molecules and have long been thought to function in the regulation of cation and H_2O binding as well as the control of macromolecular distribution by steric exclusion[4]. More recently, glycosaminoglycans have been implicated in cell adhesion[1,5,6], organogenesis[7], and differentiation[8]. In particular, the excellent correlation between cell migration *in vivo*[8–11] and *in vitro*[12] and the elevated levels of hyaluronate and chondroitin sulphate suggest that a cell–glycosaminoglycan interaction may be important for cell movement. Some of these biological effects may be due to the ability of the glycosaminoglycans to bind to cell surface components. Binding and chemical cross-linking studies[13] have indicated that the cell-surface glycoprotein fibronectin exists in close proximity to both hyaluronic acid and the sulphated glycosaminoglycans. This report demonstrates that chondroitin sulphate and hyaluronic acid are capable of a specific binding interaction with each other and this interaction occurs between the carbohydrate chains of the polymers. This observation raises the possibility that glycosaminoglycans located at the cell surface may function as binding sites and, therefore, be involved in cellular adhesive and recognition phenomena.

Derivatisation of the glycosaminoglycans

Solutions of chondroitin-4-sulphate (C-4-S), chondroitin-6-sulphate (C-6-S), hyaluronic acid (HA) dermatan sulphate, and heparin were dialysed and protein levels were shown to be <0.1%. The polymers were attached to Dowex AG 50 W-X-1 beads (50–100 mesh) by first converting the beads to the sulphonamide form and then incubating them with one of the

Table 1 Binding of chondroitin sulphate and hyaluronic acid to polysulphonamide beads

Concentration of glycosaminoglycan (μg per 100 mg beads, wet wt)	Glycosaminoglycan attached (μg per mg beads, dry wt)	Concentration of glycosaminoglycan (μg per 100 mg beads, wet wt)	Glycosaminoglycan attached (μg per mg beads, dry wt)
Chondroitin 6-sulphate		Hyaluronic acid	
15,000	100–130	15,000	25–30
1,500	10–12	1,500	12–15
150	1.0–1.4	150	5–7
15	0.1	15	1–5
1.5	<0.04		

Chondroitin-4-sulphate, chondroitin-6-sulphate, dermatan sulphate and heparin were purchased from Sigma Chemicals. Hyaluronic acid was a gift from Dr B. Toole. All the glycosaminoglycan solutions were dialysed for 24 h against distilled water, lyophylised and stored, desiccated, until use. To determine the degree of molecular weight homogeneity, the compounds were chromatographed on Sephadex G-200 in a buffer[14] containing 1% SDS (w/v), 10^{-4} M Na_2EDTA, 10^{-3} M dithiothreitol, 10^{-3} M sodium azide and 0.05 M phosphate buffer (*p*H 7.2). Fractions were assayed for carbohydrate with phenolsulphuric acid[15] and for protein by the Lowry method[16], by UV absorbance at 260 and 280 nm (ref. 17), 215 and 225 nm (ref. 18) and by the Bio-Rad protein assay[19]. Hyaluronic acid eluted in the Sephadex void volume whereas the other glycosaminoglycans were retarded and eluted as a single, symmetrical peak when assayed for carbohydrate. In assay conditions that could detect 10 μg protein, no protein was detectable in aliquots containing 10 mg of either chondroitin sulphate or hyaluronic acid. These carbohydrate preparations, therefore, contained less than 0.1% protein. To derivatise beads with the glycosaminoglycans, Dowex AG 50 W-X-1 (50–100 mesh) beads (Bio-Rad) were converted to the sulphonamide form by incubation in ammonium hydroxide (5 g beads per 10 ml NH_4 OH) at room temperature for 24 h. The beads were then washed exhaustively in distilled water and 0.1 g wet weight of the beads was added to 1 ml of an aqueous solution of either chondroitin-6-sulphate (0.0015–15 mg ml^{-1}) or hyaluronic acid (0.015–15 mg ml^{-1}). Each incubation also contained five times more (w/w) of the catalyst 1-ethyl-3-(3-dimethyl-aminopropyl)carbodiimide (Sigma) than glycosaminoglycan. The glycosaminoglycan solution and beads were incubated for 48 h at 35–37 °C after which the beads were washed extensively in distilled water and, finally, in aseptic, phosphate-buffered saline (PBS) in which they were stored. Aliquots of the derivatised beads were analysed by subjecting the beads to hydrolysis in 90% formic acid at 100 °C for 6 h. The hydrolysates were evaporated to dryness and the resultant monosaccharides were assayed for uronic acid by the Dische assay[20] in the case of hyaluronic acid. To monitor the derivatisation of the chondroitin sulphates, tritiated chondroitin sulphates (1×10^{10} c.p.m. per mg) were prepared by galactose oxidase treatment followed by reduction with sodium borotritide as described previously[12]. The labelled compound was then used in the carbodiimide-catalysed derivatisation procedure. The hydrolysed monosaccharides were evaporated to dryness, redissolved in H_2O and counted in a scintillation counter. Values represent the ranges of two separate experiments.

0028–0836/80/030268—04$01.00

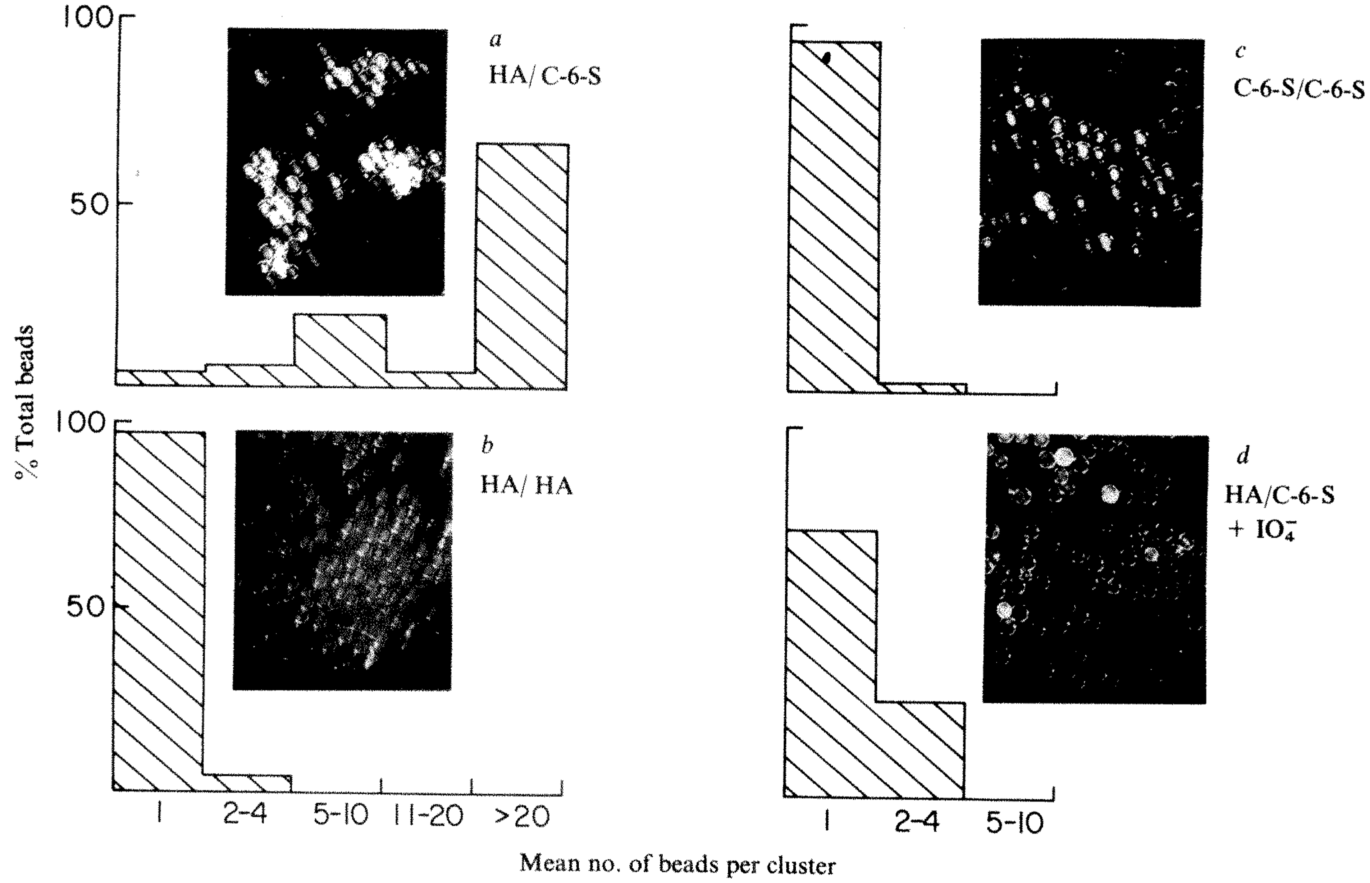

Fig. 1 The heterologous (*a*) and homologous (*b*, *c*) interaction of sulphonamide beads derivatised with either hyaluronic acid or chondroitin-6-sulphate. Agglutination assays were performed in 35 × 10 mm Falcon tissue culture dishes and initiated by adding 0.01 g of each of the desired bead types in 0.1 ml PBS (*p*H 7.4) to 2 ml of PBS at 4 °C. Approximately 30 μg of hyaluronic acid or 100 μg of chrondroitin 6-sulphate were derivatised to each mg of beads (dry weight). The dishes were agitated gently for 5 min at 4 °C. Agglutination was scored 12 h later by counting beads occurring in clusters or as single beads under a dissecting microscope. Dishes were shaken before counting the beads to separate loosely associated beads. The number of beads in each of the initial 0.1 ml aliquots was determined before the experiments were begun and the data are expressed as the mean number of beads per cluster. A total of 300 beads were counted in each agglutination assay. The experiment was repeated 20 times with different bead preparations and the results were quantitatively identical.

polymer solutions in the presence of a carbodiimide catalyst[12]. Details of the derivatisation and hydrolysis procedures are given in the legend to Table 1. The data in Table 1 show that the amount of HA and C-6-S derivatised to the beads is proportional to the amount of each compound present in solution during the incubation with carbodiimide. When HA and C-6-S were each present at 15 mg ml^{-1}, the highest concentration tested during the derivatisation incubation, more than 100 μg C-6-S became attached to 1 mg dry weight of the beads, whereas 25–30 μg hyaluronic acid became attached in identical conditions.

Agglutination assays with derivatised beads

Agglutination assays were performed as described in the legend to Fig. 1. Agglutination is pronounced when C-6-S beads are mixed with HA beads. Neither bead type shows any tendency towards self-agglutination. When HA beads are mixed with C-4-S beads, there is an agglutination reaction although it is approximately 40% as extensive as the reaction that occurs when HA beads and C-6-S beads are mixed. HA beads show only minimal agglutination when mixed with beads derivatised with heparin or dermatan sulphate. It is not clear whether the HA/CS interaction is specific for C-6-S and if this compound is contaminating our preparations of C-4-S, or whether hyaluronate will interact with either of the two chondroitins but with C-4-S to a lesser degree. The agglutination reactions described here were unaffected by temperature from 4° to 37 °C, calcium ion concentration of 0–20 mM, osmolarity of 0–300 mosM, and time of 5 min to 12 h.

Since the amount of sulphated glycosaminoglycan, other than C-6-S, bound to the beads was not measured, the decreased degree of agglutination may reflect a difference in concentration. There is no measurable agglutination among HA beads themselves or among beads subjected to the derivatisation procedures but without glycosaminoglycans. Hyaluronic acid beads initially agglutinate weakly with the underivatised beads but the interaction disperses within several hours.

C-6-S beads also show no self-agglutination, and they do not agglutinate underivatised beads or beads coated with other sulphated glycosaminoglycans. The absence of such homotypic agglutination can be seen in Fig. 1*b* and *c*. By contrast, the agglutination that occurs when these two bead types are mixed is shown in Fig. 1*a*. It is unlikely that the agglutination between the HA beads and the C-6-S beads reflects a nonspecific ionic attraction of charged polymers since neither bead type shows any tendency to self-agglutinate in the conditions tested here.

Since the glycosaminoglycans used in these experiments are 99.9% free of protein it is probable that the agglutination results from interactions between the carbohydrate chains of the hyaluronic acid and chondroitin sulphate. Further evidence for this conclusion can be seen in Fig. 2. The data in the left column of Fig. 2 show that the HA bead/C-6-S bead interaction is sensitive to mild periodate oxidation of either bead type. However, periodate oxidation of C-6-S has less effect on the HA/C-6-S interaction than oxidation of the hyaluronic acid polymer. This may reflect the relative resistance of C-6-S to periodate oxidation[19]. The right-hand column shows that HA bead/C-4-S bead interaction is abolished when C-4-S beads are treated with galactose oxidase. The lower right panel of Fig. 2

shows that the inhibition of agglutination by galactose oxidase can be partly reversed if the oxidised C-4-S beads are subsequently reduced with borohydride. C-4-S beads treated with galactose oxidase and 10–100 mM of the competitive substrate, galactose, retained their ability to agglutinate with HA beads. Heat-denatured galactose oxidase had no effect on the HA bead/C-4-S interaction and the active enzyme had no effect on HA beads. These results are consistent with the specificity of galactose oxidase for the C-6 hydroxyl group of galactosides and acetylated galactosaminides. Beads derivatised with oligosaccharide fragments of HA or C-6-S, prepared by digestion with testicular hyaluronidase and estimated to contain 8 residues by gel chromatography, agglutinated to a lesser extent than the beads derivatised with untreated polymers. Trypsin had no effect on HA bead/C-6-S bead interaction. In another experimental series, hyaluronate and chondroitin sulphate were subjected to mild base hydrolysis and reduction by sodium borohydride[22] to release residual protein. When these polymers were attached to beads, the HA bead/C-6-S bead agglutination occurred normally. These data, coupled with the relative absence of protein in the glycosaminoglycan preparations, suggest strongly that agglutination between beads containing hyaluronic acid and chondroitin sulphate represents a carbohydrate–carbohydrate interaction.

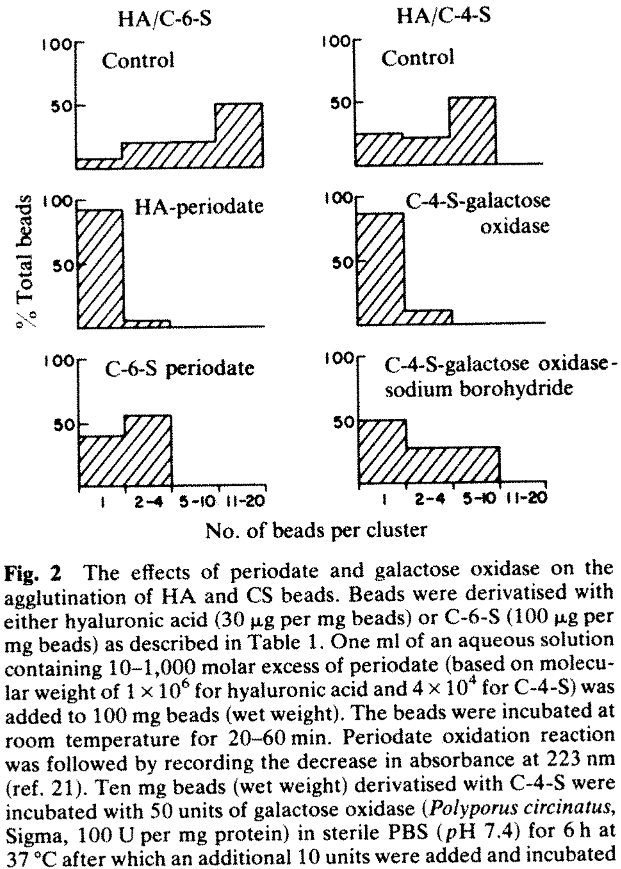

Fig. 2 The effects of periodate and galactose oxidase on the agglutination of HA and CS beads. Beads were derivatised with either hyaluronic acid (30 µg per mg beads) or C-6-S (100 µg per mg beads) as described in Table 1. One ml of an aqueous solution containing 10–1,000 molar excess of periodate (based on molecular weight of 1×10^6 for hyaluronic acid and 4×10^4 for C-4-S) was added to 100 mg beads (wet weight). The beads were incubated at room temperature for 20–60 min. Periodate oxidation reaction was followed by recording the decrease in absorbance at 223 nm (ref. 21). Ten mg beads (wet weight) derivatised with C-4-S were incubated with 50 units of galactose oxidase (*Polyporus circinatus*, Sigma, 100 U per mg protein) in sterile PBS (*p*H 7.4) for 6 h at 37 °C after which an additional 10 units were added and incubated for another 12 h. The enzyme solution was decanted and beads were washed in sterile PBS twice and heated at 100 °C for 15 min to inactivate the residual enzyme. One half of the enzyme-treated beads were subsequently incubated with 10 mM sodium borohydride for 10 h at room temperature. Unreacted sodium borohydride was then destroyed by careful addition of 0.1 M acetic acid. Oxidised and reduced C-4-S beads were again washed several times and then assayed for their ability to agglutinate with HA-beads as described in Fig. 1. Incubation of C-4-S beads with galactose oxidase and the competitive substrate, galactose, with boiled enzyme or with sodium borohydride, glycerol or acetic acid did not alter agglutination with HA beads. This experiment, like those reported in Figs 3 and 4, was repeated four times with different bead preparations and the results was quantitatively identical. A total of 300 beads were counted for each assay.

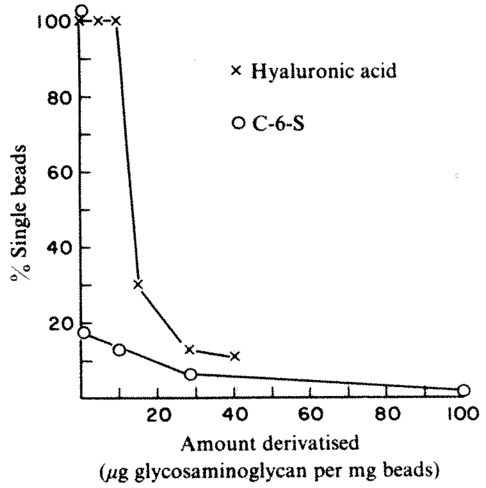

Fig. 3 The agglutination of HA beads with C-6-S beads as a function of the amount of polymer derivitised to beads. Beads were incubated with 0.1 to 15 mg per 100 mg beads of either HA or C-6-S together with 5 times (w/w) that amount of carbodiimide as described in Table 1. Aliquots of beads derivitised with 0–100 µg C-6-S per mg bead (dry weight) were mixed with HA beads (30 µg HA per mg bead, dry weight). Similarly, aliquots of beads derivatised with 0–30 µg HA per mg bead were mixed with C-6-S beads (100 µg C-6-S per mg bead). Beads were shaken gently for 5 min and then counted as described for the agglutination assay in Fig. 1. Agglutination was expressed as per cent single beads. A total of 300 beads were counted for each assay.

The agglutination between HA beads and C-6-S beads is dependent on the amount of each polymer bound to the beads. In Fig. 3, agglutination is determined as a function of the amount of HA and C-6-S derivatised to the beads. C-6-S beads with as little as 0.1 µg polymer per mg (dry weight) bead are able to agglutinate maximally with HA beads containing 30 µg HA per mg bead. Hyaluronic acid beads, however, require at least 30 µg HA per mg bead to agglutinate maximally with beads containing 100 µg C-6-S per mg beads.

The agglutination of the C-6-S beads with the HA beads is sensitive to either hyaluronic acid or C-6-S in solution. The standard agglutination reaction was performed with increasing amounts of soluble glycosaminoglycans added to the incubation mixture (Fig. 4). The agglutination appears to be more sensitive to hyaluronic acid since as little as 5 µg ml^{-1} of this polymer is able to inhibit the agglutination of the two bead types. C-6-S in solution is not an effective inhibitor below concentrations of about 50 µg ml^{-1}. After the addition of C-6-S or hyaluronic acid, the bead clusters begin to disperse so that within 1–2 h beads are no longer agglutinated. Neither oligosaccharide fragments nor monosaccharides of hyaluronic acid or C-6-S were able to inhibit bead agglutination.

Discussion

Beads derivatised with hyaluronic acid spontaneously agglutinate beads derivatised with C-6-S when the two bead types are mixed in PBS or in distilled H_2O. The agglutination occurs within minutes at temperatures between 4 °C and 37 °C and remains stable for as long as one day. Hyaluronic acid beads also interact with beads coated with other sulphated glycosaminoglycans such as C-4-S, heparin and dermatan sulphate although to a lesser extent. Homologous interactions among beads coated with one glycosaminoglycan do not occur.

The interactions described here were obtained using glycosaminoglycan preparations containing less than 0.1% protein and this fact alone suggests that the agglutination reflects an interactive specificity between the carbohydrate chains of hyaluronic acid and chondroitin sulphate. This conclusion is further supported by other observations. The HA/sulphated glycosaminoglycan interaction is sensitive to mild periodate oxidation, to treatment with testicular hyaluronidase, which hydrolyses the carbohydrate chain of the polymers to oligosaccharides, and to galactose oxidase treatment of C-4-S. The interaction was not disrupted by trypsin treatment nor by mild base hydrolysis of the polymers in conditions reported to release protein[22]. Although periodate can affect protein, the conditions used here minimise protein oxidation[23]. The galactose oxidase used in this study was not a homogeneous enzyme and the preparation may have contained other degradative enzymes that inhibited the agglutination between the HA beads and the C-4-S beads. Three experiments suggest, however, that the inhibition was due to the action of galactose oxidase and not to impurities. First, the enzyme preparation had no effect on HA-beads. Second, the inhibition of agglutination that resulted when C-4-S beads were treated with galactose oxidase could be partly overcome by subsequent treatment with sodium borohydride. Third, galactose oxidase in the presence of the competitive substrate, galactose, had no effect on C-4-S beads. These results indicate that the galactose oxidase preparation was interacting with C-4-S polymer in a manner consistent with its catalytic specificity. It seems very unlikely, therefore, that the agglutination described in this report is mediated by protein. The most reasonable explanation is that the agglutination reflects an interaction between the carbohydrate chains of chondroitin sulphate and hyaluronic acid.

In plants and bacteria, the binding between certain homologous and heterologous carbohydrate chains is known to occur. Cellulose, the most abundant biological molecule, consists of lengthwise aggregates of glucose polymers. Also, galactomannans, glucomannans, arabinoxylans and celluloses can bind to agarose and K-carageenans. The plant pathogen *Xanthomonas* may bind to host cellulose via its galactomannan chains[3]. Suggested mechanisms for such binding between carbohydrate chains include aggregated helices, interactions along specific regions to form 'egg-box' structures, or combinations of the two[3].

The mechanism of binding between the hyaluronate and sulphated glycosaminoglycan chains described here is entirely unknown. Homologous chains of glycosaminoglycans are known to aggregate[25] and to form helices in solution[26–28]. The homologous interaction seems to differ from the HA bead/CS bead agglutination described here since homologous beads did not agglutinate with one another. The ability of soluble polymers to inhibit and to reverse the agglutination of the derivatised beads suggests that the binding may be an equilibrium with an appreciable dissociation rate.

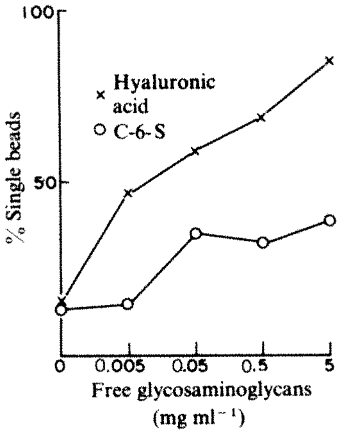

Fig. 4 The effect of soluble glycosaminoglycans on the agglutination of HA and C-6-S beads. Solutions of glycosaminoglycans were prepared by dissolving from 5 μg to 5 mg of either HA or C-6-S polymer and adding the solutions to agglutinated C-6-S and HA beads. Beads and the glycosaminoglycan solutions were incubated at 4 °C for 10 h. Beads were then counted and the extent of agglutination expressed as per cent single beads. Solutions containing monosaccharide or oligosaccharide fragments (approximately 4–8 residues) had no effect on the interaction between HA and C-6-S beads. Oligosaccharide fragments were prepared by digestion with testicular hyaluronidase (Worthington 0.4 mg ml^{-1}) in 0.1 M sodium phosphate buffer containing 0.15 M sodium chloride at *p*H 5.3[24]. The molecular weight was estimated by chromatography on Sephadex G-200 column in SDS buffer. Sephadex fractions were assayed for carbohydrate with phenol sulphuric acid[15].

There is considerable evidence to show that hyaluronate can interact with proteoglycan. Muir and her colleagues have shown, for example[29], that the elution profile of disaggregated, cartilage proteoglycans on Sepharose 2B is changed markedly by the addition of as little as 0.625% hyaluronate. The hyaluronate and the proteoglycan elute together earlier than either would have alone. It is not proposed here that the carbohydrate–carbohydrate interaction is the mechanism for such observations—merely that it is another mechanism for specific interactions among proteoglycan components.

There are at least two reasons that could account for the failure of previous experiments to detect a heterologous interaction between the carbohydrate chains of HA and CS. First, no obvious precipitation occurs when the soluble compounds are mixed. This may indicate that the number of saccharide chains involved in complex formation in solution is small. Second, when hyaluronate/proteoglycan interactions are under examination, there is no reason to believe that the heterologous interaction between the carbohydrate chains would interfere with the hyaluronate/protein interaction. The avidity with which hyaluronate binds to CS may, in fact, be much less than that with which it binds to the protein of the proteoglycans. These comparisons will require further experimentation for the precise determinations of true binding constants.

Much research has implicated the glycosaminoglycans, particularly hyaluronate and chondroitin sulphate, in cell–cell adhesion[1,5], cell–substrate adhesion[6,12], organogenesis[7], and differentiation[8]. In many embryos, the control of deposition, degradation, and the spatial arrangements of the glycosaminoglycans suggest that they may have a key role in morphogenesis. Precisely how these polymers can effect adhesive behaviour and morphogenetic phenomena is not known but a specific binding between heterologous, carbohydrate chains could represent one mechanism.

This work was supported by a postdoctoral fellowship to E.A.T. from the NCI of Canada, and by a research career development award (National Institute of Child Health and Human Development) and a research grant (NCI) to S.R.

Distribution of polarised radio emission in M31

Rainer Beck, Elly M. Berkhuijsen & Richard Wielebinski

Max-Planck-Institut für Radioastronomie, Bonn, FRG

Observations yielding the distribution of large-scale magnetic fields in nearby spiral galaxies are still extremely scarce. Optical polarisation of starlight has been observed in the disks of M31, M51, M81 and some other spiral galaxies[1–3], but these measurements are too few to reveal the general distribution and direction of the magnetic fields. Segalovitz *et al.*[4] observed the distribution of the polarised radio emission in M51 at λ21 cm and λ6 cm with sufficient linear resolution (2.6 × 3.6 kpc) and sensitivity to conclude that the magnetic field in M51 is predominantly directed along the spiral arms. The first results of detailed polarisation measurements of the emission of M31 at λ11 cm (ref. 5) indicated that in the southern part of the bright ring of radio emission the magnetic field is generally aligned along the ring. We show here that this early conclusion seems to hold for the whole of the ring.

The observations were carried out with the 100-m telescope of the Max-Planck-Institut für Radioastronomie at Effelsberg between 1977 and 1978. The dual-channel correlation polarimeter in the secondary focus operated at 2,700 MHz (system temperature, 100 K; bandwidth, 80 MHz; observed half-power beamwidth, 4.4 arc min). The flux densities and polarisation characteristics of the calibration sources 3C48, 3C138 and 3C147 were taken from Baars *et al.*[6] and Wardle and Kronberg[7]. The ratio of main beam brightness temperature T_b(K) to the flux density S(Jy) was found to be 2.3 ± 0.1. 3C147 was used to determine the spurious instrumental polarisation, which was found to be highest at 2 arc min distance from the source with ~0.5% of the total emission.

Figure 1 shows the λ11.1 cm polarisation map of M31 superimposed on an optical picture. The map covers the area $-81 < \lambda_A < +81$ arc min, $-45 < \beta_A < +45$ arc min, where the coordinates λ_A and β_A lie along the major and minor axis, respectively. The area was observed in three parts, each overlapping by 10 arc min in λ_A. The northern part and the central part were scanned both in λ_A and β_A (~10 times each), while the southern part was scanned only in β_A (~20 times). For the northern and the central parts the averages of the maps in λ_A and of the maps in β_A were combined using a technique for optimising the base levels developed by C. J. Salter. By applying this technique to the maps in Stokes parameters Q and U separately, any polarised foreground emission varying linearly across the map is eliminated. (Faraday rotation in the foreground is not affected by this procedure.)

The polarisation temperatures derived from $(Q^2+U^2)^{1/2}$ suffer from a systematic positive bias due to noise. All values in Fig. 1 have, therefore, been corrected as proposed by Wardle and Kronberg[7]. The r.m.s. noise σ in the final map is 3 mK in main beam polarisation brightness temperature T_b^p.

A map of the total intensity of the area at λ11.1 cm was obtained from the total power channels of the same observations (Fig. 2); the r.m.s. noise is 5 mK in main beam brightness temperature T_b. This new total power map does not differ significantly from the map published by Berkhuijsen and Wielebinski[8], but it has a slightly better angular resolution and lower r.m.s. noise. The new map extends further in β_A so that the

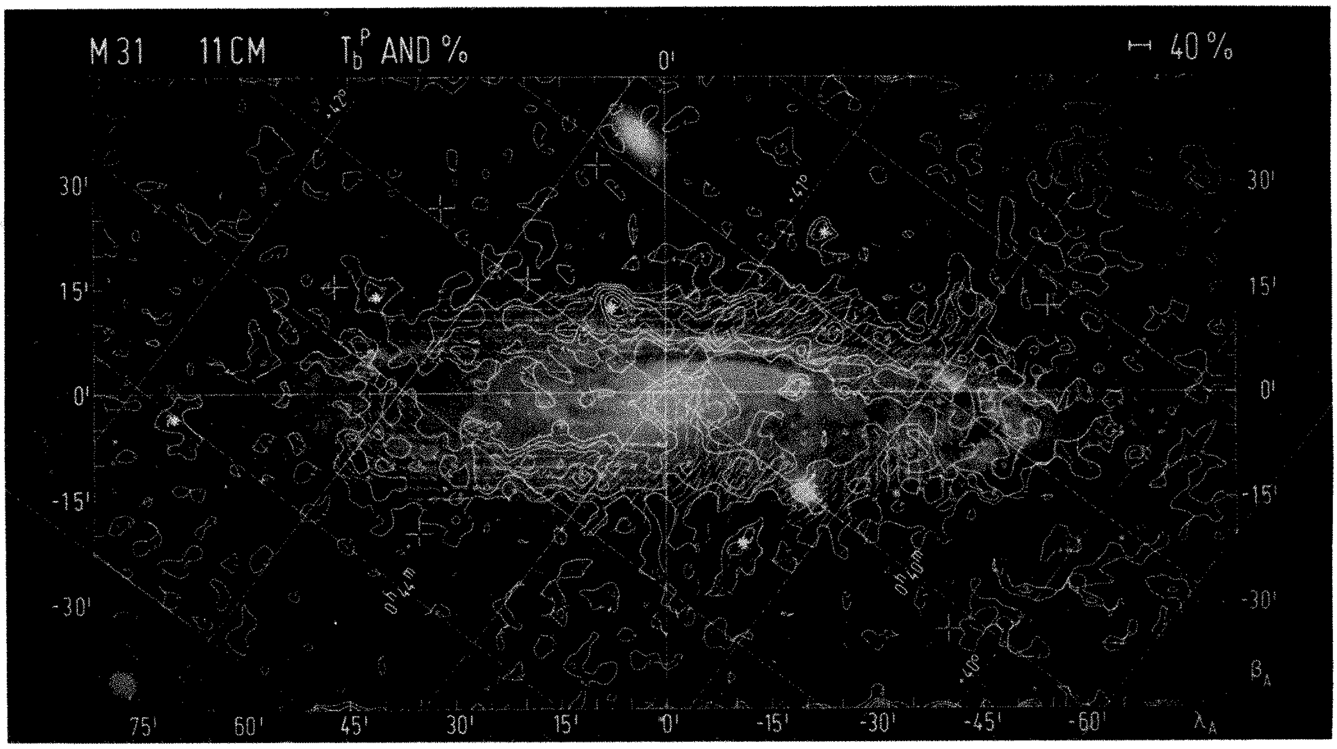

Fig. 1 Contour map of main beam polarisation brightness temperature T_b^p at λ11.1 cm superimposed on an optical picture of M31 (photograph from Hale Observatories). The first contour level is 4 mK ($=1.3\sigma$) in T_b^p; the contour interval is 4 mK. The length of the vectors is proportional to the percentage polarisation p which was only computed if $T_b^p > 3$ mK and $T_b > 15$ mK. Asterisks show the position of polarised point sources 5C3.73, 107, 120, 126 and 163.

0028–0836/80/030272—04$01.00

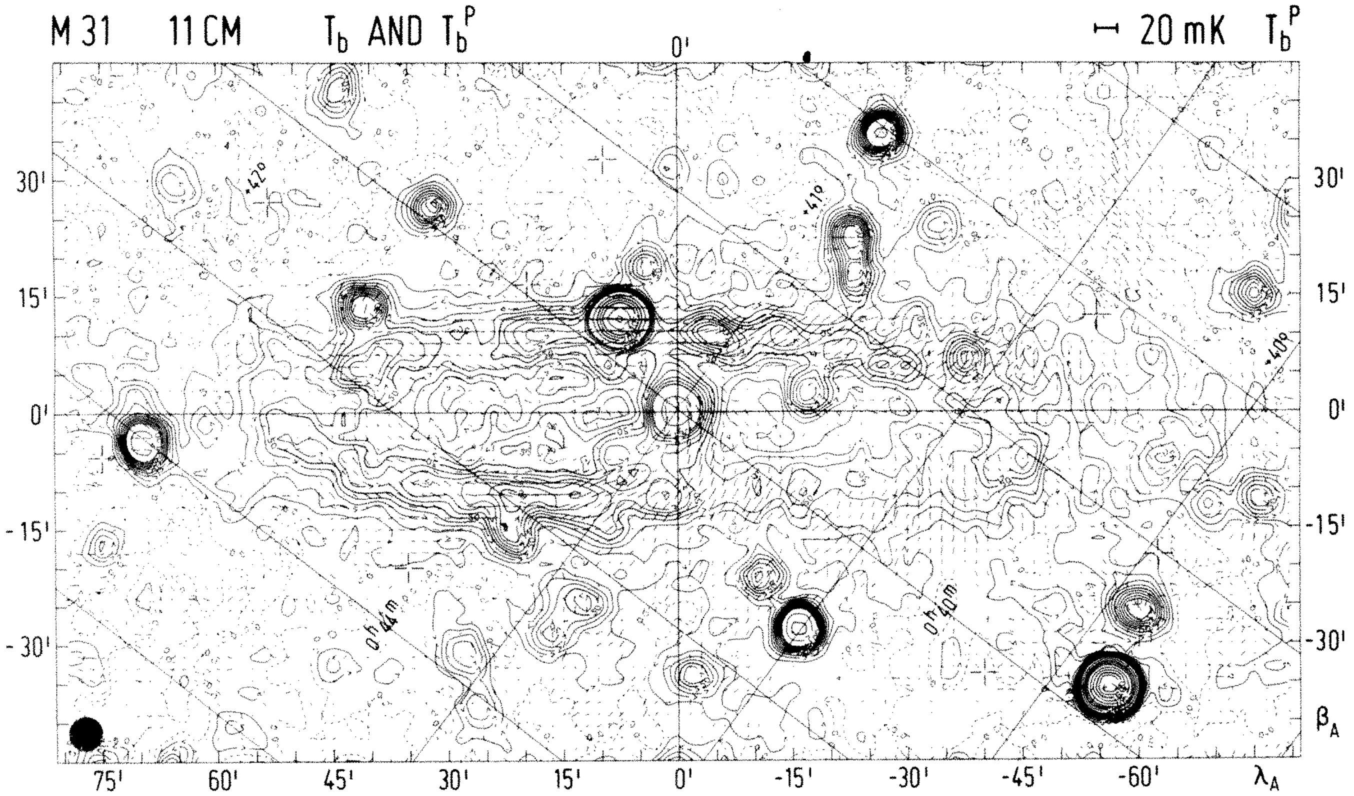

Fig. 2 Contour map of the main beam brightness temperature T_b. Contour levels are: 0, 10, ..., 100, 150, ..., 300, 400, ..., 800 mK. The length of the vectors is proportional to the main beam polarisation brightness temperature T_b^P.

zero level could be determined with more confidence. The zero level in Fig. 2 is higher by 5 ± 3 mK compared with the old map.

The total power map of Fig. 2 was used to compute the degrees of polarisation as shown by the vectors in Fig. 1.

Figure 1 contains the optically brightest parts of M31 out to a radius $R = 16$ kpc along the major axis adopting a distance to M31 of 690 kpc[9]. The resolution of 4.4 arc min corresponds to 0.9×3.2 kpc in the plane of M31 (inclination $i = 74°$; $i = 0°$ is face-on). This is the finest linear resolution used to date for observing the distribution of the polarised radio emission in a nearby spiral galaxy. Because the width of the arms on the major axis is ~1.5 kpc (ref. 10) this resolution is small enough to study the large-scale magnetic field in some detail.

The outstanding feature of Fig. 1 is the concentration of the polarised emission in a ring around the centre. This ring approximately coincides with the optically brightest arms (nos 4 and 5 in the notation of Baade[11]) which contain most of the H II regions, as well as with the rings of high intensity seen at λ 11 cm in total power (Fig. 2 and ref. 10) and in the neutral hydrogen line[9].

The radial distribution of the polarised intensity is shown in Fig. 3. In both the northern and in the southern half of M31 the bright ring extends from $R = 5$ to $R = 12$ kpc reaching a maximum intensity of $T_b^P \sim 8$ mK at $R = 8$ kpc. At some places in the ring ($\lambda_A = +20$ arc min, $\beta_A = -10$ arc min; $\lambda_A = -10$ arc min, $\beta_A = +10$ arc min) local maxima of $T_b^P \cong 18$ mK occur. Maxima due to polarised point sources are indicated in Fig. 1; the source with the highest polarised flux density (7 mJy corresponding to a degree of polarisation of 3%) is 5C3.107 at $\lambda_A = +7$ arc min, $\beta_A = +12$ arc min. In the ring several minima are seen coincident with large H II regions. At these positions the H II regions are probably in front of the synchrotron emission regions and depolarise the radiation.

In the north-east ($\lambda_A > 0$ arc min, $\beta_A < 0$ arc min), the north-west ($\lambda_A > 0$ arc min, $\beta_A > 0$ arc min), and the south-west ($\lambda_A < 0$ arc min, $\beta_A > 0$ arc min) the lines of maximum intensity (ridge lines) in polarisation as well as in total power (Fig. 2 and ref. 10) and H I (ref. 9) generally coincide with dust lanes. In the south-east ($\lambda_A < 0$ arc min, $\beta_A < 0$ arc min), however, the ridge line in total power is less clearly coincident with dust lanes, and the ridge line in polarisation is shifted outwards with respect to the optical spiral arm.

In the north-west, outside the bright ring, several weak maxima in T_b^P seem to line up along arm 5; all of these maxima coincide with dust regions. Conversely, the polarised feature at $\lambda_A = -60$ arc min, $\beta_A = +15$ to $+35$ arc min does not seem to be related to M31; this is probably a foreground irregularity within 500 pc of the Sun[5].

Close to the centre of M31 an area with $T_b^P > 12$ mK is seen which seems to connect with the bright ring to the east but not to the west. This emission might originate in a region extending up to $z \cong 2$ kpc from the nucleus. If the western side were the closer to Earth, most of this emission would be seen in front of the plane to the east, while most would be depolarised by the plane to the west.

Figure 1 shows a well ordered pattern in the distribution of the polarisation angles. Near the southern major axis ($\lambda_A < -30$ arc min) the vectors are predominantly directed perpendicular to the spiral arm to within ~30°. This orientation continues throughout the south-east quadrant, but near $\lambda_A = +5$ arc min, $\beta_A = -10$ arc min a clockwise rotation of the vectors of ~90° changes their preferential direction to along the spiral arm. In the south-west quadrant a similar clockwise rotation of the vectors occurs between $\lambda_A = -30$ and -10 arc min; the vectors remain orientated along the arm throughout the north-west quadrant and also follow the turn of the arm near the northern major axis.

In the absence of Faraday rotation the vectors are perpendicular to the projection of the magnetic field onto the plane of the sky. The orientation of the vectors perpendicular to the arm in the south-west and south-east then implies that the magnetic field is directed along the arms. Between $\lambda_A = -45$ and -30 arc min the angle ϕ between the arm and the line of sight varies between 16° and 60°, in which interval the rotation measure (RM) should increase by a factor of 2. As the perpendicular orientation of the vectors to the arm is maintained over

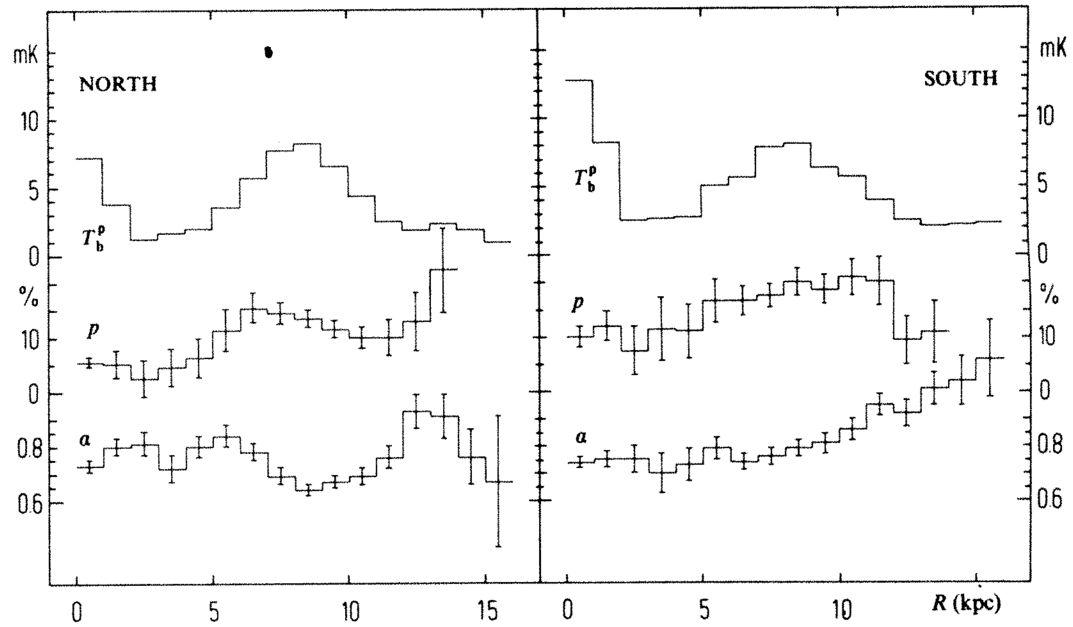

Fig. 3 Dependence of T_b^p, p and $\alpha_{408}^{2,700}$, as determined in circular rings in the plane of M31, on the distance R to the centre, shown for the north ($\lambda_A > 0$ arc min) and the south ($\lambda_A < 0$ arc min) separately.

this interval, an upper limit to the internal Faraday rotation on the major axis can be set of $\Delta\theta < 30°$, or RM < 42 rad m^{-2}. With a field component along the line of sight of 2 μG (ref. 12) and a path length through the arm on the major axis of 200 pc/cos 74° the mean density of the thermal electrons is found to be $N_e < 0.04$ cm^{-3}. This is comparable to the mean electron density of ~0.03 cm^{-3} derived by Ables and Manchester[13] for the local region in our Galaxy.

The clockwise rotation of ~90° observed all over the northern part of M31 is believed to originate in the galactic foreground because: (1) the rotation is independent of ϕ; and (2) it is unlikely that N_e in the entire northern part of M31 is at least three times higher than in the southern part because the north/south ratio of the thermal fraction is only ~1.5 (see Table 1). A rotation of −90° corresponds to RM $= -127$ rad m^{-2} which is in the range of rotation measures found by Simard-Normandin and Kronberg[14] near M31.

Figure 1 shows that the average intensity of the polarised emission in the ring exceeds 10 mK near the minor axis but is only ~3 mK near the major axis. If the velocity field of the relativistic electrons is isotropic, such an effect is to be expected in the case of a magnetic field preferentially orientated along the bright ring: on the minor axis we are then looking perpendicular to the field ($\phi = 90°$) and see high T_b^p, while on the major axis we are looking nearly along the field ($\phi = 16°$) and find low T_b^p. Faraday effects would enhance this difference.

Thus both the variation of T_b^p in the ring of emission and the orientation of the vectors indicate that the magnetic field is preferentially aligned along the arms that form the ring.

In Fig. 1 the lengths of the vectors are proportional to the degree of polarisation, $p = T_b^p/T_b$, where T_b is the sum of thermal and nonthermal emission. The nucleus of M31 is ~7% polarised. The degree of polarisation is generally higher in the south than in the north. The maximum percentage observed is $p = 42\%$ at $\lambda_A, \beta_A = -10, +12$ and $-24, +12$ arc min in the south-west, and $\lambda_A, \beta_A = -12, -15$ and $-20, -15$ arc min in the south-east; in the north-east the highest percentage is $p = 37\%$ at $\lambda_A, \beta_A = +27, -5$ arc min. Several minima in the degree of polarisation are coincident with complexes of H II regions seen on the map of Pellet *et al.*[15] (that is, $\lambda_A, \beta_A = +40, +6$ arc min; $\lambda_A, \beta_A = +12, -12$ arc min; $\lambda_A, \beta_A = -45, -9$ arc min) which may cause depolarisation.

To study the dependence of the degree of polarisation on distance to the centre, the average value of p was determined in circular rings in the plane of M31 so that the average of the angle ϕ is the same for every ring. The variation of p with R is shown in Fig. 3 for north and south separately. The variation of the mean spectral index $\alpha_{408}^{2,700}$ (ref. 12) is also shown. In the north, p increases from 5% near the centre to 15% at $R \sim 7$ kpc on the inner side of the bright ring, and then decreases in the ring to 10% at $R \sim 11$ kpc. The spectral index also decreases markedly in the bright ring. This variation may be due to an increase of the thermal fraction in the ring, which will cause a decrease in p by a larger thermal contribution to T_b and an increase in Faraday depolarisation. In the south the situation is different: p and $\alpha_{408}^{2,700}$ are higher than in the north and show a constant increase with R across the bright ring.

Average values out to $R = 16$ kpc of p, $\alpha_{408}^{2,700}$, the thermal fraction f_{th} and the degree of polarisation corrected for the thermal contribution, p_n, are collected in Table 1 (ref. 12). The higher degree of polarisation in the southern half is only partly due to lower thermal fraction: there remains an excess of the polarised emission while there is no asymmetry in the total nonthermal emission.

Locally p_n will be much higher than the average values: at positions where $p = 42\%$, clearly $p_n > 42\%$. In the north-east similar high values of p_n are found if $f_{th} \sim 70\%$. In the case of a uniform field the intrinsic degree of polarisation of the nonthermal emission for $\alpha_n = 0.85$ is $p_i = 73.5\%$. Assuming that values of $p_n > 42\%$ are not affected by Faraday depolarisation, but that the difference between p_i and p_n is entirely due to irregularities of the magnetic field in the emission regions along the line of sight, the ratio of random field to uniform field is <0.9, corresponding to a degree of uniformity of >50% on the scale of the beamwidth[16]. With the model of Segalovitz *et al.*[4] a degree of uniformity >40% and a ratio of random field/uniform field <1.5 is derived. Thus the degree of uniformity of the magnetic field in M31 on a scale of 0.9 × 3.2 kpc is about three times higher than that found in M51 on a scale of 2.6 × 3.6 kpc (ref. 4). As the width and the separation of the arms as seen in the plane of the sky is comparable in these galaxies, the difference in the degree of uniformity of the field may be caused by a larger depolarisation across the approximately three times larger scale of the beam area used for M51.

Table 1 Average values for $R \leq 16$ kpc

Area	$\bar{p}$ (%)	$\bar{\alpha}_{408}^{2,700}$	$\overline{f_{th}}$ (%)	$\overline{p_n}$ (%)
Total	14.6 ± 1.5	0.76 ± .05	30 ± 5	21 ± 3
North	11.7 ± 1.4	0.71 ± .05	35 ± 6	18 ± 3
South	18.3 ± 1.9	0.82 ± .05	24 ± 4	24 ± 3

An estimate of the Faraday depolarisation and a study of the intrinsic polarisation angles in the bright ring of M31 can be made when our observations at λ 18 cm (underway) and λ 6 cm (planned) are complete.

Peculiarities of binary galaxies

Nigel Sharp & Bernard Jones

Institute of Astronomy, Madingley Road, Cambridge, UK

A recent analysis of a sample of close binary galaxies[1] by White and Valdes[2] has revealed some peculiar features: in particular, they tend to be brighter than field galaxies. Binary galaxies are important because the relative simplicity of the two-body problem in dynamics should make it possible to obtain good estimates of the masses of paired galaxies. This would help in determining whether there are massive haloes of dark, unseen matter, and in the problem area of galaxy formation. Much effort has therefore been expended (ref. 3 and refs therein), but conclusions about the existence of massive haloes and about the mass-to-light ratios have varied. Because we do not have complete information, various statistical assumptions must be made in these analyses. Detailed arguments[2] suggest that one of these assumptions has been in error in previous work. We present a test which supports this claim. (The sample used here and in ref. 2 seems to be the only set of paired galaxies with quantitative selection criteria and velocity information for an unbiased subsample.) Furthermore, it was shown[2] that binary galaxies are drawn from a luminosity function which has a characteristic luminosity brighter than that for field galaxies by almost one whole magnitude. We discuss one of the possible explanations and some suggestive evidence.

The basic observational information available includes the apparent magnitude of the two galaxies, their redshifts, and their angular separation on the sky, θ. The (probably reasonable) assumption that the centre of mass of the system partakes of the Hubble flow enables these data to be converted to absolute luminosities, a line-of-sight velocity difference, and a projected rectilinear separation r_p (see ref. 3). Further analysis of a single pair would require knowledge of the angle between the true separation vector and the line-of-sight, ϕ, the orbital eccentricity, and the orbital phase. Since we do not have these data, we must make assumptions about them. Such assumptions are usually statistical in nature, because samples usually comprise many pairs. Thus, for example, one can assume a distribution of eccentricities in the sample. This seems to indicate the need for low eccentricity, but is apparently not crucial to mass determinations[3].

Another important assumption is the distribution of the angle ϕ, which relates the true separation r to the projected separation r_p by $r_p = r \sin \phi$. Previous analyses[3–5] have used a distribution $N(\phi)\,d\phi \propto (\sin\phi)^\alpha\, d\phi$ with an exponent $\alpha = 0.5$, derived from the data. The recent analysis of White and Valdes[2], however, uses the covariance function to derive $\alpha = -(2-\gamma)$ for a two-point function $\xi(r) = (r_0/r)^\gamma$. The accepted value for γ of 1.8 thus leads to $\alpha = -0.2$. It seems that the earlier authors erroneously assumed that pairs isolated from correlated objects have the orientation distribution appropriate to pairs isolated from an uncorrelated population. The change from $\alpha = 0.5$ to $\alpha = -0.2$ increases mass determinations, made using Turner's method[3], by about 40%, and can affect rank–sum techniques[4] by as much as a factor two[2] (although the use of overlapping bins in this analysis may have introduced other sources of uncertainty). It is therefore very important to decide which exponent is correct.

It was suggested by D. Lynden-Bell (personal communication) that it should be possible to use a test analogous to the V/V_{max} test used to study the space distribution of quasars[6]. For the present sample, we consider the angular separation θ and the maximum separation that the pair could have had and still be included in the sample, θ_{max}. This latter angle is either one-fifth of the distance to the third galaxy nearest the pair, or 8 arc min, whichever is the smaller (see the selection criteria of ref. 1). Figure 1 shows a plot θ/θ_{max} against θ_{max} for the full sample of 156 pairs[1]. (Because the values for θ are the precise measurements of Turner, whilst the values for θ_{max} come from neighbour calculations using the positions given in the Zwicky catalogue, some ratios are greater than one. This increases the scatter without introducing any significant problems).

Assuming a power-law distribution as above gives $n(\theta)d\theta \propto \theta^{-\alpha}d\theta$, which then predicts that the average value $\langle\theta/\theta_{max}\rangle$ is $[(1+\alpha) \pm N^{-1/2}(1+\alpha)^{1/2}(3+\alpha)^{-1/2}]/(2+\alpha)$ for a sample size of N. For 156 pairs, the data give $\langle\theta/\theta_{max}\rangle = 0.52 \pm 0.02$; the predictions are 0.33 ± 0.02 ($\alpha = 0.5$) and 0.55 ± 0.02 ($\alpha = -0.2$). This suggests that $\alpha = -0.1 \pm 0.1$. Various subsamples have been used in different works based on binary galaxies[2,3,7,8], and there is no obvious systematic variation in the values of $\langle\theta/\theta_{max}\rangle$ for them. In addition, there does not seem to be any clear dependence on θ_{max} for any of the sets. The recent argument is thus clearly supported.

The second puzzling aspect is the apparently increased luminosity of paired galaxies. An obvious explanation is that the interaction of the two galaxies induces star formation and thus

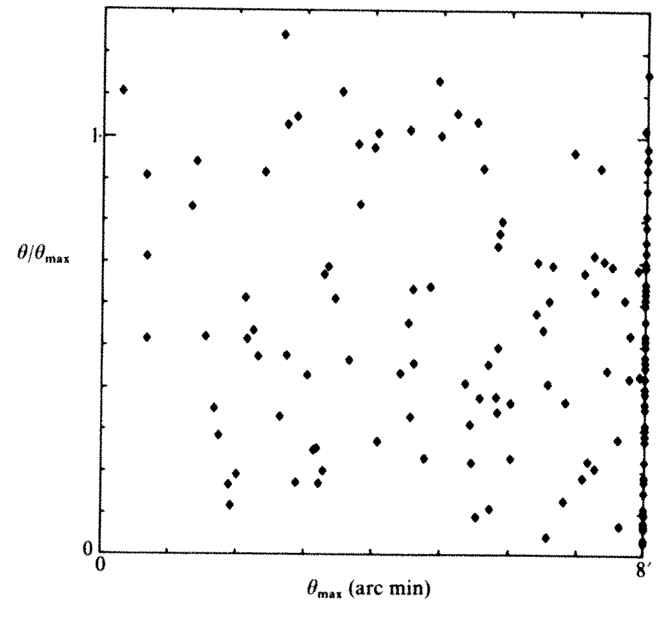

Fig. 1 The ratio θ/θ_{max} plotted against θ_{max} for the 156 pairs of ref. 1.

0028-0836/80/030275—03$01.00

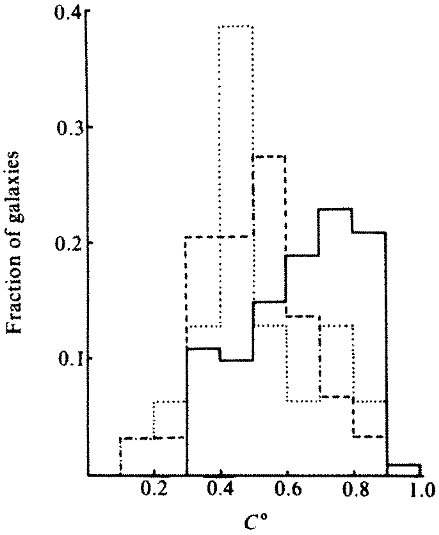

Fig. 2 The distribution of the absorption corrected, integrated B–V colour index $C°$. solid line: 100 randomly chosen non-elliptical galaxies. Dashed line: close spiral–spiral pairs. Dotted line: wide spiral–spiral pairs.

makes them brighter. This idea is supported by work on normal and peculiar galaxies[9]. As the method by which star formation might be enhanced is not clear, possible correlations between separation, morphological type, and/or luminosity excess, are not well predicted.

An excellent check would be to consider the colours of the binary galaxies, since one would expect that sufficient star formation to increase the luminosity to the required extent would make the galaxies quite distinctly bluer[9]. These data are not available for the Turner sample, but some suggestive evidence comes from a survey (B. J., unpublished) based on the data of Holmberg[10], split into 'wide' pairs, 'close' pairs, and the field. By 'close' is meant a pair whose separation is of the order of or less than the sum of the face-on diameters of the components. 'Wide' comprises systems which are essentially not touching.

Figure 2 compares three histograms showing the distribution of the absorption-corrected integrated B–V colour index $C°$. The solid line is for 100 randomly chosen non-elliptical galaxies; the dashed line is for close spiral-spiral pairs; the dotted line is for wide spiral–spiral pairs. The mean colour index for the three classes goes from 0.64 (field) to 0.50 (wide) and to 0.49 (close), with r.m.s. deviations of 0.16, 0.17 and 0.16 respectively. In addition, it is clear that the distributions for the paired galaxies are skewed to the blue of the 'ordinary' galaxies.

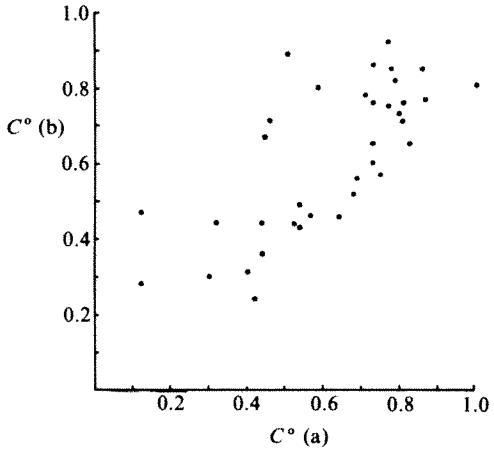

Fig. 3 The correlation between the colour index of the brighter (or larger) galaxy, $C°$(a), and that of its companion, $C°$(b).

That this colour change is due to interaction is strongly supported by the correlation between the colours of the two components. In Fig. 3 the colour index for the brighter (or larger) galaxy, $C°$(a), is plotted against that of its companion, $C°$(b), for the spiral–spiral pairs. The correlation coefficient is 0.7: red (blue) galaxies tend to have red (blue) companions. (There is also a suggestive correlation of morphological type[5].)

Let L_B and L_V be the B and V luminosities of a galaxy before interaction, and let l_B and l_V be the contributions from stars formed as a consequence of the interaction. Then $L_V/L_B = 10^{0.4C}$ and $l_V/l_B = 10^{0.4C_*}$, where C is the colour index of the pre-interaction galaxy and C_* is the mean colour index of the newly created stars. The colour change is than

$$\Delta C = -2.5\log_{10}\left\{\frac{1+10^{0.4(C-C_*)}l_V/L_V}{1+l_V/L_V}\right\} \qquad (1)$$

and the associated magnitude changes are $\Delta M_V = -2.5\log_{10}(1+l_V/L_V)$ and $\Delta M_B = \Delta M_V + \Delta C$. Figure 4 shows a few curves of $-\Delta C$ plotted against l_V/L_V, labelled by their values of $C - C_*$. The upper scale gives $(-\Delta M_V)$, and some curves of constant ΔM_B are also shown.

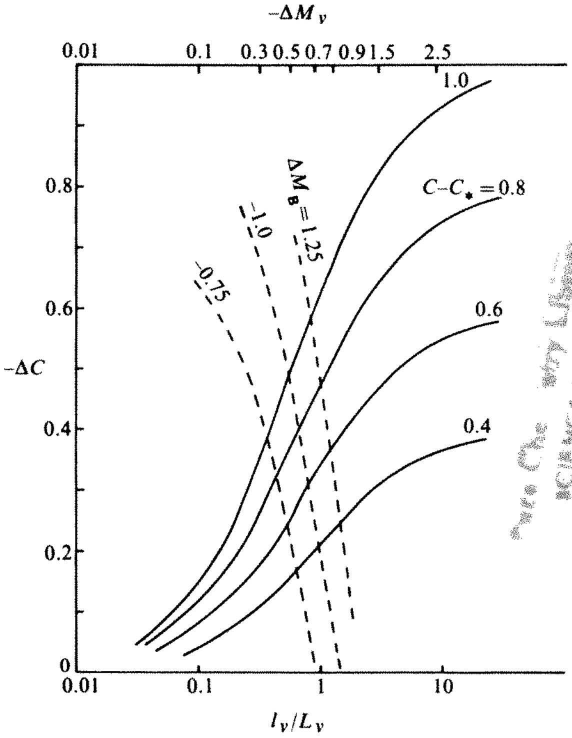

Fig. 4 The relation between the colour change ΔC and the magnitude changes ΔM_V and ΔM_B, for different values of $C - C_*$ (see equation (1)).

Figures 2 and 3 here, and Fig. 1 of ref. 9, suggest that a colour change of about 0.3–0.5 mag is required. The value of C_* to take is given roughly by the time elapsed since the interaction: choose the stars that spend that amount of time on the main sequence. (The finer details depend on the mass function of the stars.) If the galaxies interacted between 10^8 and 10^9 yr ago, C_* is in the range -0.15 to $+0.15$. An initial galaxy of C about 0.7 therefore has $C - C_*$ in the range 0.55 to 0.85. Figure 4 then indicates a value for ΔM_V of 0.5 to 0.8 mag, and for ΔM_B of 0.75 to 1.25 mag.

Although the samples are selected differently[1,10], the same physical processes should occur in both. In addition, it is not certain which stage in a binary galaxy's life is most propitious for induced star formation and the ages of the binary systems are difficult to determine. Although the orbital times for the Turner sample are so short that significant interaction (of a dynamical sort at least) seems inevitable[7,11], it also seems that the disk galaxy pairs were probably not dynamically isolated from other galaxies at the time of their formation[8]. This makes consideration of the induced star formation yet more complex.

However, the evidence presented here shows that significant colour changes are induced by interaction, and that these are of such a magnitude and take place over such a time scale that the B magnitude of a galaxy would increase by about one magnitude, as required by White and Valdes[2]. To confirm this, better data are required—particularly a detailed study of the colours of the Turner pairs.

Note added in proof: The extension of the covariance function to small scales[12] adds more weight to the arguments here and in ref. 2.

Spectral evidence for a carbonaceous chondrite surface composition on Deimos

Kevin D. Pang

Planetary Science Institute, 283 South Lake Avenue, Suite 218,
Pasadena, California 91101

Jack W. Rhoads, Arthur L. Lane & Joseph M. Ajello

Pasadena, California 91103

The good match between the reflectance spectra of Phobos and Ceres, an asteroid inferred to have a composition analogous to carbonaceous chondrites because of its low density, ~2.2g cm^{-3} (ref. 1), and spectral signatures that include a water of hydration band centred at 3.0 μm (refs 2, 3), has led to the conclusion[4] that the surface composition of the inner martian satellite is similar to that of carbonaceous chondrites. Pollack *et al.*[5] independently reached the same conclusion by comparing Phobos' spectral albedo with reflectance spectra of meteorites and basalts. Mass and density estimates (~2g cm^{-3}) for the satellite were made based on the perturbations on the orbit of Viking 1 by Phobos, during a series of close encounters[6]. The density of Phobos is consistent with the same composition as that inferred for its surface. Among materials expected to be common in the Solar System only ices or water-rich carbonaceous chondrites (20% H_2O by weight in type C1) have densities as low as Ceres and Phobos[7]. The compositional results have forced a re-evaluation of hypotheses concerning Phobos' origin. Scientific opinion now seems to favour an origin by capture of a body that came too close to Mars[8]. The analysis of data on Deimos reported here reveals a spectral reflectance very similar to that of Phobos, indicating a surface composition analogous to that of carbonaceous chondrites.

High-resolution pictures of Deimos obtained by Viking Orbiter 2 in recent close flybys showed a surface that appears to be morphologically different from that of Phobos[9]. Although the two satellites have equal densities of impact craters, on Deimos craters 50 m in diameter are filled in with fine-grained material, accounting for the relatively smooth appearance of the outer martian moon. Grooves are found over most of Phobos, but are conspicuously absent from the surface of Deimos. Why is the surface of Deimos but not Phobos mantled with large amounts of loose material, including clusters of house-sized blocks? One possibility is that the surfaces of the two satellites have significantly different mechanical properties. For example, an impact might produce a larger fraction of low-velocity fragments on Deimos than it would on Phobos. A second explanation is that it might be easier to knock material off Phobos than off Deimos, because Phobos is closer to Mars[10]. We will evaluate the first hypothesis by comparing the surface composition of the two satellites, that is by comparing the UV–visible reflectance spectrum of Deimos with that of Phobos.

The UV–visible reflectance spectrum of Deimos is compiled from the following sources: Mariner 9 UV spectrometry (UVS) and Canopus star tracker photometry, and ground-based colorimetry and polarimetry. Mariner 9 UV spectra of Deimos at a resolution of 1.5 nm were obtained on the 73rd revolution of the spacecraft around Mars. The phase angle of observation was 22°. Analysis of the Deimos spectra follows the procedure developed for Phobos[4] with the exception that a broader bandwidth was used, because the signal-to-noise ratio for Deimos was not as good as that for Phobos. Both preflight laboratory and inflight stellar calibrations show the absolute uncertainty of the UVS measurements to be ±20%, with a relative uncertainty of about ±7%. The relative uncertainty is shown in Fig. 1 as error bars.

Zellner and Capen[11] determined the slope of Deimos' polarisation curve at phase angles between 15° and 40°. Interpreting this slope on the basis of the new slope–albedo law[12,13], we arrive at a geometric albedo for Deimos in blue light of ≤ 0.057 (arrow in Fig. 1). They also made photoelectric observations of Deimos and derived a visual (V) geometric albedo of 0.070 ± 0.008, blue-visual colour index $B - V = 0.65 \pm 0.03$ and ultraviolet-blue colour $U - B = 0.18 \pm 0.03$, and phase coefficient $\beta_v = 0.036 \pm 0.05$ magnitude per degree for phase angles $< 20\%$.

Ground-based absolute photometry of the martian moons is very difficult due to their proximity to Mars (hence interference by light scattered from a bright primary). Photometric observations of Phobos from the martian surface with Viking Lander cameras did not have such a handicap[5]. We, therefore, made a new determination of Deimos' geometric albedo, using observations of the satellite made by the Mariner 9 Canopus star tracker (CST). Viewing Deimos from a Mars-orbiting platform avoids the problems caused by halation from Mars. Details of CST functions and data analysis are given elsewhere[14–17]. We shall first test CST data analysis on Phobos.

Following the procedure of Bowell and Zellner[18], we obtained Phobos' geometric albedo by extrapolating 83 CST measurements to a phase angle of 0°, using our own phase coefficient for angles 72–98° (ref. 19) and Noland and Veverka's β_v for 0–72° (ref. 20). [Similar values for the phase coefficients have been obtained by Klaasen *et al.*[21].] We assumed that Phobos' phase coefficient in the unobserved range of phase angles 0–18° is the same as that for the range 18–72°, because its phase curve is closely similar to that of Earth's moon (ref. 19), which has a nearly constant slope in the 0–70° region[22]. The average of 83 geometric albedo determinations is 0.046, with an absolute uncertainty of about ±0.01. It is slightly smaller than a similar broadband geometric albedo found from Viking lander imaging, 0.05±0.01 (ref. 5). The small difference is due to different assumptions made in analysing the Viking lander data. When extrapolating Viking lander observations, made at 35° phase, to 0° phase, we had assumed that Phobos' phase coefficient between 0° and 22° is the same as that of Deimos[4,5]. Because of the grossly different surface roughness of the two objects we now prefer a lunar-like phase curve between 0° and 72°. Using the same β_v as in the CST analysis we find that Viking Lander camera albedos for Phobos to be near 0.045 (see Fig. 1). The CST albedo for Phobos is plotted as a continuous line. The

0028-0836/80/030277—02$01.00

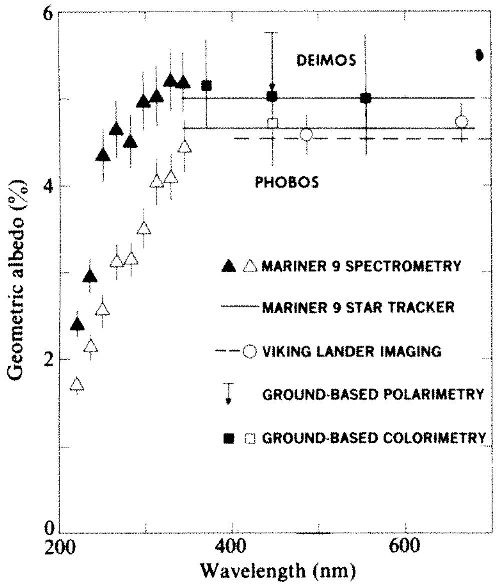

Fig. 1 The spectral albedo of the martian satellites. UV geometric albedos at 15-nm band centres: ▲, Deimos; △, Phobos. Photometry: ○, narrow band; – – –, —, broad band. Polarimetry ↓. Colorimetry: ■, Deimos; □, Phobos.

lengths of the lines indicate the bandwidths of the CST and Viking Lander camera broadband photometry. The CST has a blueish response so that CST magnitudes are similar to the commonly used photographic magnitudes. Kuiper's $B-V$ colour index for Phobos has been converted into a blue albedo after normalising to the Viking Lander imaging results[5] (open square in Fig. 1).

Following the same procedure as that for Phobos, analysis of 12 CST measurements yielded an average geometric albedo of 0.050, with an absolute uncertainty of about ±0.01 for Deimos. Zellner and Capen's colour indices were converted to *UBV* geometric albedos after normalising to the CST value. *B* and *V* albedos are the same for both Phobos and Deimos as the satellites have the same $B-V$ colour as the Sun. Viking Lander photometry has an absolute accuracy of ±20% and relative accuracy of ±5% (error bars). Ground-based data are accurate to ±0.01 (error bars). The ratio of Deimos' geometric albedo to Phobos' is now 1.1, as required by relative photometry of the satellites[20].

To a first approximation the reflectance spectra of Deimos and Phobos are very similar: both have low and flat reflectivities in the visible, dropping off sharply in the UV. Searches through spectral signatures of asteroids of known compositions and laboratory reflectance measurements of rocks, minerals and meteorites yielded carbonaceous chondrites as best matches for the spectral albedo of Phobos[3–5]. Only carbonaceous chondrites possess all three required spectral characteristics: low albedo, flat visible–IR reflectivity, with sharp downward bend in the UV. On the basis of a good match between the reflectance spectra of Deimos and Phobos, and with the composition of Phobos known to be similar to that of carbonaceous chondrites, it is reasonable to believe that the surface composition of Deimos is also similar to that of carbonaceous chondrites. Our identification of a carbonaceous chondrite composition for Deimos is consistent with the implications of a recent mass estimate for the satellite based on the perturbations on the orbit of Viking Orbiter 2 by Deimos, during a series of close encounters. This mass estimate yields preliminary densities that are equal to or less than the density of Phobos[23].

Why then do the surfaces of the martian satellites appear to be morphologically different? Any explanation requiring Phobos and Deimos to have surfaces with different mechanical strength seems to be unrealistic in view of their similar compositions and densities; instead, the states of the satellites' surfaces are probably due to their different orbital history.

We thank Ian Gatley, and members of the Mariner 9 UVS and Guidance and Control teams for their support. Funds for this research are derived in part from a NASA contract (Mars Data Analysis Program).

High time resolution riometer and X-ray measurements of conjugate electron precipitation from the magnetosphere

T. J. Rosenberg & J. C. Siren

Institute for Physical Science and Technology, University of Maryland, College Park, Maryland 20742

L. J. Lanzerotti

Bell Laboratories, Murray Hill, New Jersey 07971

In this letter we describe the comparison of cosmic noise absorption data recorded by a riometer at Siple Station, Antarctica (76 °S; 84 °W; $L\sim4.2$) with simultaneous balloon measurements of bremsstrahlung X rays from the conjugate region near Roberval, Canada (48.3° N; 72.1° W). Both the cosmic noise absorption and the production of X rays are caused by the precipitation of energetic electrons ($E\geqslant15$ keV) from the magnetosphere. The time resolution and spatial coverage of the measurements enable us for the first time to show the similarity and simultaneity of rapid fluctuations of electron precipitation at ionospheric conjugate points. Furthermore, the data suggest that fast-response riometers are capable of resolving temporal structures in electron precipitation on a time scale which approaches that of electron microbursts (of the order of 1 s). The relative simplicity of riometers for the measurement of precipitating particle effects opens up important new avenues of research in studies of upper atmosphere ionisation phenoma.

The Siple riometer operates at 30 MHz and has a response time of 0.25 s to increases or decreases in signal intensity[1]. It utilises a zenith-directed dipole antenna with half-power at 30°. The antenna pattern projected to 100 km altitude covers a circular area of approximately 120 km diameter. The riometer data and the output of a three-axis fluxgate magnetometer are digitised at 2-s intervals and written in computer-compatible format on magnetic tape[2,3]. The X-ray measurements in the conjugate region were made at 35 km altitude with a zenith-directed uncollimated sodium iodide scintillation counter. An energy spectrum covering the range from 25 to 500 keV in seven

0028–0836/80/030278—03$01.00

differential channels is obtained with a time resolution of 0.01 s. The effective response of this detector projected to 100 km altitude covers a circular area equal to that of the Siple riometer. Calculations place the Siple conjugate point within 60 km of Roberval[4,5]. At the time of measurement, the balloon was located 30 km northeast of Roberval. Thus, portions of the effective areas of balloon and riometer gave overlapping coverage of the same field line(s). Uncertainty in the relative timing of the measurements in opposite hemispheres was ≤ 1 s.

A 1-min segment of X-ray, riometer and magnetometer data obtained during a microburst precipitation event on 9 July 1975 is presented in Fig. 1. Panel *a* illustrates the X-ray counting rate of the 45–65 keV energy channel at a resolution of 0.1 s. At this time, individual microbursts[6], the spikes of 0.2-s duration spaced 0.5–1 s apart, were occurring in groups separated by 5–10 s. The same X-ray data are plotted in Fig. 1*b* as 2-s averages, a reduction by a factor of 20 in time resolution. The Siple riometer and *D*-component magnetometer data, both limited in this event to the 2-s sampling rate, are shown in Fig. 1*c* and *d*, respectively.

It is evident on comparing *b* and *c* of Fig. 1 that each increase in X-ray counting rate at Roberval was followed several seconds later by an increase in cosmic noise absorption at Siple. Absorption variations as small as 0.02 dB are significant (the total ionospheric absorption caused by electron precipitation above Siple at this time was about 2 dB). At this resolution (2 s), the intensity–time profiles of absorption and X-ray pulses show some striking similarities. In general, however, the absorption pulses are somewhat broader than the associated X-ray pulses. This is to be expected from considerations of ionospheric response time even if the precipitation were identical at the conjugate points.

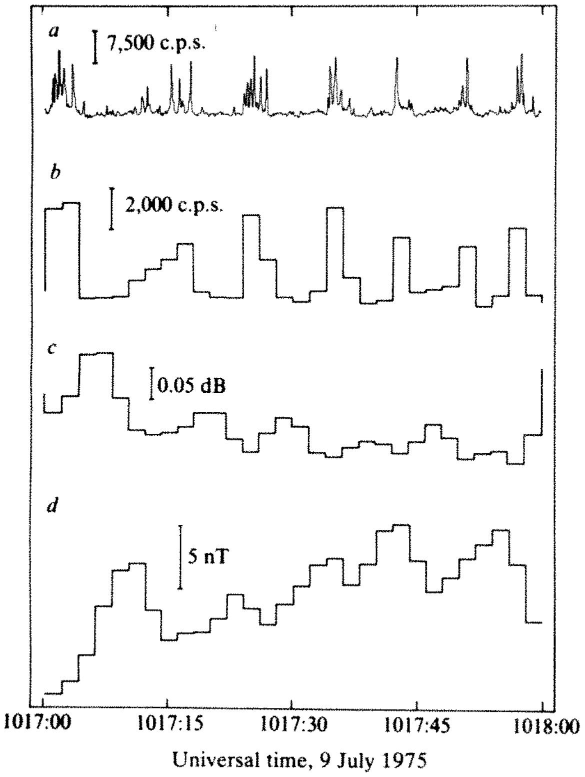

Fig. 1 *a*, Atmospheric bremsstrahlung X rays produced near Roberval, Canada ($L \approx 4.1$) by the precipitation of energetic electrons during a magnetic substorm. Individual microbursts are well resolved at 0.1-s resolution. *b*, The same X-ray data as in (*a*) but with a factor of 20 less resolution. The microburst structure is no longer apparent. *c*, Ionospheric absorption fluctuations at Siple Station, Antarctica (magnetically conjugate to Roberval) obtained by a 30-MHz riometer with resolution (2 s) equal to that of the X-ray data in *b*. Increasing absorption is upward. A time-delayed correlation (absorption lags X rays by ~4 s) is evident. *d*, Variations of the *D* component of the surface magnetic field at Siple at 2-s resolution. LT = UT − 5 hours.

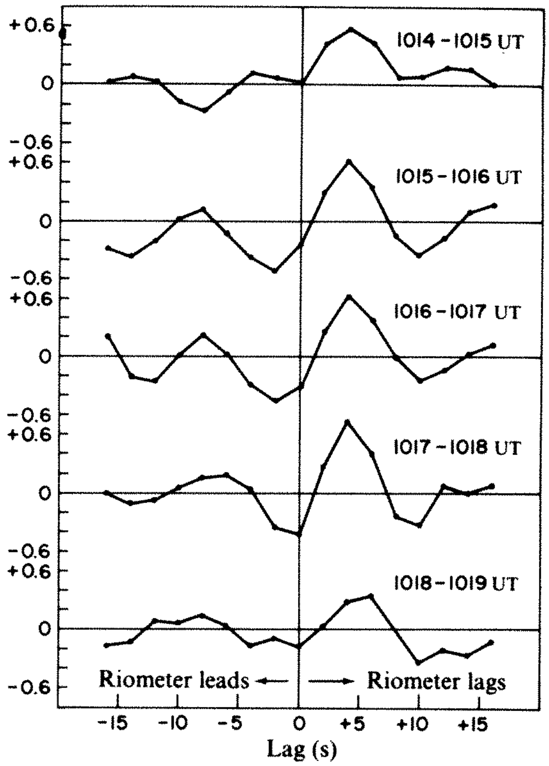

Fig. 2 Cross-correlation of 2-s resolution Siple riometer and Roberval X-ray data for consecutive 1-min segments. The correlation peak at +4 s exceeds the 99% confidence level in each of the first four segments.

Magnetic variations on a comparable time scale also occurred. Further details of the accompanying magnetospheric substorm and of the association of ultra low frequency (ULF) magnetic variations and absorption fluctuations have been given previously[2,7].

The data in Fig. 1 represent part of an extended period of disturbance. Figure 2 shows the results of cross-correlating the Roberval X-ray and Siple riometer data (2-s resolution) for consecutive 1-min segments between 1014 and 1019 UT. The peak at +4 s (riometer lags X rays) is confirmation that rapid fluctuations of electron precipitation are highly correlated at magnetic conjugate points. Approximately 1.8 s of the time delay is due to a phase shift introduced by a low-pass anti-aliasing filter in the riometer data system. For the data sets 1015–1016 and 1016–1017 UT, the probability of obtaining the observed correlation by chance is less than 0.001. For 1017–1018 UT the probability of obtaining the observed correlation by chance is less than 0.0001. For the interval 1015–1018 taken as a whole the probability is less than 1 in 10^8 that the correlation could have occurred by chance.

Previous studies of riometer pulsations accompanying X-ray[8] and luminosity[9] pulsations, using data from one end of a field line only, have found time delays of peak absorption of several seconds. This suggests, therefore, that the ≈ 2 s by which the absorption pulses lag the X-ray pulses in the present event may be accounted for by ionospheric response. Our investigation of this point will be presented elsewhere[10].

Because the data sampling rate did not take full advantage of the response capability of the Siple riometer, it was not possible to verify the presence of microburst structure in absorption. However, it should be possible to achieve finer time resolution. Considerations of ionospheric response suggest that absorption fluctuations caused by microbursts could be observed if the ionospheric time constant[8] [$\tau \approx (2\alpha N_e)^{-1}$, where N_e is the electron density and α is the effective recombination coefficient] were $\leqslant 5$ s, given the sensitivity (~ 0.02 dB) and instrumental time constant (~ 0.1 s) that can be achieved with riometers. Ionospheric time constants of this order may apply in the *D* region during absorption events associated with some magnetic storms and substorms.

The research at the University of Maryland was supported by NSF grants DPP74-01704, DPP76-82041 and ATM77-22937. Additional support for balloon operations in Canada was provided by the Office of Naval Research (contract N00014-67-A-0239-0033). Bell Laboratories acknowledge the NSF for logistics support for the Siple measurements. We thank Dr H. Chivers for cooperation in the riometer data acquisition.

Charge dependence of pion production in heavy ion collisions

G. Bertsch

Department of Physics and Cyclotron Laboratory,
Michigan State University, East Lansing, Michigan 48824

Benenson *et al.*[1] measured the pion production cross-section in nuclear heavy ion collisions in the energy range 100–400 MeV per nucleon with the aim of determining whether collective effects associated with the larger number of nucleons were present in the pion field. An instability in the pion field, such as the putative pion condensation phase transition[2], would give rise to an enhanced number of physical pions. The expected production cross-section, in the absence of collective effects, is found from two simple models. One of these is a statistical model, in which the number of pions is calculated from a statistical equilibrium. At the other extreme, the nucleons in the target and projectile are assumed to be free and independent, except for their Fermi momentum, and create pions by two-body collisions. The experimental cross-section at the lowest energy was found to be larger than either model by at least an order of magnitude[3], suggesting that collective effects are indeed present. Interestingly, the cross-section had unexpectedly strong dependence on the charge of the pion produced. At the highest energy studied, 400 MeV per nucleon, many more π^- than π^+ were produced in the forward direction. At the lowest energy studied, 100 MeV per nucleon, the relative yields are reversed, with more π^+ produced. The experimental ratios of π^- to π^+,

$$R_{-/+} = \frac{\mathrm{d}\sigma_{\pi^-}}{\mathrm{d}^3p} \Big/ \frac{\mathrm{d}\sigma_{\pi^+}}{\mathrm{d}^3p}$$

are quoted in Table 1. Benenson *et al.*[1] explain the π^- enhancement in terms of the Coulomb distortions of the pion wavefunctions. Here I include in the same framework an explanation of the low energy result.

Table 1 Experimental ratios of π^- to π^+

E_{proj} (MeV per nucleon)	Pion kinetic energy (MeV)	$y_\pi - y_{\text{proj}}$*	$R_{-/+}$
~100	34	0.23	0.7
	54	0.40	0.6
	76	0.54	0.5
400	34	−0.20	3.0
	54	−0.04	10.0
	76	0.11	2.5
	123	0.36	1.4
	155	0.49	1.2

* Rapidity, the Lorentz-additive measure of velocity, is defined as $y = \frac{1}{2}\ln(E+pc)/(E-pc)$.

My starting point for the pion production rate is the formula

$$W = 2\pi \sum_{\mathrm{f}} \langle \mathrm{i}|H_{\pi\mathrm{N}}|\mathrm{f}\rangle^2 \rho_{\mathrm{f}}$$

where ρ_{f} is the density of final states and $H_{\pi\mathrm{N}}$ is the pion creation part of the nuclear hamiltonian. The ρ_{f} is a product of density of pionic states ρ_{f}^{π}, and density of nucleonic states $\rho_{\mathrm{f}}^{\mathrm{N}}$. Normalising the pion wavefunction to plane waves at infinity, the pionic density of states is the usual $\rho_{\mathrm{f}}^{\pi} = \frac{\mathrm{d}^3p}{(2\pi)^3}$. The transition matrix element $\langle \mathrm{i}|H_{\pi\mathrm{N}}|\mathrm{f}\rangle^2$ will be proportional to the probability of these normalised wavefunctions in the collision region, $|\phi_{\pi^\pm}|^2$. Benenson *et al.*[1] compute the charge dependence as

$$R_{-/+} \approx \frac{|\phi_{\pi^-}(R)|^2}{|\phi_{\pi^+}(R)|^2}$$

where $\phi_{\pi^\pm}$ contains the Coulomb distortion of the projectile. Thereby the large effect seen for pion velocities close to the beam velocity is qualitatively explained. The effect of the nuclear density of states will now be included. To describe $\rho_{\mathrm{f}}^{\mathrm{N}}$, it is assumed that there is a thermal equilibrium among nucleons. The final state density then depends on pion energy and charge according to

$$\rho_{\mathrm{f}}^{\mathrm{N}} \sim \exp\left[-(E_{\pi^\pm} \mp (\mu_{\mathrm{p}} - \mu_{\mathrm{n}}))/kT\right] \qquad (1)$$

Here kT is the temperature of the nucleons, and μ_{p} and μ_{n} are the chemical potentials of the protons and neutrons. In view of the relatively small number of nucleons involved in the collision, and the fact that the pions are most likely to be created at the initial stages of the collision, before any sort of equilibrium is established, the statistical assumption may be questioned. However, it is a fact that energy spectra tend to be exponential, with a coefficient close to the 'temperature' calculated as below[4]. Thus we at least find phenomenological justification for equation (1).

$R_{-/+}$ is now compared at the two energies, for the same velocity of the pion with respect to the projectile. The Coulomb distortion effects should be nearly the same, so the ratio of $R_{-/+}$ would be given by

$$R_{-/+}/R'_{-/+} \approx \exp\left[2(\mu_{\mathrm{p}} - \mu_{\mathrm{n}})\left(\frac{1}{kT'} - \frac{1}{kT}\right)\right]$$

In the system studied experimentally, $^{20}\mathrm{Ne} + \mathrm{NaF}$, the chemical potentials differ mainly because of the Coulomb field. Assuming that the pion production takes place in an overlap region between the colliding nuclei, the difference between chemical potentials may be estimated as

$$\mu_{\mathrm{p}} - \mu_{\mathrm{n}} = \frac{Ze^2}{R} \approx \frac{20(1.44)}{3.3}\,\mathrm{MeV} \approx 8.7\,\mathrm{MeV}$$

To estimate the temperature at 100 MeV per nucleon projectile energy, note that the energy available in the centre of mass, per nucleon, is ~25 MeV. With Boltzmann statistics, this implies a temperature of $\frac{2}{3}(25) = 16.7$ MeV. A more detailed calculation taking into account such things as quantum statistics and binding energy effects yields a temperature of 13.5 MeV. Similar considerations for 400 MeV per nucleon yield a temperature of

0028-0836/80/030280—02$01.00

55 MeV. Then for a given pion velocity with respect to the projectile, we expect a diminution of π^- at the lower energy of

$$R/R' \approx \exp\left(17.4\left(\frac{1}{55}-\frac{1}{13.5}\right)\right) \approx 0.37$$

This agrees with the experimental ratio $0.5/1.2 \approx 0.42$ found for pions of high rapidity.

From these considerations, it seems that $R_{-/+}$ will be a useful probe of the nucleonic density of states in the early stages of heavy ion collisions at lower bombarding energies, and seems to be conveniently interpretable as a temperature. This complements the usefulness of $R_{-/+}$ at higher energies as a probe of the geometry of the collisions, via the dependence on the Coulomb distortions.

I thank W. Benenson for discussions, and the NSF for support under grant no. PHY-7620097.

Improved planar solar convertor based on uranyl neodymium and holmium glasses

Renata Reisfeld & Yehoshua Kalisky

Department of Inorganic Chemistry and Energy Center,
The Hebrew University, Jerusalem, Israel

The use of uranyl doped glasses for solar energy conversion and concentration was discussed by Reisfeld and Neuman[1]. While the UO_2^{2+} ion is an efficient energy convertor, its maximum emission peaking around 500 nm does not coincide with the maximum sensitivity of the existing solar cells which is around 700–1,000 nm. The use of Nd^{3+} doped glasses for solar energy collectors was described by Levitt and Weber[2]. While the emission of Nd^{3+} peaking at 880 nm ($^4F_{3/2}\rightarrow{}^4I_{9/2}$) and at 1.06 μm ($^4F_{3/2}\rightarrow{}^4I_{11/2}$) is ideal for matching with the maximum sensitivity of solar cells, its absorbance arising from the forbidden transition 4f–4f is low and the overlap of the absorption spectrum of Nd^{3+} with the solar spectrum is rather weak. To increase the operational efficiency of solar collectors, a maximum overlap between the absorption spectrum of the collector and the solar spectrum is required[3]. In this report we suggest that glasses doped by uranyl and neodymium and uranyl and holmium increase the response to the solar spectrum, thus increasing the collection efficiency, and convert the absorbed light in the wide spectral range into the narrow fluorescence band at 1.06 μm and 880 nm in uranyl–neodymium glasses and 660 nm ($^5F_5\rightarrow{}^5I_8$) and 750 nm ($^5F_4, {}^5S_2\rightarrow{}^5I_7$) in the uranyl–holmium co-doped glasses.

Energy transfer from $UO_2^{2+}\rightarrow Nd^{3+}$ in barium crown glasses was discussed by Gandy *et al.*[4] and Melamed *et al.*[5] for small concentrations of UO_2^{2+} in the glasses. The use of energy transfer for lowering the laser threshold in rare earth doped glasses is a well-known phenomenon[6]. Here we present quantitative calculations on energy transfer between $UO_2^{2+}\rightarrow Nd^{3+}$ and $UO_2^{2+}\rightarrow Ho^{3+}$ at a much higher concentration range than in ref. 4. This higher concentration range is suitable for solar energy conversion. The absorption, excitation and emission spectrum of UO_2^{2+} doped phosphate glasses may be found in ref. 1.

The excitation spectrum of the $^4F_{3/2}\rightarrow{}^4I_{11/2}$ (1.06 μm) transition of a glass doped by 2 wt % Nd^{3+} and co-doped by 2 wt % Nd^{3+} + 1 wt % UO_2^{2+} in the spectral range 360–500 nm is presented in Fig. 1. Due to the energy transfer from UO_2^{2+} to Nd^{3+}, the integrated fluorescence intensity of Nd^{3+} excited in this region is increased 8.5-fold. In the total spectral range from 360–800 nm this increase amounts to 150%. This percentage is equal to the number of photons of the solar spectrum affecting the co-doped glass divided by the number of photons affecting the Nd^{3+}-only doped glass. This ratio was calculated using the formula:

$$\frac{S_{cod}}{S_{dop}} = \frac{A^1\times\eta_{tr}\times\eta^1 + A^2\times\eta^2}{A^2\times\eta^2}\times 100 \tag{1}$$

Where S_{cod} is area under the excitation spectrum of the co-doped glass, and S_{dop} the area under the excitation spectrum of the Nd^{3+} doped glass. The area of the excitation spectrum was corrected for the spectral response of the xenon source and the excitation monochromator. η_{tr} is energy transfer efficiency from UO_2^{2+} to Nd^{3+}, A^1, A^2 = absorbance of UO_2^{2+} and Nd^{3+} respectively, and η^1, η^2 = fluorescence quantum efficiency of UO_2^{2+} and Nd^{3+} respectively.

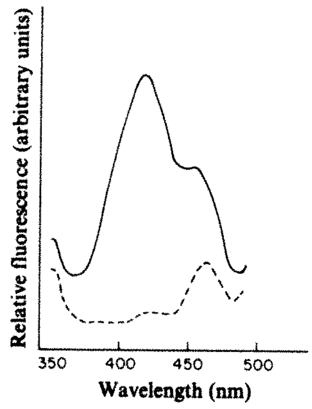

Fig. 1 Excitation of Nd^{3+} (– – –) and $Nd^{3+} + UO_2^{2+}$ (——). Emission monitored at 1,055 nm.

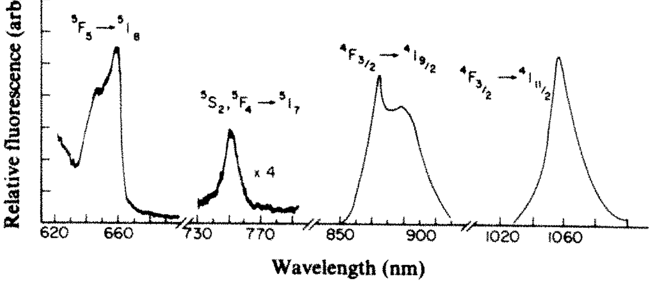
The emission spectrum of Nd^{3+} and Ho^{3+} glasses co-doped with UO_2^{2+} are presented in Fig. 2. The emission maxima correspond to the maximum sensitivity of the silicon solar cells[7]. The efficiency of energy transfer was calculated using equations (2) and (3) and is presented in Table 1.

$$\eta_{tr} = 1 - \frac{\tau_d}{\tau_d^0} \tag{2}$$

$$\eta_{tr} = 1 - \frac{I_d}{I_d^0} \tag{3}$$

Where τ_d is the first *e*-folding time[6] of UO_2^{2+} in the presence of Nd^{3+} and τ_d^0 is the first *e*-folding time of UO_2^{2+} alone. I_d and I_d^0

Fig. 2 Fluorescence emission spectra of Nd^{3+} and Ho^{3+} co-doped with UO_2^{2+} when excited into the maximum absorption peak of UO_2^{2+}.



0028-0836/80/030281—02$01.00

Table 1 Energy transfer efficiency between $UO_2^{2+} \rightarrow Nd^{3+}$ and $UO_2^{2+} \rightarrow Ho^{3+}$ using equations (2) and (3) (excitation at 420 nm)

Concentration (wt %)	Decay time (μs)	η_{tr} eqn (2)	η_{tr} eqn (3)
1 wt % UO_2^{2+}	205		
1 wt % UO_2^{2+} + 2 wt % Nd^{3+}	90	0.56	0.65
1 wt % UO_2^{2+} + 2 wt % Ho^{3+}*	145	0.29	0.55

* The discrepancy of η_{tr} obtained by the two methods in the case of Ho^{3+} will be discussed in a following paper.

are the fluorescence intensities of UO_2^{2+} with Nd^{3+} and UO_2^{2+} alone respectively.

From the above it can be seen that the efficiency of the previously proposed fluorescent collector can be significantly increased by utilisation of energy transfer from UO_2^{2+} to Nd^{3+}.

The practical application of Ho^{3+} co-doped glass is still doubtful because of the low branching ratio of the $^5F_4$, $^5S_2 \rightarrow {}^5I_2$ and $^5F_5 \rightarrow {}^5I_8$ transitions.

We thank Enrique Berman and Professor Fred Singer for their interest in this work. Patents for the convertor described here are pending.

Zirconolite—a fluorite-related superstructure

H. J. Rossell

Engineering Ceramics and Refractories Laboratory, CSIRO Division of Materials Science, PO Box 4331, GPO, Melbourne 3001, Australia

Synthetic zirconolite, $CaZrTi_2O_7$, has attracted interest recently, as it has been proposed as a constituent phase of an artificial rock (SYNROC) which may immobilise, in solid solution, the elements occurring in high-level nuclear reactor wastes[1]. Although it is known that zirconolite is a superstructure phase, derived by ordering of an anion-deficient fluorite (CaF_{2-x} or Mo_{2-x}) type of substructure[2], the crystal structure proper, and thus the nature of the ordering, is not known. This has hampered discussion of the crystal chemistry of the phase. A crystal structure determined from powder X-ray diffraction intensities and adequate for such discussion purposes is reported here.

Single-phase $CaZrTi_2O_7$ was made by heating the component oxides mixed in stoichiometric proportions at 1,450 °C for 4 days. Some of the product was crushed and examined in an electron microscope fitted with a tilting stage. Single crystal fragments were selected, and appropriate electron diffraction patterns were recorded. These confirmed the published crystallographic relationship of the supercell to the subcell[2], and enabled the space group of the supercell to be identified as either the centrosymmetric C2/c or the non-centrosymmetric Cc. Lattice parameters were determined from a powder X-ray diffraction photograph taken with a Guinier camera using CuKα_1 radiation and with thoria ($a = 5.5972$ Å) as an internal standard (Table 1).

Well crystallised zirconolite may be prepared quite readily[2,3], but at least one attempt to determine the structure from single-crystal X-ray diffraction data has been unsuccessful (W. G. Mumme, personal communication). It was suspected that the data may have been affected by multiple twinning in the crystal: this frequently accompanies the crystallisation of materials with a high degree of pseudosymmetry, and may not be readily detectable. Therefore, powder X-ray diffraction intensity data have been used to determine the structure. This technique has been successful for some other oxides with fluorite-related superstructures which could not be prepared as suitable single crystals.

Powder X-ray diffraction intensities for $\theta < 40°$ were recorded on chart, using a powder diffractometer and filtered CuKα radiation. Peaks were separated where practicable, and their areas measured with a planimeter. A reflection or group of reflections was assigned to each such observation, giving a data set composed of 295 reflections distributed among 155 observations. Structure refinement was carried out using a full matrix least-squares computer program for the treatment of powder data.

As the unit cell is composed of eight fluorite M_4O_8 subcells, it has the contents $Ca_8Zr_8Ti_{16}O_{56}\square_8$ (□, oxygen vacancy), an assignment confirmed by density measurement. The structure was determined by trial and error according to procedures used in similar circumstances[4–6]. Trial structures, comprising all possible ordered arrangements of metal atoms allowed by the space groups, with atoms on the ideal fluorite positions of the supercell and all oxygen sites occupied, were refined, due care being taken in the removal of initial degeneracy. These trial structures were rejected or retained according to the value of the crystallographic residual R, which expresses the agreement between observed and calculated intensities.

It was found that one structure in C2/c (and its equivalent in Cc) was greatly superior to all the others. With this model, the site of the oxygen vacancy was found by refining the occupancies of the eight oxygen atoms in the asymmetric unit, when one fell immediately to zero, while the others were unaffected. The extent of disorder in the metal atom array was assessed by refining cation occupancies. The refinement converged satisfactorily to $R = 0.054$, with reasonable values for the refined parameters and their calculated standard deviations. An overall isotropic temperature factor was used, and on refinement, it assumed a value close to zero, with a relatively large standard deviation. As powder work involves low-angle data and non-ideal specimen surfaces, the temperature factor may have little significance as a structural parameter.

There was no indication that the structure was not centrosymmetric: refinement of the trial structure in Cc (which has 4-fold sites only) produced the same structure as that found in C2/c within calculated standard deviations of atomic parameters, and there was no significant improvement in the fit of observed and calculated intensities, despite the greater number of variable parameters. Also, a test for the absence of a

† There is only one formal occupancy variable, because of the stoichiometry restraint.

centre of symmetry, based on the detection of nonlinear optical effects[7], yielded a null result.

The structural parameters determined are collected in Table 2. In this structure, Ca atoms are coordinated by eight oxygen atoms at the corners of a distorted cube, Zr atoms (overlooking the minor components at mixed-occupany sites for convenience) by oxygen at seven of the eight vertices of a distorted cube, and Ti by six oxygen atoms, either at the vertices of octahedra (M3 and M5) or a trigonal prism (M4). All these results accord with crystal-chemical expectations[8,9]. The 'vacant' oxygen sites occur in pairs, separated by a lattice vector of the type $\frac{1}{2}$ [111] (fluorite), with a Ti atom M3 or M5 in between, and, as expected on electrostatic grounds, the relaxation of atoms from their ideal fluorite positions is such that the tetrahedron of metals (cations) surrounding a vacancy is expanded, whereas the octahedron of oxygens around it is contracted. Similar effects have been found in all of the anion-deficient fluorite-related superstructures studied so far.

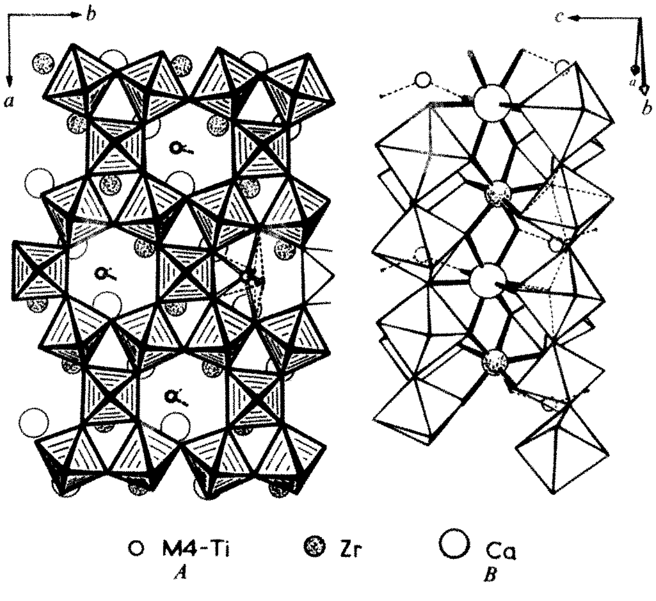

Fig. 1 A, (001) sheet of TiO_6 octahedra with parallel plane of Ca + Zr below it. The Ti atoms M4 in the sheet are associated with two O atoms X2, which are not in the octahedra: The trigonal prismatic coordination of one M4 is outlined. B, Portion of the structure viewed down [1$\bar{1}$0] approximately, showing coordination of Ca and Zr.

In the superstructure, there are planes of metal atoms parallel to (001) which are derived from the f.c.c. fluorite 'close-packed' metal-only (111) planes. The cation ordering is such that these planes alternately contain Ti only (A planes) and Ca + Zr (B planes). The (001) sheets of TiO_6 octahedra (Fig. 1) are similar to the sheets of octahedra parallel to {110} in the pyrochlore structure[10]. Within each B layer, Ca and Zr occupy alternate rows, which run parallel to [110] and [1$\bar{1}$0] in alternate B planes.

This structure determination provides an adequate basis for discussion of the crystal chemistry of zirconolite. However, crystals suitable for X-ray study have been produced in the CSIRO Division of Mineral Chemistry, and the structure has been determined independently from single crystal data, using direct methods. The refined results are more precise than those above, and reveal some interesting new structural effects; nonetheless, the overall agreement between the two determinations is excellent. The single crystal work has been done jointly with I. E. Grey, R. J. Hill and A. F. Reid (Mineral Chemistry) and B. M. Gatehouse (Monash University), and will be published elsewhere. Also, a structure study of non-stoichiometric zirconolite, and of zirconolite containing various oxides in solid solution has been completed and will be reported in the near future.

OCS, stratospheric aerosols and climate

Carbonyl sulphide (OCS) is found to be the predominant sulphur-bearing compound in our atmosphere[1–3]. It contributes to the formation of stratospheric sulphate aerosol particles[4], which affect the Earth's radiation balance and climate[5–7]. Using recently obtained data, we estimate that OCS has a global source of ~5 tg per year (tg = 10^{12} g) and a lifetime of roughly 1 yr. We calculate that increasing anthropogenic emissions of OCS could cause measurable climate alterations within the next century.

Numerous sources of OCS have been identified (see Fig. 1). Crutzen *et al.*[8] estimate that natural and agricultural fires contribute 0.2–0.3 tg of OCS to the atmosphere each year. Adams *et al.*[9] measured average OCS emission rates for a variety of common soils of about 0.004 g m^{-2} yr^{-1}, which may be extrapolated to a global OCS source of nearly 0.5 tg yr^{-1}. Adams *et al.*[9] also noted OCS emissions several thousand times greater than average above saline marshes. Carbonyl sulphide has been detected near cattle feedlots in concentrations as high as 6,000 p.p.b.v.[10]. Volcanoes and fumaroles seem to represent a minor source of OCS (refs 11, 12). We estimate that the direct contributions of biospheric processes to the OCS budget may be ~1 tg yr^{-1}.

0028-0836/80/030283—04$01.00

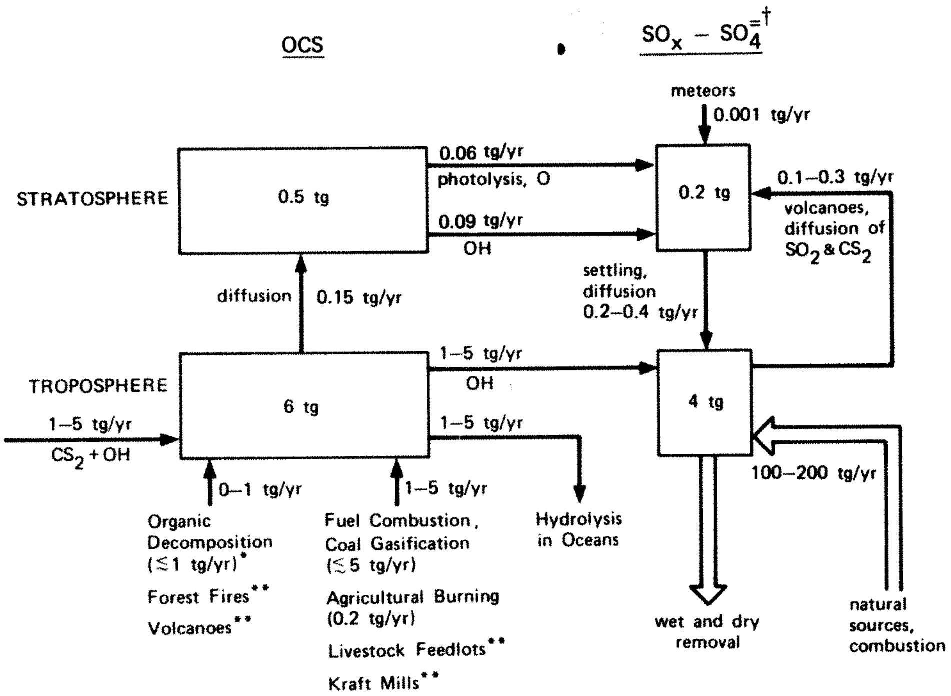

Fig. 1 Atmospheric budget of carbonyl sulphide, and of other sulphur compounds. Masses are given in teragrams (tg). (The small mass difference betwween OCS and SO_2 molecules is ignored.) † Masses are expressed in terms of an equivalent amount of SO_2. * The source is difficult to quantify, but appears to be significant. ** The source is small, probably much less than 1 tg yr^{-1}.

Kurylo[13] has suggested that carbon disulphide is a precursor of OCS via the reaction

$$CS_2 + OH \rightarrow OCS + SH (k = 1.9 \times 10^{-13}\ cm^3\ s^{-1} \text{ at } 296\ K) \quad (1)$$

Using Kurylo's rate constant and observed daytime OH concentrations[14–17], the CS_2 lifetime against conversion into OCS appears to be ~1–3 months[18]. CS_2 concentrations of 0.07–0.37 p.p.b.v. have been measured by Sandalls and Penkett[19] in the UK. Interestingly, these amounts are roughly consistent with the quantity of CS_2 found dissolved in the Atlantic Ocean by Lovelock[20] (~5×10^{-13} g ml^{-1}) assuming equilibrium between the atmosphere and oceans. Adopting a uniform tropospheric CS_2 concentration of 0.07 p.p.b.v. (taking the lowest value observed by Sandalls and Penkett as the background abundance), an average CS_2 lifetime of two months, and unit conversion of CS_2 into OCS, we estimate that 5 tg yr^{-1} of OCS could be generated from CS_2.

Sources of atmospheric CS_2 could include the oceans[20], marshes[9] and industrial processes[21,22]. Until more quantitative information concerning the global budget of CS_2 is gathered, however, we favour an estimate of 1–5 tg yr^{-1} of OCS from the decomposition of natural and manmade CS_2.

The refining and combustion of fossil fuels currently releases about 100–150 tg of SO_2 to the atmosphere each year. The average sulphur residue in coal is ~1% by mass, and in petroleum, 0.2% (refs 25, 26). Assuming that 6% of the emitted sulphur is OCS (where 6% is a maximum value for existing sulphur recovery systems[21]) the OCS combustion source could be 6–9 tg yr^{-1}. Of course, only a small fraction of worldwide combustion emissions are processed for sulphur removal, and untreated stack gases generally have very low OCS concentrations[21]. Hence, the OCS emission might be less than 1 tg yr^{-1}.

During coal gasification and liquification, highly reducing conditions prevail, and OCS may be produced in fractional quantities as large as 10^{-3} of the total gas volume. After scrubbing of the tail gases, however, emissions of OCS from these coal plants should (typically) amount to less than 1% of the sulphur in the coal processed[21]. Catalytic converters used in cars occasionally generate large quantities of H_2S and OCS (ref. 27). Although car petrols have very low sulphur contents—commonly 0.03–0.06% S by weight (ref. 21)—all of the sulphur is released to the atmosphere. Thus, a small contribution to the global OCS budget from petrol consumption could be expected. Negligible anthropogenic sources of OCS include direct commercial production[21], cigarette smoke[28], vapours from cooking grain mashes[29], and Kraft mills[30].

We conclude that the total global source of atmospheric OCS may be in the range of 1 to 10 tg yr^{-1} (see Fig. 1), and that a large fraction of this, perhaps as much as 50%, may result from anthropogenic activities related mainly to fuel processing and consumption.

Ultraviolet photolysis of OCS above 20 km is a sink for OCS and a source of sulphur for stratospheric aerosols[4], but leads to an overall OCS atmospheric lifetime of 50 years or more. Reaction with OH may be the largest atmospheric

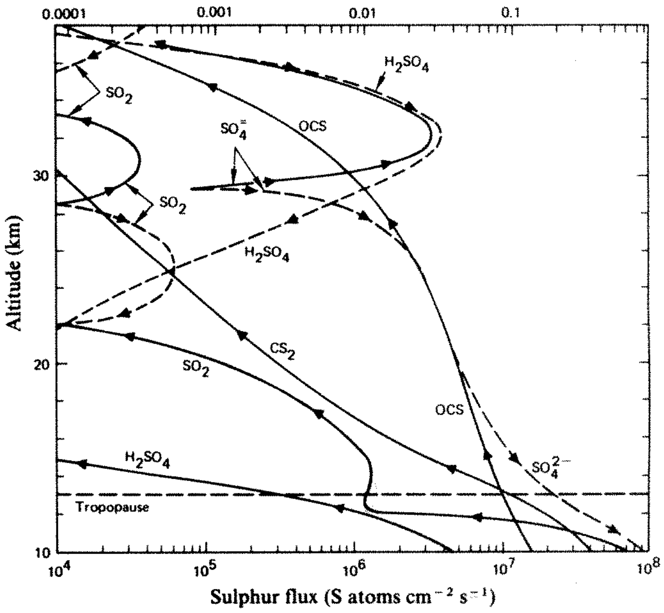

Fig. 2 The stratospheric balance of gaseous sulphur and aerosol sulphate in a one-dimensional model[33,34]. Equivalent sulphur atom fluxes are given. The arrows indicate direction of sulphur flow (also, solid lines correspond to upward fluxes, dashed lines to downward fluxes). The SO_2 flux divergence is complicated because of SO_2 sources near 15 km due to CS_2 decomposition, 29 km due to OCS photodissociation, and 50 km due to H_2SO_4 photolysis[33]. An H_2SO_4 source exists above 30 km as a result of aerosol droplet transport and evaporation[34].

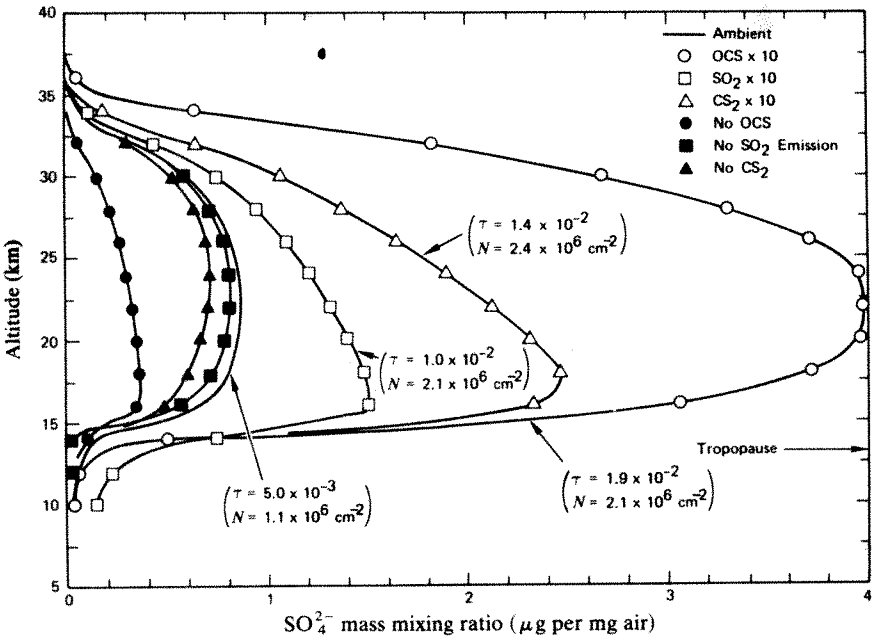

Fig. 3 Stratospheric aerosol sulphate (SO_4^{2-}) mass mixing ratios predicted for ambient and perturbed conditions. A 10-fold enhancement in OCS, SO_2 or CS_2 is simulated by increasing its surface concentration 10-fold, resulting in roughly a factor of 10 increase in its surface emission rate and tropopause concentration, while the abundances of the other two constituents are essentially unaltered. For several of the cases treated, the total large particle ($r > 0.15$ μm) column concentration in the stratosphere (N) and the optical depth of the sulphate layer at 550 nm (τ) are given in brackets.

sink for OCS[13],

$$OCS + OH \rightarrow CO_2 + SH (k = 5.7 \times 10^{-14} \text{ cm}^3 \text{ s}^{-1} \text{ at } 296 \text{ K}) \quad (2)$$

For likely tropospheric OH concentrations[14–17] reaction (2) implies roughly a one-year atmospheric lifetime for OCS. Reactions of OCS with ground state and excited oxygen atoms can be ignored.

Although hydrolysis of OCS is rapid in basic solutions, it is quite slow (weeks to months) in neutral[21] and acidic[31] solutions. OCS also has only a moderate solubility (1.4 g l^{-1} H_2O STP). Accordingly, we deduce that scavenging of OCS by clouds, aerosols and rainfall may be neglected. Seawater, by contrast, has a *p*H greater than 7, which implies efficient OCS hydrolytic decomposition. It has been estimated (F. S. Rowland; personal communication) that oceanic hydrolysis could lead to a global OCS lifetime as short as a year.

Carbonyl sulphide has been measured extensively in the troposphere[1–3,19] and lower stratosphere[32] and is the predominant sulphur-bearing compound in the atmosphere. OCS has a ubiquitous tropospheric concentration of about 0.5 p.p.b.v. with no apparent gradient between the boundary layer and the upper troposphere. OCS also has a small (~5%) interhemispheric contrast[3]. In addition, OCS variability (from one measurement to another) is found to be less than 10% (refs 2, 3, 19). All these observations are consistent with an OCS lifetime of the order of one year.

With reference to Fig. 1, the 6 tg of OCS measured in the atmosphere is compatible with an OCS source of 6 tg yr^{-1} and a tropospheric lifetime of one year, similar to the values we have estimated. Recent model calculations of the ambient atmospheric sulphur balance[33,34] indicate that observed OCS, CS_2 and SO_2 abundances are roughly consonant with global surface emission rates of 3 tg yr^{-1} OCS, 4 tg yr^{-1} CS_2 and 100–150 tg yr^{-1} SO_2.

The stratospheric sulphur balance for non-volcanic conditions is shown in Fig. 2 (based on a one-dimensional model calculation[33]). The dominance of OCS is clearly brought out, although CS_2 and SO_2 also contribute significantly to the stratospheric sulphur cycle. This raises the possibility that increased fossil fuel consumption rates, as have been projected by Rotty[35] (approximately a fourfold increase by 2025, to 23,000 tg carbon per year), may cause greater sulphur vapour emissions, which can alter the stratospheric sulphate aerosol, or Junge[36], layer. Using an appropriate model[33,34], we have studied the sensitivity of aerosol mass loading to changes in OCS, SO_2 and CS_2 concentrations (Fig. 3). Obviously, changes in the OCS level have the largest impact on the aerosol layer. Even so, a 10-fold increase in CS_2 emissions could lead to a greater aerosol enhancement. Most of the CS_2 emissions might be chemically converted into OCS and SO_2 in the lower atmosphere. Hence, if CS_2 is the primary source of OCS, a CS_2 increase could produce an effect nearly as large as the combined effects of the CS_2 and OCS increases shown in Fig. 3.

The ambient aerosol layer has an optical depth of about 0.005 at 550 nm (ref. 37). For a 10-fold increase in OCS, the estimated optical depth is about 0.019. This can be compared to the optical depths observed following volcanoes Fuego (0.02–0.03) and Agung (0.02–0.04 in the Northern Hemisphere, and 0.2–0.3 in the Southern Hemisphere). Thus, a 10-fold increase in OCS produces an optical depth perturbation comparable to that of a modest volcanic eruption.

When we use these OCS optical depths in an improved version of the radiation transport model of Pollack *et al.*[5–7], we find a possible decrease in the average global surface temperature of about 0.1 K, and a possible comparable increase in stratospheric temperatures. The surface temperature change is at the threshold of climatic significance. However, OCS, like CO_2, can create a 'greenhouse' effect in which far IR radiation emitted by the Earth is trapped in the lower atmosphere, warming its surface and compensating somewhat the aerosol cooling.

Because of man's apparently strong influence on the atmospheric sulphur cycle, and because of the established role of sulphur emissions in air pollution episodes and possible climatic changes, we suggest that future use of fossil fuels be carefully monitored for released sulphur compounds, including OCS and CS_2.

We thank F. S. Rowland, P. J. Crutzen and R. J. Cicerone for useful conversations on the global OCS budget. This work was supported in part by NASA grant NAS2–9881.

Low-aspect ratio ignimbrites

G. P. L. Walker, R. F. Heming & C. J. N. Wilson*

Department of Geology, University of Auckland, Auckland,
New Zealand

Conventionally[1], three important characteristics of ignimbrites are that they show a very pronounced tendency to pond in topographic depressions, possess a flat, horizontal or gently sloping upper depositional surface, and have a thickness generally between 10 and 1,000 m. The youngest major ignimbrite, that of 1912 in the Valley of Ten Thousand Smokes (Alaska)[2–4] shows these characteristics well, being ponded in a valley 25 km long with a flat upper surface sloping down-valley at an average of 1.3°, and having an estimated thickness exceeding 100 m in places. All three characteristics are commonly used as field criteria to distinguish ignimbrites from other pyroclastic rock bodies. Here we look at certain ignimbrites which depart significantly from this conventional form in that a major part of them occurs as a thin layer mantling the landscape, resting on slopes as steep as 30°, and with an upper surface sensibly parallel with the underlying surface. We have studied two examples, the 1,800-yr-old[5] Taupo ignimbrite (New Zealand), and the 1,400-yr-old Rabual ignimbrite (New Britain)[6,7]. We also cite several others. These ignimbrites have a remarkably low aspect ratio. This ratio, previously applied to lava extrusions[8,9], provides a useful means of quantifying the overall geometry of rock bodies. The ratio is that of average thickness to lateral spread; conveniently the latter is taken as the diameter of the circle which covers the same area as the rock body.

The young age of the Taupo and Rabaul ignimbrites, and their occurrence in humid areas where a luxuriant vegetation anchors and protects pyroclastic deposits very soon after they have formed, has resulted in their remarkably good structural preservation. These ignimbrites shown new features which require that a reappraisal be made of emplacement mechanisms, and new diagnostic criteria be made for recognising pyroclastic types.

'Ignimbrite' is a rock body made predominantly from pumiceous material (pumice, glass shards), which may or may not be welded, and has characteristics indicating that it was emplaced as a hot and concentrated particulate flow. By concentrated we mean that the volumetric particle:gas ratio in the moving flow was relatively high; pumice density[10] and fluidisation[11] studies on non-welded flows indicate that they were little expanded beyond their observed density. We thus use the word ignimbrite in a genetic sense, more or less synonymously with ash flow.

The outstanding feature of the Taupo and Rabaul ignimbrites is that both occur in two contrasted forms (Fig. 1) having quite different relationships to the pre-existing land surface: one form occurs as a mantling layer generally less than 2 m thick which more or less completely drapes the landscape; the other form occurs in the 'conventional' way as valley-ponds having a nearly horizontal upper surface and locally attaining a depth exceeding 10 m. The name 'ignimbrite veneer deposit' is proposed for the landscape-blanketing form which connects the valley-ponds in a continuous sheet.

At the edge of the valleys the ignimbrite veneer deposit is visibly continuous with the ponded ignimbrite, and this continuity is observed at so many points that there is no doubt that both forms are part of a continuous rock body. The ignimbrite veneer deposit has practically identical grain size and constitution to the ponded ignimbrite, except that it lacks the coarsest pumice clasts, and it shows a crude layering in which the layers are 1–20 cm thick and differ from one another mainly in maximum pumice size. Locally it also contains discontinuous lenses of well rounded and well sorted pumice.

Our interpretation of the veneer deposit is that the pyroclastic flow surmounted more or less the entire landscape when spreading outwards from source, and after the passage of the main body of the flow the material drained only very incompletely into the valleys, leaving behind a mantling layer on the interfluves. This layer lacks the coarser pumice which, being concentrated in the upper or middle parts, moved on with the body of the flow. The veneer is a 'tail' deposit left in the wake of the pyroclastic flow.

The significance of an ignimbrite veneer deposit is that it is deposited from, and records the passage of, a pyroclastic flow. In the Taupo example, its presence shows that the flow surmounted hills rising more than 1,000 m above the present level of the vent.

The closest analogue to the Taupo and Rabaul ignimbrites in the literature is the Koya flow (Japan)[12] which extends to 60 km from the vent with a thickness of generally less than 1 m. The Lajes ignimbrite in Terceira (Azores)[13] reaches a thickness of 10 m at several places around the coast of the island which are interconnected by a thin layer, now interpreted as a veneer deposit, draped over the intervening country. An example of a densely welded ignimbrite is known on Fantale (Ethiopia)[14] where it clearly occurs as two forms, one as a layer 1–2 m thick spread over much of the surface of the volcano, including some upstanding lava domes, and the other ponded at the foot of the volcano. The continuity of the densely welded Skessa tuff of Tertiary age in Iceland[15], which extends over 430 km^2 with an average thickness of 6 m, appears to have more the characteristics of a veneer deposit than those of a 'conventional' ignimbrite.

Recognition of the ignimbrite veneer deposit as a distinct type requires that the diagnostic criteria for the various pyroclastic types be updated. Similarly to a pyroclastic fall deposit, it mantles the topography and has internal layering. However, it is distinguished by the rapid lateral variations in thickness and occasional cross-bedding shown by the layers, and by the local presence of laterally discontinuous pumice lenses. Like a base surge deposit[16] it shows a distinct cross-bedding, but the angle between layers is commonly less than 10°, much less than in surge deposits. Moreover, the grain-size contrast between layers is negligible compared with that in surge deposits and it also contains carbonised vegetation.

The extensive ignimbrite literature concentrates on the larger-volume and more impressive examples, those which are generally in part at least welded and have smothered the existing landscape to create their own new aggradational surface.

---

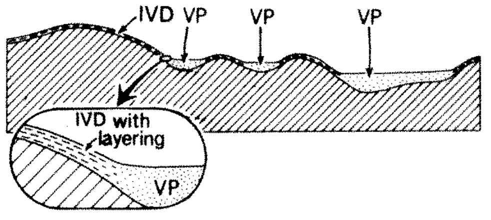

Fig. 1 Sketch showing the relationship between the landscape-mantling ignimbrite veneer deposit (IVD) and the associated valley-ponded ignimbrite (VP) as exhibited by the Taupo and Rabaul ignimbrites.

Workers in volcanic areas have therefore tended to regard the features of these big ignimbrites as characteristic of all ignimbrites; there is a reluctance to apply 'ignimbrite' or its synonym 'ash flow' to thin non-welded sheets, particularly when they mantle the topography and display a crude layering.

The word ignimbrite was originally applied to welded ash flows[17], but it has since become clear that welding of an ignimbrite is largely an accident of circumstance; it depends for example on the eruptive column height (as this determines the magnitude of the heat loss at the vent[1,18]) and on the thickness of the sheet. If 'ignimbrite' is applied in a genetic sense to rock bodies which have been emplaced by a common pyroclastic flow mechanism, then its definition should include non-welded as well as welded examples. Similarly, thin and thick, landscape-mantling and valley-ponded, variants should also be included.

The veneer deposit of the Taupo ignimbrite covers about 15,000 km^2 with an average thickness of ~1 m, and it contains roughly half of the total volume of the ignimbrite. The veneer deposit of the Rabaul ignimbrite covers well over 1,200 km^2—we did not attempt to trace it to its extremities—with an average thickness of ~2 m, and constitutes probably more than half of the total volume. The description of the Koya flow suggests that it probably consists entirely of a veneer deposit. Even the Valley of Ten Thousand Smokes ignimbrite shows a 'high sand mark'[19] which is especially well developed in the near-vent area and described as reaching 60 m above the adjacent valley-pond level towards which it slopes at 10–15°, and may be interpreted as a veneer deposit. We propose that ignimbrites form a spectrum of types, ranging from those in which the veneer deposit constitutes the entire volume, to those in which it constitutes none.

Ignimbrites such as Taupo, Rabaul (and Koya?), in which the veneer deposit constitutes a large proportion of the total volume, may be characterised as ignimbrites of low aspect ratio type. These three examples have an aspect ratio of 1:70,000, 1:7000 and ~1:200,000 respectively, and the Skessa Tuff 1:4,000. In contrast, the VTTS ignimbrite has an aspect ratio of about 1:400 and the Bishop Tuff[20] about 1:250.

It remains to consider why these ignimbrites have a low aspect ratio. It is known that the Taupo ignimbrite eruption was immediately preceded by a plinian phase in which the eruptive column, judged from the wide dispersal of the plinian pumice, was quite exceptionally high[21], and the low aspect ratio is attributed to the high momentum imparted to the pyroclastic flow when catastrophic collapse from this high column occurred and also to the high magma discharge rate. There is good evidence that the Rabaul column was similarly very high. We lack detailed information on the Koya event. In all three ignimbrites the density of the pumice is unusually low, but we think that this is more significant to the dynamics of the explosive eruption than to the mobility of the pyroclastic flows.

Exploring pictures tactually

Lochlan E. Magee & John M. Kennedy

Division of Life Sciences, Scarborough College, University of Toronto, West Hill, Ontario, Canada M1C 1A4

Raised-line drawings of common objects can be identified by congenitally and early blind subjects[1,2] and displays of this type are being devised for use in education (for example, ref. 3). Although a teacher may think it helpful to guide a blind student's hand around one of these drawings, several theories of perception predict that the guidance would be detrimental as passive perception is generally considered to be inferior to active perception (for review see ref. 4). We show here, however, that guidance is helpful and leads to better identification than unguided exploration. We also report that the information used to identify raised-line drawings is predominantly kinaesthetic.

Our first two studies compared active and passive conditions for recognition of raised-line drawings. Although the practical application of this comparison concerns the blind, the issue can be tested using blindfolded subjects. In the first study, eight raised-line drawings of familiar objects were presented individually to 40 blindfolded students. Half of the subjects were passive, that is, the experimenter traced the index finger of the subject's preferred hand around a figure, controlling the direction, extent and speed of movement. The performance of these passive subjects excelled that of the active subjects, who determined their own exploration. The passive group successfully identified 42 drawings compared with 20 identified by the active group, a highly significant difference according to a ranked sums test ($P < 0.005$). This study has the practical implication that a blind student could profit from the guidance of a sighted instructor when first trying to identify raised-line drawings.

Our unexpected result prompted us to carry out a yoked comparison of the two types of exploration in which the movements of a passive subject's finger were matched moment by moment to those of an active subject. Yoking was accomplished with the use of a computer system and a digitised tablet on which the drawing rested. The position of a small coil surrounding the index finger of a subject's preferred hand was monitored within the area of the tablet to the nearest 0.25 mm and recorded every 200 ms to retain a detailed record of exploratory behaviour. The record of the path traced by an active subject could be 'played-back' on a television monitor situated next to the digitised tablet. The entire path was outlined by dots, each dot specifying the location of the centre of the coil at a particular time. A small cursor moved to each dot in turn, thus retracing the subject's exploratory movements.

Eight naive subjects participated as active explorers. One of 12 raised-line drawings was taped to the tablet surface as each blindfolded subject individually explored the complete set of drawings. Each subject was instructed to trace the figure in a clockwise direction, without repetition (retracing). A complete set of tracings was recorded for each of the active subjects exploring each of the 12 drawings presented in different random orders. As an example, Fig. 1 shows a copy of a tracing by an active subject.

0028-0836/80/030287—02$01.00

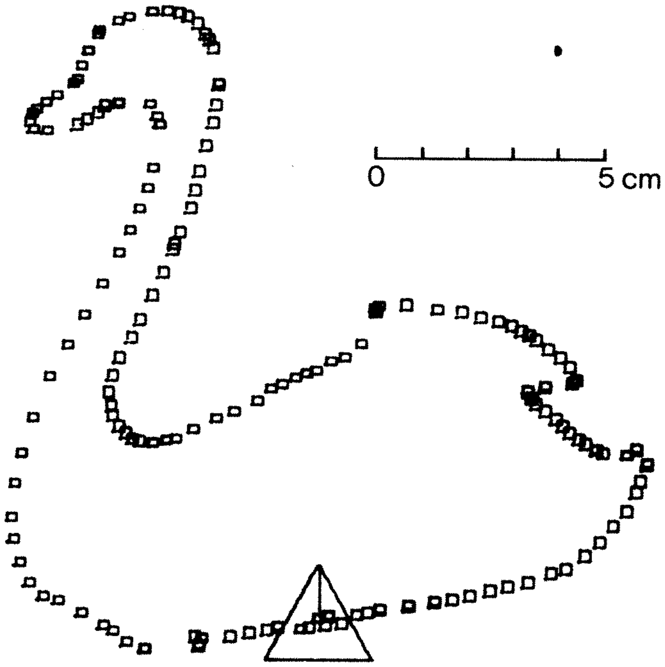

Fig. 1 A tracing of a raised-line drawing of a swan by an active subject. Each small square represents the position of the subject's finger at 200-ms intervals. Exploration began at the centre of the large triangle (not actually present as a raised-line) and proceeded in a clockwise direction. The density of squares therefore indicates the speed at which the finger was moved over each part of the display. An analogue of this figure was available on a monitor to guide the experimenter when passive subjects participated in exploring the form. All raised-line drawings for this experiment were formed by a single continuous line defining the outline of an object easily identifiable by sight. These included a drawing of a butterfly, a boat, a crown, a fish, a goblet, a claw hammer, a hand, a body, a rabbit, an umbrella, a swan and a flower.

Eight passive subjects encountered each of the drawings as presented to their active counterparts. At the same time as the recording of an active subject's performance was replayed by the monitor, the experimenter traced the passive subject's finger along the drawing. A second cursor on the monitor showed the current location of the passive subject's finger. The experimenter, watching the monitor, kept the passive subject's cursor as close as possible to the replay.

A record of the passive subject's finger locations was kept so that the degree to which the active and passive tracings departed could be determined. This involved a calculation of the distance between the active and passive subjects' positions for each interval averaged over the number of intervals needed to complete the trace. As the cursor for the passive subject normally followed the cursor for the active subject, mean deviation was computed for various time lags and a minimum value for mean absolute deviation was specified for each drawing. Averaged over the set of drawings and across pairs of subjects, the overall mean deviation was found to be 2.28 mm, at an average lag of approximately 161 ms. This value represents an average of only 0.67% difference in the areas of the two patterns. Therefore, a difference in identification rates between the two groups is unlikely to be accounted for by a difference in exposure. In agreement with the previous study, passive subjects performed better than active ones. The passive group identified 25 drawings, whereas 16 were identified by the active group, a difference significant under a Wilcoxon matched-pair signed-rank test ($P < 0.05$).

The success of passive participation readily allowed determination of the source of information subserving identification. This involved a comparison of two more groups. For one of these groups ($n = 10$), the subject's index finger was held stationary while the raised-line drawing was moved underneath the fingertip so that the twists and turns of the raised-line could be detected cutaneously unaccompanied by any movement on the subject's part. For a second group ($n = 12$), exposure to the raised-line drawings allowed for kinaesthesis but not for cutaneous input. Here, the subject's finger was moved passively around the outline of a figure where the raised line was not present. The experimenter simply used a clear plastic sheet superimposed on a pencil drawing for guidance. Only five figures were successfully identified by the 'cutaneous' group, whereas 25 figures were identified by the 'kinaesthetic' group. This difference is highly reliable according to a Mann-Whitney *U*-test ($P < 0.001$). Clearly, the ability to identify raised-line drawings does not depend on cutaneous information as it would in braille reading. It seems that information arising from limb position and limb movement is predominant. This does not mean that the raised line fails to serve a useful purpose. Obviously, the raised line is needed to guide movement during active exploration but it is on the resultant kinaesthetic information that identification of the pattern rests.

The importance of kinaesthesis suggests that the difference between active and passive performance may be accounted for by considering how initiation, execution or monitoring of movements differs in these conditions. Active subjects have the additional requirement that they must plan exploratory movements. Some of these intended movements will be translated into activity whereas others may fail to be initiated or be only partially executed. The active group may find it difficult, in memory, to separate intended movements which are acted on from those which are not. Further, the act of planning movements may draw on the limited resources of the haptic system so that less processing capacity is available to monitor and distinguish relevant from irrelevant kinaesthetic input.

We thank our colleagues at Scarborough College, University of Toronto, for valuable comments. This research was supported in part by the NRC of Canada.

Influence of brood hosts on host preferences of bark beetle parasites

Louis H. Kudon & C. W. Berisford*

Department of Entomology, University of Georgia, Athens, Georgia 30602

The southern pine beetle, *Dendroctonus frontalis* Zimmerman (SPB) is attacked by several species of hymenopterous parasites[1,2] the most common of which also parasitise other bark beetles[3–5] including the engraver beetles *Ips grandicollis* (Eichhoff), *I. avulsus* (Eichhoff), *I. calligraphus* (Germar), *I. pini* (Say); and the eastern juniper bark beetle, *Phloeosinus dentatus* (Say). The increasing importance of pest management has focused attention on the role of their natural enemies. However, the dynamics of bark beetle parasite populations is not generally known beyond estimates of mortality caused by parasites. The hymenopteran parasite guild of *D. frontalis* may kill up to 30% of a given brood[2]. Since *D. frontalis* is cyclic in most areas with epidemics followed by very low population

densities[1], other beetle hosts probably act as reservoirs for certain species of these parasites[3]. Conversely, during *D. frontalis* epidemics, other beetles, such as *I. grandicollis* and *P. dentatus* may compete as alternate hosts. Information on preferences for *D. frontalis* and other associated bark beetles is necessary to understand the interactions of this host–parasite complex. We report here the results of a study designed to determine if several known *D. frontalis* parasites display any host preferences among *D. frontalis, I. grandicollis* or *P. dentatus.*

Infestations of *D. frontalis, I. grandicollis* and *P. dentatus* were located in Camden, Clarke and Oglethorpe Counties, Georgia. Bolts, ~0.5 m long and 20 cm in diameter, that were uniformly infested predominantly with late instar larvae, were cut as trap bolts. Camors and Payne[6] showed that *Heydenia unica* Cook and Davis prefers third instar larvae of *D. frontalis*, and many other parasites have similar preferences (Berisford *et al.* unpublished data). Lengths of the trap bolts were adjusted according to diameter, to maintain approximately 3,000 cm^2 of bark surface. Each trap bolt was infested with only one species of bark beetle. *D. frontalis* and *I. grandicollis* trap bolts were cut from loblolly pine (*Pinus taeda* L.) and *P. dentatus* trap bolts were from eastern red cedar (*Juniperus virginiana* L.). Concurrent with the above collections, bolts of similar size which had beetle pupae or callow adults with parasites that were about to emerge were cut as a source of the parasites.

All the bolts were removed to University of Georgia School of Forest Resources Whitehall experimental forest near Athens, Georgia. Traps constructed from 30 × 20 cm aluminium metal screening (16 × 18 mesh) were affixed to the trap bolts which contained third instar larvae and the screens were coated with a thin layer of 'Stikem Special'. The trap bolts were then suspended by hooks from wooden frames inside 6 × 6 × 6 ft (1.83 m) saran screen cages (32 × 32 mesh). The cages were erected under a light pine overstory. Source bolts were placed at the bottom of the cages. Sunlight was blocked from the cages by a sheet of 100 μm thick black plastic draped over the top. This prevented the parasites from orientating to the light at the top of the cages. Four trap bolts of each beetle species involved in the experiment, and four source bolts, all infested with the same beetle species were used in each cage. Uninfested control bolts were used in preliminary experiments but discontinued when they were found to be unattractive to parasites. All possible two- and three-host combinations were tested except *P. dentatus* and *I. grandicollis* alone.

The sticky traps on the infested bolts were inspected daily for up to 2 weeks depending on parasite emergence from the source bolts. Parasites were removed from traps, cleaned in petrol and saved for identification. Trap bolts were checked as long as parasites emerged from source bolts or until larvae in trap bolts began to pupate. Responses of parasites to beetle hosts from which they were reared was compared using the normal approximation to the binomial in a one-tailed test.

During 25 field cage experiments, 681 parasites comprising six species were trapped. Parasites trapped included *Heydenia unica* Cook and Davis, *Roptrocerus xylophagorum* (Ratzeburg), *Coeloides pissodis* (Ashmead), *Dendrosoter sulcatus* Muesebeck, *Cecidostiba dendroctoni* Ashmead, *Spathius pallidus* Ashmead and *Spathius impus* Matthews.

Some of the parasites are somewhat host-specific but were included for comparison. They were not considered in the overall analysis. *S. pallidus* parasitises *I. grandicollis*[5] and *D. frontalis*[2] but not *P. dentatus*. However, *P. dentatus* is parasitised by *S. impus*[7] which is apparently host specific to *Phloeosinus* spp., *D. sulcatus*, although a frequent parasite of *Ips grandicollis* and *D. frontalis*[5] probably does not parasitise *P. dentatus*. The orientation of these host-specific parasites to their proper host is indicative of the efficacy of the experimental technique. *Cecidostiba dendroctoni* has been suspected of parasitising *I. grandicollis*[8]. All *Cecidostiba* reared from *I. grandicollis* came from trees removed from the same site in Camden County, Georgia. Apparently, in that area, *C. dendroctoni* is a relatively common parasite of *I. grandicollis. H. unica, R. xylophagorum* and *C. pissodis* attack all three host beetles[2–5,9,10].

Parasites which emerged from a given host returned to that host in significantly greater numbers (Fig. 1). Parasites reared from *D. frontalis* and exposed to *P. dentatus* and *D. frontalis* as

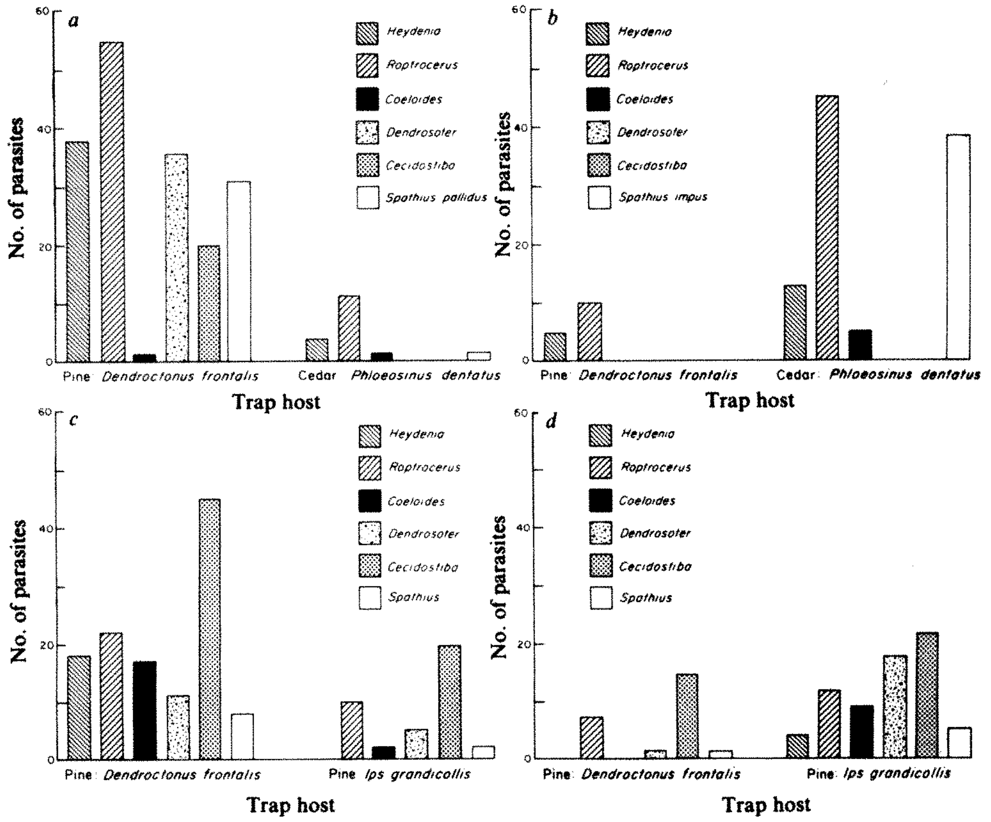

Fig. 1 Numbers of hymenopterous parasites collected from trap bolts in field-cage experiments. *a*, Parasites reared from *Dendroctonus frontalis* and trapped on logs containing late instar larvae of *D. frontalis* and *Phloeosinus dentatus* during simultaneous exposure to the parasites. *b*, Parasites reared from *Phloeosinus dentatus* and trapped on logs containing late instar larvae of *P. dentatus* and *D. frontalis* during simultaneous exposure to the parasites. *c*, Parasites reared from *Dendroctonus frontalis* and trapped on logs containing late instar larvae of *D. frontalis* and *I. grandicollis* during simultaneous exposure to the parasites. *d*, Parasites reared from *Ips grandicollis* and trapped on logs containing late instar larvae of *I. grandicollis* and *D. frontalis* during simultaneous exposure to the parasites.

hosts showed an almost tenfold preference for *D. frontalis* (Fig. 1*a*). When parasites reared from *I. grandicollis* or *D. frontalis* were given a choice of these two pine beetles, the split was not so pronounced, with about three times as many parasites returning to the 'parent' host (Fig. 1*c* and *d*). This difference is probably due, in part, to parasites orienting to the tree host (pine vs cedar). *Ips* spp. parasites may manifest differential responses to different tree hosts[11], but both *I. grandicollis* and *D. frontalis* were in loblolly pine in our study. Differences in response in this case probably could not be attributed to the host tree.

Parasite totals for each combination of hosts were shown to be significant at the 5% level except the three host combination with parasites reared from *Ips*. Although statistically non-significant, probably due to the relatively small sample, more parasites selected bolts infested with *I. grandicollis*. These data were significant (5% level), however, when combined with the two host combinations (*Ips* and *Dendroctonus*, with parasites reared from *Ips*). Most counts for individual parasite species from each combination also showed significantly stronger attraction to the species of host from which they were reared.

This host preference phenomenon is an apparent example of Hopkins' host selection principle[12]. Although the principle was proposed for phytophagous insects and has been demonstrated[13,14], exceptions have been noted[15,16]. Our study is one of few apparent demonstrations of Hopkins' host selection principle involving parasites of animals[14,17] and the first for parasites of bark beetles.

Parasites which are not host specific tend to attack the host on which they were reared but they retain the ability to use other hosts if the preferred host is unavailable. This behaviour is advantageous to the parasites in that they may use all potential hosts more efficiently by switching to relatively more abundant alternate hosts when populations of preferred hosts decrease. This phenomenon may also increase prey diversity[18]. The switching mechanism should be particularly helpful to species with relatively low host-finding efficiencies. The most common parasite in our study, *R. xylophagorum*, is unable to locate potential hosts in low numbers proportional to the number located when hosts are abundant[3] but its ability to attack a variety of hosts apparently allows it to maintain substantial populations.

The impact of the parasite guild of the southern pine beetle may be affected by numbers of alternate hosts. Parasites may switch from other hosts during expansions of *D. frontalis* populations if *D. frontalis* becomes much more abundant than the 'preferred' host. Therefore, the host selection mechanism serves to concentrate the parasites on the epidemic host after a period of time. As the epidemic populations decline, the parasites can accept other hosts as they become relatively abundant, thereby reducing the impact of parasites on declining host populations.

We thank Drs. M. C. Birch, H. M. Kulman and F. M. Stephen for help with this manuscript and Dr. G. O. Ware for statistical expertise. These studies were supported by the USDA programme entitled 'The Expanded Southern Pine Beetle Research and Applications Program' through GAES-USFS Cooperative Agreement 18–475.

Mate choice increases a component of offspring fitness in fruit flies

Linda Partridge

Department of Zoology, University of Edinburgh, West Mains Road, Edinburgh, UK

The authors of two influential accounts of the genetic consequences of mate choice consider that animals cannot produce fitter offspring by mating with a fitter than average individual[1,2]. Their main reason for this is that in a population at genetic equilibrium any genetic variation which affects fitness should not be heritable[3]. Other accounts have suggested ways in which mate choice might improve offspring fitness[4]. Data are now presented which show that one component of offspring fitness can be increased by mate choice in *Drosophila melanogaster.* The component of fitness measured was intraspecific competitive success during the part of the life history from first instar larva to adult fly.

The flies used were an outbred stock collected in Dahomey in 1970 and maintained in approximately constant conditions in a population cage at the Department of Genetics, Edinburgh University. Two different experimental comparisons were made. In the first (experiment 1), the offspring of inseminated adult females which had mated in the population cage where many males were present were compared with offspring of females collected from the cage as virgins and mated with a randomly chosen male from the cage. The comparison was made by taking first instar larvae from eggs laid by the 'choice' and the 'no choice' females and competing each set of larvae against an equal number of larvae of Dahomey stock made homozygous for a fourth chromosome bearing the recessive mutant *sparkling.*

Table 1 The competitive success of offspring of flies which had chosen (choice) or not chosen (no choice) their mates

		% Wild type		No. of
		Mean	Variance	vials
First replicate	Choice	51.1	7.1	23
	No choice	48.9	8.7	18
	$t = 2.45$	$P < 0.02$		
Second replicate	Choice	49.8	2.2	21
	No choice	48.1	5.8	14
	$t = 2.45$	$P < 0.02$		

Experiment 1: The experimental details were as follows. Adult male and inseminated female flies were collected from the population cage using a pooter. After anaesthetisation with carbon dioxide, 100 males and 100 females were taken and placed individually in shell vials with food. Eclosing virgin females (100) were then collected from bottles in the population cage and placed individually in the 100 vials containing single males. After 2 days the 'no choice' females were separated from the males, and females of both groups were then set up in batches of 10 and allowed to lay eggs on 10% agar medium with a small amount of yeast present. At the same time, other batches of 10 females were set up using the Dahomey *sparkling* stock. All females were allowed to lay for 24 h before being moved on to fresh agar, and after a further 16 h first instar larvae were collected from the surface of the original agar using a paintbrush. The larvae were then placed in two groups of vials. Vials in the first group each contained 200 larvae from the 'choice' females and 200 *sparkling* larvae; vials in the second group each contained 200 larvae from the 'no choice' females together with 200 *sparkling* larvae. The vials were set up in this way over a period of 10 days, repeatedly taking offspring from the same females which used stored sperm during this period. It was therefore not known how many larvae each female contributed to each vial. The 400 larvae in each vial were allowed to compete and pupate, and the number of wild-type and *sparkling* flies emerging from each vial was recorded. Competitive success was measured as the percentage of wild-type (as opposed to *sparkling*) flies emerging from each vial. Significance levels are on a two-tailed *t*-test.

0028–0836/80/030290—02$01.00

Table 2 The competitive success of offspring of females of the same age which had chosen (choice) or not chosen (no choice) their mates

	% Wild type		No. of vials
	Mean	Variance	
Choice	50.45	2.0	28
No choice	49.44	2.0	32
$t = 2.72$	$P < 0.01$		

Experiment 2: Adult flies were collected from the population cage using a pooter; after anaesthetisation with carbon dioxide the females were discarded, 100 males were placed individually in shell vials with food and 300 were placed in a single bottle with food. Eclosing females were then collected from bottles in the cage, and 100 were placed in the bottle containing 300 males and 100 individually in the 100 vials containing single males. The flies were left for 2 days, after which laying pots and competition vials were set up as in experiment 1. Competitive success was measured as the percentage of wild-type flies emerging in each vial. Probability level is on a two-tailed *t*-test.

Larvae were allowed to compete in vials which contained the same food medium as that used in the population cage, and the number of wild-type and *sparkling* flies emerging from each vial was recorded. The point of this experimental procedure was to ensure that the wild-type parent flies were exactly matched for nutrition and numbers of anaesthetisations, and that the larvae were competing under circumstances similar to those encountered by larvae in the population cage, both with respect to the nature of the food and the genotype of the competitors. The experiment was done twice, and the results, shown in Table 1, indicate that in both replicates the percentage of wild-type flies emerging was slightly, but significantly, higher when the parents of those flies had chosen their mates.

Because the 'choice' flies in experiment 1 were collected at an older age than the 'no choice' females, experiment 2 was carried out to control for any effect of maternal age. First instar larvae were collected from parents of the same age who had either chosen or not chosen their mates, and the larvae were again competed against *sparkling* larvae. The results are shown in Table 2. Again, the percentage of wild-type flies emerging was larger if the parents of those flies had chosen their mates.

The results show that matings between randomly chosen pairs of flies produce offspring with lower survival between larvae and adult than matings where mate choice can occur. The results do not show whether the overall fitness of the offspring is affected, because some other component of fitness may be negatively correlated with the one measured.

The result could be produced by various genetic mechanisms. First, fitness may indeed be heritable, possibly as a consequence of mutational load[5]. If this were the case, the results could be produced in two ways. (1) Fitter flies may be better at detecting or obtaining access to mates. Members of the other sex could then mate with a fly that was successful in some sort of competition with members of its own sex. (2) Flies may be able to detect heritable fitness in members of the other sex. Fitter flies could then be actively chosen as mates. Both possibilities would suggest that all flies should prefer the same sorts of mates. Alternatively, flies with high levels of heterozygosity may have high fitness. In this case, flies might produce fitter offspring by mating with individuals genetically unlike themselves, so that their offspring will have higher levels of heterozygosity. This last possibility would imply that genetically dissimilar flies would show different patterns of mate choice.

I thank Drs N. P. Ashmole, A. Ewing and L. Nunney and Professor A. Robertson for helpful advice.

Larval competition and brood sex ratios in the gregarious parasitoid *Pachysomoides stupidus*

John Pickering

Department of Entomological Sciences, University of California,
Berkeley, California 94720

The haplodiploid genetics of the Hymenoptera, by which males and females develop from unfertilised and fertilised eggs, respectively, give rise to certain asymmetrical coefficients of relatedness among family members[1-3]. These asymmetries, and predictions concerning the sex ratio that are based on them[2,4,5], make the Hymenoptera ideal for the study of social behaviour. Work has focused on the more highly social groups of ants, bees and wasps[6-10]. Although there has been considerable work on the parasitoid Hymenoptera with respect to sex ratio theory[11-15], no study has examined the social interactions of gregarious parasitoids in the light of inclusive fitness theory[1]. I discuss here conflict among family members of a parasitoid wasp over the allocation of host resources, and argue that males are the more altruistic/less selfish sex. This provides a further explanation for hymenopteran males being generally smaller than females and for investment ratios being biased towards females[4,16]. Conflict is predicted between mothers and their daughters over the allocation of resources to the sexes. The observed brood sex ratios are interpreted as a means by which egg-layers equalise investment in the sexes[17].

Pachysomoides stupidus (Hymenoptera, Ichneumonidae) is a parasitoid of the social wasp *Polistes canadensis* (Hymenoptera, Vespidae). A female alights on a host nest and lays her eggs within a cell containing an early-stage pupa. Up to 31 parasitoids develop together on a host pupa. The larvae feed externally, starting with the pupa's abdomen and finishing with its head. Before a host is consumed, some larvae may be excluded by their siblings from feeding. The wall of the cell surrounding the host constrains the larvae. When the larvae are small there is room for all of them to feed. As they move forward, when their girths fill the cross-sectional area of the cell, one larva loses access to the host while the others continue to feed. In larger groups this process is repeated. For example, at pupation in broods of 13, only six or seven are near the host's remains. The individuals farther from the remains are generally smaller.

Between August and October 1977, 56 *P. canadensis* nests with pupae were collected around Barro Colorado Island in Panama. The 70 broods of *P. stupidus* were allowed to develop in the laboratory. They came from 26 nests. Whenever possible the sex and position of brood members were recorded. Complete sex ratios were obtained for 50 broods. In the other broods 46 individuals were not sexed because of larval death, eclosion before nest capture, escape or hyperparasitism. The aggregate sex ratio for all 70 broods was close to 1:1 (292 males:308 females).

Dry weight was used as a measure of size. Males, on average, were smaller than females (means of 2.16 and 2.76 mg, respectively); however, the modal size of both sexes was equal (2.2 mg). Ranges were 0.4–5.0 mg for males and 0.5–5.7 mg for females. The large, 14-fold range in size reflects among and within brood differences. Smaller individuals came from larger broods with, on average, less food per individual. In any given brood the males were generally smaller than the females and usually pupated at the end farthest from the host's remains. Of

0028–0836/80/030291—02$01.00

42 non-unisexual broods that were weighed, the heaviest individual was female in 37 and male in three; two contained a male and female of equal weight. The smallest individual was male in 33 and female in nine. Of the viable individuals for which position was known, 41 males and 155 females pupated at the host's head-end of the cell, and 95 males and 28 females at the abdomen-end.

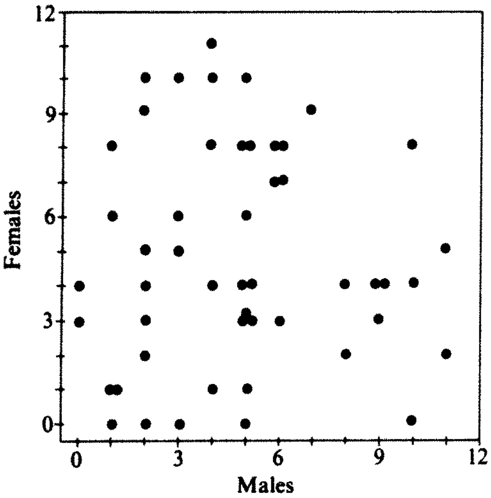

Fig. 1 Number of males and females in broods of *Pachysomoides stupidus*. The individuals from 50 complete broods reared in 1977 were sexed. Brood size ranges between 1 (a single male) and 18 (10 males and eight females), with a mean of 9.5 and a mode of 13. There are 238 males and 239 females in this sample. The distribution of sex ratios within broods was tested for overdispersion by using the statistic $D = \Sigma|M - F|$, where M is the number of males and F is the number of females within a brood, and the summation is over all broods. The sampling distribution of D was obtained by simulation. Males and females were assigned with equal and independent probabilities to 50 artificial broods of the sizes observed in the real sample, and the corresponding value of D was computed. This procedure was repeated 10,000 times. The resulting distribution of D values ranged between 75 and 171, with a mean of 119 and a standard deviation of 13.2, and was slightly skewed right. The value of D corresponding to the 50 real broods represented is 177. Thus the observed brood sex ratios are significantly overdispersed ($P < 0.0001$).

This competition is interesting in the light of inclusive fitness theory[1] because asymmetrically related brothers and sisters were developing where access to food by some siblings could be blocked by others. With haplodiploidy, where females develop from fertilised eggs and males from unfertilised eggs, asymmetries in the coefficients of relatedness (b) arise[2,3]. Assuming no inbreeding, a male is more related to his sister ($b = 1/2$) than she is to him ($b = 1/4$). Sisters are related to each other by more ($b = 3/4$) than are brothers ($b = 1/2$). A mother is equally related to sons and daughters by $b = 1/2$. That males are usually smaller than females when food is limited, and yet that males are nearly as large as females if given adequate food, is explained in part by the asymmetry in relatedness between brother and sister. If the cost (C) to an altruist and benefit (B) to the recipient of an act are ranged as the change in the proportion of progeny produced, then the threshold for selection to favour a brother helping a sister ($C < B/2$) is lower than for a sister helping a brother ($C < B/4$). By similar reasoning, a female will be selfish to a brother at a higher cost (to recipient) to benefit (to actor) ratio than he will be to her; thus she is more likely to push him away from the food than vice versa. It is not known whether males feed less because they are altruistic or because females are selfish. However, female selfishness is suggested in that male mortality is greater and in that males are more likely to have deformed antennae, legs or wings. Eleven of 308 females were dead compared with 25 of 292 males.

Conflicts are expected between a mother and her offspring, particularly her daughters, over the allocation of host resources. The distribution of adult sizes produced from a host that would give a mother her highest inclusive fitness is not necessarily the distribution that would give an individual brood member its highest inclusive fitness. Let a certain amount of food, if eaten by a male, increase his expected reproductive success by B_m and, if eaten by a female, increase her expected reproductive success by B_f. Sisters are selected to allow each other to feed in preference to brothers more often than their mother would be selented to allow them to do so. Applying the appropriate coefficients of relatedness, sisters favour a female feeding whenever $3/4B_f > 1/4B_m$, while a mother favours a daughter feeding only when $1/2B_f > 1/2B_m$. Thus a conflict between a mother and her daughters occurs when $3B_f > B_m > B_f$. There is no similar conflict between a mother and her sons: all are favoured if a female feeds when $B_f > B_m$ and a male feeds when $B_m > B_f$. Individuals of both sexes are selected to be more selfish than selection on the mother favours[18,19]. When individuals benefit from eating the food themselves by B_s, a male is selected to eat in preference to his brother when $B_s > B_m/2$ and to his sister when $B_s > B_f/2$; a female is selected to eat in preference to her brother when $B_s > B_m/4$ and to her sister when $B_s > 3/4B_f$. A mother is selected to allow an individual to feed when $B_s > B_m$ and $B_s > B_f$. Because the mother is absent, it appears that the parasitoid hosts are divided up by the offspring.

The sexes were not distributed among broods at random but were clumped within broods. In general some broods contained more females than would be expected and others more males (Fig. 1). This skewing of brood sex ratios increases the average coefficient of relatedness within sibling groups and reduces contact between asymmetrically related brothers and sisters. As females of many Hymenoptera species accurately control the sex of their offspring by controlling fertilisation[13,14,20], female *P. stupidus* may have been selected to adjust brood sex ratios to reduce the number of situations in which there is a conflict with offspring over the distribution of resources. Daughters are selected to take a greater proportion of the resources than their mother is selected to give them[4,17,21-23]. The observed distribution of brood sex ratios suggest that more resources went to males than would have, had broods been comprised of equal numbers of each sex.

Chemical modification reduces the conductance of sodium channels in nerve

Tetrodotoxin (TTX) and saxitoxin (STX) are extremely potent poisons that prevent nerve and muscle cells from producing action potentials by blocking sodium channels[1,2]. If the channels are modified by reagents that act on carboxyl groups, however, both the binding of these toxins[3,4] and their effect on the action potential[5] are reduced. One such reagent, trimethyloxonium ion (TMO) converts channels into a form that is not blocked by TTX concentrations 10^5 times greater than its normal K_d (ref. 6). Most such chemical modifications of sodium channels also reduce the measured membrane sodium current, but it has not been known whether such reductions were due to a change in the number of channels, in permeability properties, or in gating properties. We now report that TMO-modified, TTX-resistant sodium channels have a smaller single-channel conductance (γ) with a more linear instantaneous current–voltage relationship than that of normal channels, and that the measured reduction in γ accounts for all of the decrease in sodium current after TMO treatment. This change in sodium channel permeability properties can be explained by the removal of a fixed negative charge near the outside of the channel.

Single nodes of Ranvier from the frog *Rana pipiens* were voltage–clamped by the method of Dodge and Frankenhaeuser[7]. Single-channel current amplitudes were estimated by ensemble fluctuation analysis[8] from the mean current variance in sets of 100–500 current records from identical depolarisations. The analysis yielded estimates for the single-channel current i and the total number of channels N available for conduction. The single-channel chord conductance γ was calculated from values of i obtained at membrane potentials near 0 mV.

Brief treatment of nerve fibres with TMO ($(CH_3)_3O^+$), reduced the size of the sodium currents in Ringer solution, and the currents were reduced further when 200 nM TTX was added to block nearly all of the unmodified channels (Fig. 1). As discussed below, the reduction in current after TMO treatment was completely accounted for by the conversion of channels with a normal single-channel conductance ($\gamma = 7.1$ pS) to TTX-resistant channels having a reduced single-channel conductance ($\gamma = 2.4 \pm 0.3$ pS) (Fig. 2). Unfortunately, the fluctuation analysis technique does not allow us to distinguish between a homogeneous population of channels and a population having a spectrum of γ values, but for the sake of simplicity we consider both the normal and modified channel populations to be homogeneous.

Table 1 compares the values of γ, N and peak current I_{peak} obtained with 70 mV depolarisations from rest before and after TMO treatment. Estimates for the number of unmodified and modified channels open at the peak, N_{open}, are also given. Values of N_{open} for each component were obtained from the ratios of the peak current to the corresponding single-channel current value. The total number of channels open at the peak is seen to be the same (within 10%) before and after TMO treatment. This indicates that the only effect of the TMO treatment appears to be conversion of normal to TTX-resistant channels; the total number of available channels remains constant. These comparisons of numbers of open channels rely on the observation, described below, that channel gating is not appreciably changed by TMO treatment. Similar values for the fraction of channels modified by TMO are obtained from comparisons of the total number of unblocked channels (N) estimated from the current fluctuations. These estimates of N are not based on many assumptions about channel gating but tend to be less reliable than γ values because of their increased sensitivity to the magnitude of background noise[8].

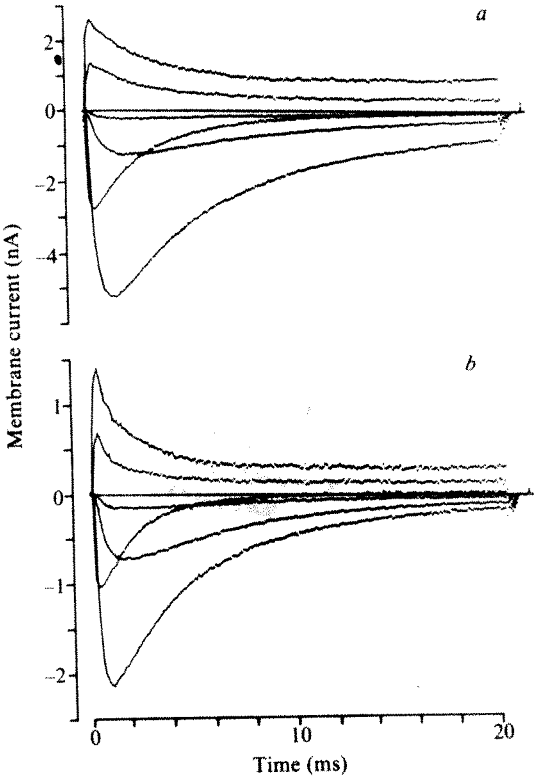

Fig. 1 Comparison of currents through *a* normal and *b* TMO-modified, TTX-resistant sodium channels in fibre 39 during 20 ms depolarisations to −45, −35, −15, 25, 85 and 125 mV from the holding potential of approximately −75 mV. Nerve fibres were treated with TMO as described in Table 1; the external solution in *b* contained 200 nM TTX. Fibres were voltage-clamped[7] at 5 °C in a Ringer solution containing 100 mM Na^+ as well as 20 mM tetraethylammonium ion (TEA) to block potassium current[9,10]. TEA was also present in the end pools. (TMO treatment reduced potassium current by less than 20%, and did not change its susceptibility to block by TEA.) A 30 ms prepulse to −105 mV preceded each depolarisation in *b*. Leakage and capacitance currents were subtracted using scaled current records obtained with 40 mV hyperpolarising pulses. The currents were signal-averaged and plotted with different vertical scales.

To determine whether TMO treatment changed the gating of sodium channels, we observed the voltage dependence of activation of the TTX-resistant currents. This voltage dependence corresponded, within 4 mV, to that for currents in the fibres before modification. The shorter activation and inactivation time constants seen in the TTX-resistant currents of Fig. 1 almost certainly arose from a small (2 °C) temperature rise during the experiment, because the change was not consistently seen, and the voltage dependence of the activation and inactivation time constants was also essentially unchanged.

Although the sodium current reversal potential was unchanged (within 4 mV) by TMO treatment, the TTX-resistant currents showed relatively larger outward currents at large depolarisations. We believe that this deviation is due to a change in the permeability properties of open channels. The instantaneous current-voltage (I–V) relationship, generally assumed

Fig. 2 Variance–mean current plots in normal and TTX-resistant sodium channels from fibre 43. Current variance and mean current values from depolarisations to −15 mV were obtained as described in Table 1. Smooth curves were obtained by fitting the points with the relation $\sigma_I^2 = \gamma(E - E_{Na})I - I^2/N$ after correction for background noise. Scales have been chosen so that a conductance of 5 pS corresponds to a slope of one in each part of the figure. The shallower slope in *b* reflects the smaller value of γ in TMO-modified channels. *a*, Before TMO treatment; the curve was drawn taking $\gamma = 7.0$ pS and $N = 20{,}800$. *b*, After TMO treatment and in the presence of 200 nM TTX; the curve was drawn taking $\gamma = 2.6$ pS and $N = 9{,}300$.

to reflect the ion permeation properties of the channel at a constant state of the gating system[11], is plotted together with estimates of *i* at various potentials in Fig. 3. The instantaneous *I–V* relationship is less curved for the TTX-resistant currents than for the control. The close correspondence between the voltage dependence of the instantaneous current and the single-channel current estimates, like that already seen in untreated fibres[8], suggests that the modified channels have only one non-zero conductance level. Assuming this to be the case, we have scaled the instantaneous current curves in Fig. 3 using the single-channel current estimates, and identify the curves with the current-voltage relationship of single open channels.

We conclude that TMO modification of sodium channels changes the permeability properties of the channels, but leaves the gating properties essentially unchanged. The changes in single-channel conductance and rectification resemble those observed by Appel *et al.*[12] in hybrid channels formed from *O*-pyromellityl gramicidin A (OPG) and gramicidin A (G). They attributed the lower conductance and rectification of normal G–G channels, relative to hybrid OPG–G channels, to the absence of the electrostatic effects due to the negatively charged pyromellityl moiety. We expect that TMO removes a negative charge in the vicinity of the sodium channel by the esterification of a normally ionised carboxyl group. Normally, the negatively charged carboxyl group would increase the local cation concentrations near the outside of the sodium pore above that of the bulk solution. The modified channels, lacking this charge, would have a lower local concentration and would exhibit reduced conductance and rectification.

This view is supported by the observation that the effect of the hypothesised changes in the local potential and ion activities at the membrane surface may be partially simulated by suitable changes of the bulk solution potential and ionic activities. As shown in Fig. 3, the substitution of 80% of the sodium by impermeant tetramethylammonium (TMA) ions produced single-channel currents in an untreated fibre similar in size and voltage-dependence to the toxin-resistant currents in standard Ringer solution. This simulation is not exact because the concentrations of the other ions were not also suitably changed, and because TMA, although it is better than other ions in this regard, may interfere with sodium ion permeation.

In another experiment, we investigated the relationship between the site at which TMO acts to reduce γ and the toxin binding site by pretreating fibre 105 with 200 nM TTX and then treating it with TMO in the presence of TTX. After a 10 min wash in toxin-free Ringer, peak sodium current returned to 40% of its original value and fluctuation analysis revealed no decrease in γ (Table 1). Following this treatment, application of 200 nM TTX reduced sodium current to undetectable levels. Apparently, TTX prevents TMO from reaching the site at which it acts to reduce γ. This experiment also shows that the decrease in γ is not due to nonspecific action of TMO, buffer solution, or the products of TMO hydrolysis (methanol and dimethyl ether). Furthermore, other experiments[6] show that at least 80% of the sodium conductance returns on washing after treating a frog skeletal muscle fibre with TMO in the presence of STX, indicating that TMO treatment does not obstruct the movement of toxin between its receptor and the bulk solution. It seems likely that toxin resistance and reduced γ are both due to TMO action at the toxin binding site, although the possibility that TMO may act to reduce γ at a different site which is inaccessible in the presence of bound toxin cannot be ruled out.

Although in aqueous solution TMO reacts preferentially with carboxyl groups, it should be noted that the possibility that the effects we describe are due to reaction with other functional groups cannot be completely excluded. The specificity of TMO has been discussed more fully elsewhere[6].

Reversible reductions in γ have previously been observed at low *p*H (ref. 8) and in the presence of Ni^{2+} (ref. 13). Small reductions in γ have also been observed in sodium channels with modified inactivation[13]. However, this is the first report of a chemical modification of sodium channels resulting in a large change in γ with essentially no change in channel gating. It will

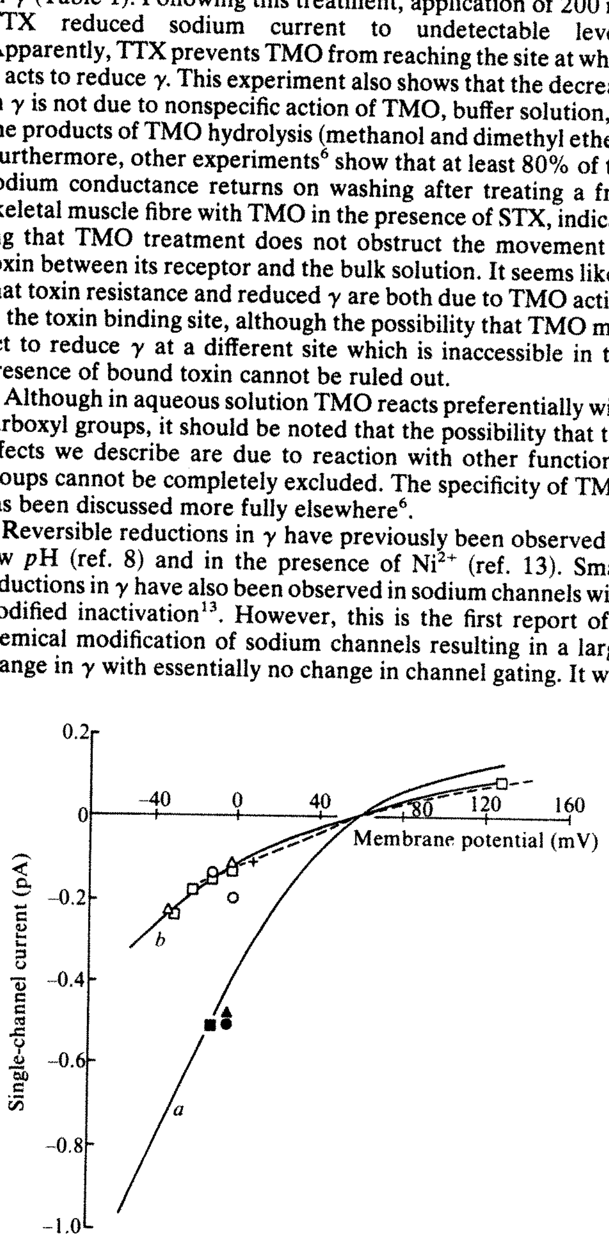

Fig. 3 Instantaneous current–voltage relations (curves) from fibre 43 and single-channel current estimates (symbols) from the same fibre (□, ■) and from fibres 38 (○, ●) and 39 (△, ▲). Filled symbols and curve *a*: normal currents, before modification with TMO; open symbols and curve *b*: TTX-resistant current; (+) and broken curve: normal currents before TMO modification from fibre 43 in one-fifth normal Na^+ (20 mM), shifted by 36 mV to superimpose the reversal potentials. The instantaneous current values, obtained at the test potential after a 1-m activating pulse to +45 mV, were scaled to fit the single-channel current values. The scaling factor is equivalent to the number of channels open at the end of the activating pulse.

Table 1 A comparison of sodium conductance before and after TMO treatment

Fibre	Treatment	N	γ (pS)	I_{peak} (nA)	Calculated N_{open} Unmodified	Calculated N_{open} Modified
38	Before TMO	22,000	7.3	7.0	13,900	—
	After TMO, no TTX	*	*	5.5	11,100	3,500
	After TMO, 100 nM TTX	7,000	3.1	0.6	—	3,500
39	Before TMO	41,000	7.2	12.0	25,600	—
	After TMO, no TTX	*	5.1*	6.5	10,300	13,100
	After TMO, 200 nM TTX	22,000	2.1	1.9	—	13,100
43	Before TMO	21,000	6.9	6.0		
	After TMO, 200 nM TTX	10,000	2.3	0.8		
105†	Before TMO + TTX	42,000	6.8	7.4		
	After TMO + TTX, no TTX	17,000	7.5	2.9		

Nerve fibres were treated with TMO by quickly dissolving the fluoborate salt (20 mM for fibre 38, 40 mM for fibres 39 and 43) in cold buffer solution (80 mM morpholinopropane sulphonic acid, MOPS) and applying this solution to the preparation. After 10 min the solution was washed out with Ringer solution. TMO reacts rapidly with water, so the concentration of reactive species that actually comes into contact with the membrane could be as little as one-half the values quoted. The tabulated values of N and γ were obtained by ensemble fluctuation analysis. A series of 100–500 sodium currents from repeated identical depolarisations was recorded, I, calculated by signal averaging, was subtracted, and the variance σ_I^2 was calculated for each point in groups of four digitised records. After a correction for background noise, the functional relationship between the variance and mean current was fitted by the quadratic function predicted by binomial statistics. For a homogeneous population of N independent channels having currents of 0 or i, the current variance is given by $\sigma_I^2 = iI - I^2/N$. The values of γ were calculated as the chord conductances, $\gamma = i/(E - E_{Na})$ where E, the membrane test potential, was chosen to be near 0 mV. E_{Na} is the reversal potential for current in sodium channels, which averaged 54 mV in these experiments. I_{peak} is the peak inward sodium current observed during a depolarisation to $E = -5$ mV, preceded by a 30 ms prepulse to −105 mV. N_{open}, the number of channels open at peak I_{Na}, was calculated for fibres 38 and 39 from measured values of I_{peak} and the corresponding γ values using the relation $N_{open} = I_{peak}/\gamma(E - E_{Na})$. The contribution of unmodified channels to the value of I_{peak} after TMO, in Ringer solution without TTX, was estimated by the difference between the I_{peak} values with and without TTX. The number of open, unmodified channels after TMO was therefore calculated as $N_{open} = (I_{peak,noTTX} - I_{peak,TTX})/\gamma(E - E_{Na})$, where the γ value from the untreated fibre was used.

* Only apparent values of N and γ can be measured after TMO treatment in the absence of TTX, since two populations of channels are present. The apparent γ value is an average of the γ values of each population, weighted by the current due to each population; the interpretation of apparent N values is less simple and these values have been omitted from the table.

† Fibre 105 was pretreated with 200 nM TTX and then treated for 10 min with 40 mM TMO dissolved in buffer solution containing 200 nM TTX. The values 'after TMO + TTX' were measured following a 10 min wash in toxin-free Ringer.

be interesting to see if naturally occurring toxin-resistant channels have properties similar to those of TMO-modified channels.

We thank Dr Charles F. Stevens for his encouragement and for laboratory facilities, Dr Bertil Hille for helpful advice, and Dr S. Y. Chiu for dissecting some of the fibres used in this study. Met-enkephalin circulates in human plasma

Vicky Clement-Jones, P. J. Lowry, Lesley H. Rees & G. M. Besser

Departments of Endocrinology, Chemical Pathology and Chemical Endocrinology, St Bartholomew's Hospital, London EC1, UK

The physiological roles of Met-enkephalin and Leu-enkephalin[1] are still unknown. They may act as neurotransmitters in the central and peripheral nervous sytems[2]. Met-enkephalin has been detected in several species in a variety of tissues including brain, spinal cord and gut using bioassays, opiate receptor assays and radioimmunoassays (RIA)[3–8]. It has also been detected in human gut immunocytochemically and in human brain and cerebrospinal fluid by opiate receptor assay and RIA[9–11]. However, all reported assays show some degree of cross-reaction with Leu-enkephalin and unequivocal differentiation between the two enkephalins and the larger endorphins has not always been possible. Thus the existence of Met-enkephalin in human tissues and fluids remains in doubt. Using a highly specific RIA, we have now obtained evidence that Met-enkephalin-like material circulates in the plasma of normal subjects and may be secreted by the adrenal gland. Chromatographically the material exists in plasma mainly as the intact pentapeptide and not as the biologically inactive degradation product Gly-Gly-Phe-Met as would be expected from metabolic studies[12,13].

Although bioassays and opiate receptor assays have the advantage of measuring biological and related activities they are unable to discriminate fully between related opiate peptides. To date all reported RIAs for Met-enkephalin cross-react with Leu-enkephalin and the larger endorphins. Thus to establish the presence or absence of Met-enkephalin in plasma we needed (1) to develop a sensitive RIA which did not cross-react with Leu-enkephalin and β-endorphin (the latter is known to be present in human CSF[14] and plasma of normal subjects[15]); (2) to develop a system for extracting Met-enkephalin from plasma in order to concentrate it and to remove interference in the RIA by proteins and to minimise proteolysis; (3) to demonstrate any measured Met-enkephalin immunoreactivity is not an artefact of sample collection, extraction and the RIA system and (4) to demonstrate that any measured immunoreactivity extracted from plasma would co-elute on chromatography with standard Met-enkephalin. These aims have been achieved by the novel approach of developing a RIA to the methionine sulphoxide analogue of Met-enkephalin and oxidation of all samples by hydrogen peroxide before assay and after extraction by octadecasilyl-silica (ODS-silica). The RIA and extraction methodology will be described in detail elsewhere[16].

We have observed that the C-terminal methionine residue of Met-enkephalin was unstable and underwent variable spontaneous oxidation to methionine sulphoxide (1–10%) during storage, extraction and assay procedures. No reported RIAs would detect this and yet, because of the oxidative conditions of iodination ^{125}I-labelled Met-enkephalin is likely to have a C-terminal methionine sulphoxide. We decided to raise high-titre antibodies to the methionine sulphoxide analogue of enkephalin (Met-O-enkephalin) in rabbits using as the antigen Met-O-enkephalin coupled via the N-terminus to bovine thyroglobulin by the glutaraldehyde method. This antibody does not cross-react with 1,000 molar excess of Leu-enkephalin, or with purified human β-lipotrophin (β-LPH) or β-endorphin (Fig. 1) before or after their oxidation by hydrogen peroxide. Purified human LPH 61–79 cross-reacts minimally (0.02%) after oxidation. There is minimal cross-reaction with synthetic α-endorphin (0.025%) and β-endorphin (0.25%) after oxidation. We

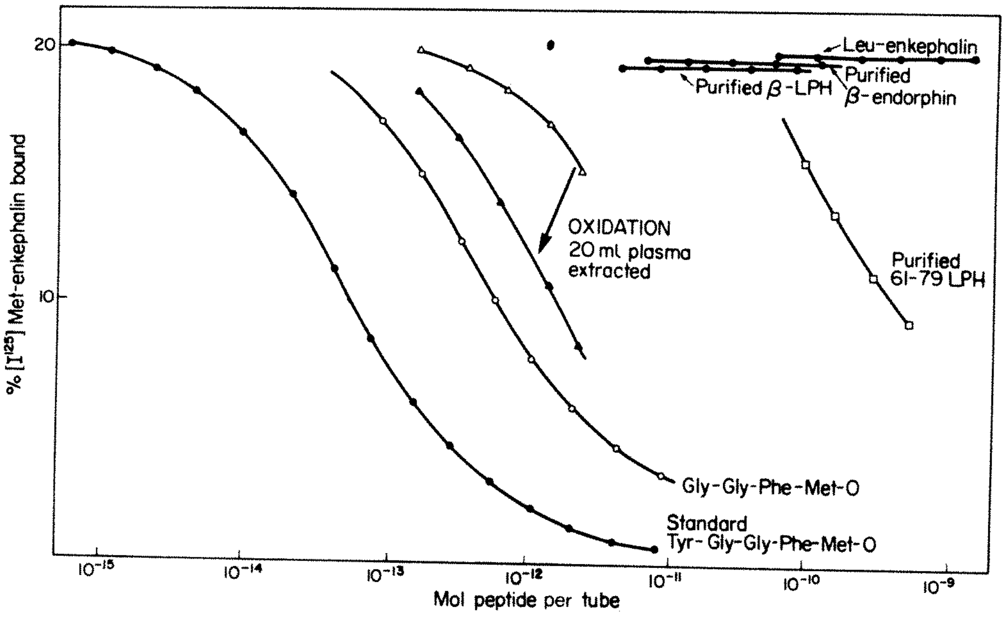

Fig. 1 Standard curve for Met-O-enkephalin and cross-reactivity studies. 50 μl of antiserum (1 in 9,000 final dilution for antibody E2) was added to 200 μl buffer containing doubling dilutions of standard Met-O-enkephalin and incubated for 24 h at 4 °C. Mono-iodinated Met-enkephalin (10 pg in 50 μl diluent buffer) was added with further incubation for 24 h before separation of bound from free [I^{125}] Met-enkephalin by double antibody precipitation. The cross-reactivities of Leu-enkephalin, purified human β-LPH, LPH 61–79 and β-endorphin and Gly-Gly-Phe-Met are shown after oxidation by 100 nmol hydrogen peroxide. A sample of 20 ml of plasma from a normal subject was extracted in duplicate on ODS-silica (as described in legend to Fig. 2) and the 80% methanol/1% formic eluates treated with (▲) or without (△) 100 nmol hydrogen peroxide before drying down by air, reconstitution and assay for Met-enkephalin.

have found that 60% and 90% respectively of their cross-reaction is due to the contamination of these synthetic preparations by Met-enkephalin. Using this antibody and mono-iodinated Met-enkephalin tracer highly purified on ODS-silica (10-μm particles) the RIA has a sensitivity of 0.01 pmol ml^{-1}. Our extraction system uses coarse ODS-silica (35–70 μm) in 1% formic acid. It allows concentration of 1–25 ml of plasma, is able to exclude the nonspecific depression of binding of tracer by plasma proteins and minimises proteolytic activity by virtue of being carried out at *p*H 1.5. This system also maximises the recovery of Met-enkephalin since the larger peptides β-LPH and β-endorphin elute poorly from coarse ODS-silica with 80% methanol/1% formic acid. When Met-O-enkephalin is added to 1 ml plasma and extracted there is 80–90% recovery. The poorer recovery of Met-enkephalin (20–30%) after extraction is related to losses during the oxidation by hydrogen peroxide. Our extraction and assay system has the inbuilt control of increased immunoreactivity diluting in parallel after treatment with hydrogen peroxide if the material is Met-enkephalin.

With this extraction and assay system and suitable collection of plasma samples to minimise degradation, 4 ml plasma samples from 20 normal subjects taken at 9 a.m. yielded Met-enkephalin immunoreactivity of 14–140 pg ml^{-1}. Repeated assay of samples from the same plasma pool gave an intra-assay variation of 10.2% ($n = 8$) at a mean value of 22 pg ml^{-1}. When 20 ml of plasma was extracted and treated with or without H_2O_2 an increase in immunoreactivity with H_2O_2 was seen (Fig. 1) suggesting this material is Met-enkephalin. The assay does have a slight cross-reaction (0.5%) with the tetrapeptide Gly-Gly-Phe-Met and 10% with Gly-Gly-Phe-Met-O. There was no cross-reaction however with smaller fragments of Met-enke-

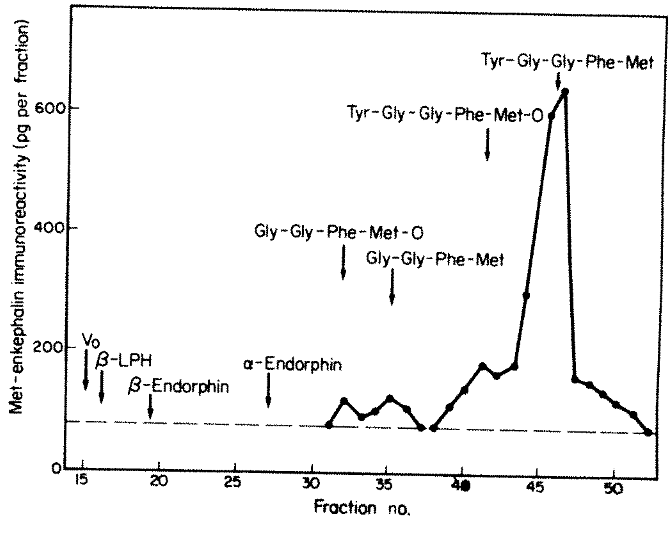

Fig. 2 A 100 × 1 cm BioGel P4 (200–400 mesh) column was equilibrated with 1% formic acid and pumped at room temperature at 3 ml h^{-1}. The column was presaturated with human serum albumin 3 mg (HSA, Blood Products Laboratory, Elstree) and calibrated initially for standard synthetic Met-enkephalin (Bachem) and then synthetic Gly-Gly-Phe-Met (Reckitt and Colman). The amino acid composition of both peptides was checked by amino acid analysis after acid hydrolysis. Fractions of 2 ml were collected and assayed for Met-O-enkephalin after oxidation by 100 nM H_2O_2, drying down with air and reconstitution with 0.05 M sodium phosphate *p*H 7.4 containing 0.25% HSA and 0.1% 2-mercaptoethanol and phenol red as indicator. V_0 indicates the void volume as shown by the HSA marker. Purified β-LPH, β-endorphin and synthetic α-endorphin were loaded and elution pattern determined by RIA of N- and C-terminal β-LPH[14,21] and α-endorphin. Samples of 160 ml of whole blood were collected from normal subjects at 9 a.m. into 10 ml lithium heparin tubes containing 10,000 KIU (Kallikrein inactivator unit) aprotinin (Trasylol) and centrifuged immediately at 4 °C. Pooled plasma (80 ml) was acidified to *p*H 1.5 by the addition of 150 μl glycine-HCl (1.6% glycine in 1M HCl) per ml of plasma and formic acid to final concentration of 1%. Plasma was extracted and concentrated in 8-ml batches on 1.5 × 0.5-cm columns containing 35–70 μm ODS-silica[16]. Acidified plasma was loaded in 800 μl aliquots followed by 800 μl of a solution of 0.9% NaCl and 1% formic acid containing 1.5 ml glycine-HCl per 100 ml. After loading 8 ml of acidified plasma a final wash with 800 μl 1% formic acid was followed by 1.6 ml of 80% methanol/1% formic acid which eluted the adsorbed peptides into a round-bottomed plastic tube containing 100 μg polypeptide (Sigma Polypep P5115) and 10 mg mannitol. Each 1,600 μl eluate was evaporated to dryness by oxygen-free nitrogen at 50 °C and each reconstituted in 200 μl 1% formic acid. After centrifugation at 2,000*g* the 2 ml of combined supernatant was loaded on BioGel P4 column after addition of 3 mg HSA. The column was eluted with 1% formic acid and pumped at 3 ml h^{-1} at room temperature and 2 ml fractions collected. H_2O_2 100 nmol was added to each fraction and left for 12 h before evaporation by compressed air in a sandbath at 50 °C and assay in duplicate for Met-O-enkephalin after reconstitution in assay buffer. If required *p*H was corrected to 7.4 by dropwise addition of 1.1M $NaHCO_3$.

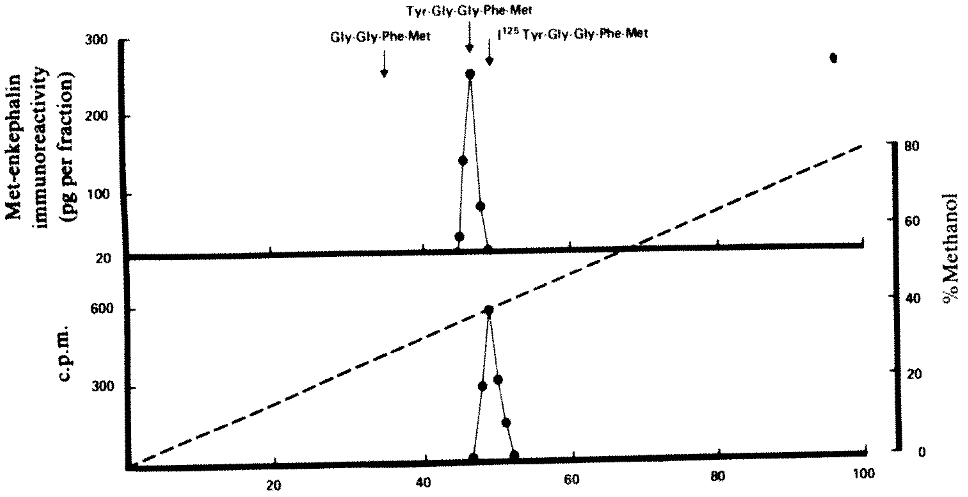

Fig. 3 High-pressure liquid chromatography (Pye Unicam LCXP) of the main plasma Met-enkephalin peak from BioGel P4 chromatography. The column (50 mm × 4 mm, Spherisorb ODS 10 μm) was developed with a linear gradient (– – – –) from 1% trifluoroacetic acid to 80% methanol/1% trifluoroacetic acid at 2 ml min^{-1} collecting 0.2 min fractions. All fractions were assayed for Met-enkephalin as described in the legend to Fig. 2. The limit of detection was 20 pg per fraction. Immunoreactive enkephalin eluted in the expected position of synthetic Met-enkephalin (upper chromatogram) two fractions earlier than 2 pg of monoradioiodinated Met-enkephalin[16] (lower chromatogram) added as internal marker. The arrows indicate the elution positions of synthetic Gly-Gly-Phe-Met, Tyr-Gly-Gly-Phe-Met and monoradioiodinated Tyr-Gly-Gly-Phe-Met appearing at fractions 35, 47 and 49 respectively in this system.

phalin[16]. Thus we could be detecting the inactive Gly-Gly-Phe-Met which, from degradation studies, might be the expected main circulating form of Met-enkephalin[12]. To examine this possibility we subjected plasma concentrated on ODS-silica to chromatography on BioGel P4. We initially calibrated the column for synthetic Met-enkephalin, Gly-Gly-Phe-Met, β-LPH, β-endorphin and α-endorphin as shown in Fig. 2. Met-enkephalin elutes in fraction 45 with a smaller peak at fraction 42 corresponding to Met-O-enkephalin generated by spontaneous oxidation. The elution of Met-enkephalin is retarded on BioGel P4 because of its hydrophobicity. This would explain the earlier elution position of Met-O-enkephalin which is less hydrophobic. Gly-Gly-Phe-Met similarly elutes into two peaks of oxidised and native peptide but well separated from the peaks of Met-enkephalin.

Figure 2 shows the chromatography of 80 ml of ODS-extracted plasma on BioGel P4. The elution profile shows the main peak of immunoreactivity at fraction 45 co-eluting with the known position of Met-enkephalin and a smaller peak at fraction 35 corresponding to the position of Gly-Gly-Phe-Met. There are also small peaks corresponding to Met-O-enkephalin and Gly-Gly-Phe-Met-O; these might be expected from spontaneous oxidation during extraction and chromatography. Further evidence for the identity of the main peak from the BioGel P4 column was obtained from reverse phase HPLC (Fig. 3).

These data suggest that the bulk of immunoreactivity in plasma after extraction in conditions which inhibit proteolytic degradation is Met-enkephalin (85%), a small amount (15%) may be due to the tetrapeptide Gly-Gly-Phe-Met which has lower cross-reactivity. Since we can demonstrate that the recovery after ODS extraction of Gly-Gly-Phe-Met and Met-enkephalin added to acidified plasma is equal we cannot have preferentially extracted either peptide before BioGel P4 chromatography.

When human plasma containing exogenous or endogenous β-LPH or β-endorphin was incubated for several hours at room temperature[16] we failed to detect an increase in Met-enkephalin immunoreactivity suggesting that the Met-enkephalin we detect in plasma is unlikely to be an artefact of our extraction system formed by degradation of plasma β-LPH or β-endorphin.

Dexamethasone treatment (2 mg at midnight) of seven normal subjects suppressed plasma immunoreactive ACTH and β-LPH to undetectable levels but did not alter the circulating Met-enkephalin levels significantly ($P > 0.2$). Samples collected from two normal subjects at 9 a.m. and midnight did not show a nyctohemeral rhythm in Met-enkephalin secretion as is observed for ACTH and β-LPH[17]. These data suggest that the Met-enkephalin-like immunoreactivity in plasma is independent of circulating ACTH, β-LPH and β-endorphin, which have been shown to be secreted in parallel from the pituitary gland in response to different stimuli[18]. To determine the source of circulating Met-enkephalin we measured samples collected at selective venous catheterisation of a patient undergoing investigation for hirsuties. Although the level of Met-enkephalin in venous blood taken from the left internal jugular (55 pg ml^{-1}) was the same as the peripheral level (53 pg ml^{-1}), simultaneous peripheral and left adrenal vein samples showed twice the concentration in the adrenal effluent (116 pg ml^{-1}). These results suggest that Met-enkephalin is secreted into the circulation from the adrenal glands. Immunoreactive Met-enkephalin has been detected in whole rat adrenal by RIA[19]. Furthermore immunocytochemical studies of the adrenal show the Met-enkephalin located mainly in the adrenal medulla[20]. Fresh human adrenal tissue was carefully dissected into medulla and cortex and each homogenised in boiling 0.1 m HCl. After the addition of formic acid to the supernatant to final concentration of 1%, Met-enkephalin was measured after coarse ODS extraction, using the method as described for plasma. The majority of the immunoreactive Met-enkephalin was located in the medulla (0.8 μg per g) with small but detectable amounts in the cortex (0.02 μg per g).

We conclude that Met-enkephalin circulates as the intact pentapeptide in human plasma and is possibly secreted by the adrenal medulla. Plasma levels of Met-enkephalin are unrelated to the levels of endogenous ACTH, β-LPH and β-endorphin which adds further support to the argument that Met-enkephalin belongs to a separate neuropeptide system with its own precursor.

GABA and picrotoxinin receptors in clonal nerve cells

γ-Aminobutyric acid (GABA) is a neurotransmitter which seems to mediate inhibitory synaptic transmission in many regions of the central nervous system (CNS) of vertebrates and invertebrates[1]. GABA has been shown to act by increasing membrane chloride permeability in invertebrate muscle[2,3], and a similar mechanism has been suggested for the vertebrate CNS[4]. The response to GABA is inhibited noncompetitively by the convulsant picrotoxinin[1–5]. Binding sites for radioactive GABA[6–8] and picrotoxinin[9–11] (the active component of picrotoxin) have been described in homogenates of invertebrate muscle and mammalian CNS; these binding sites show many properties expected of postsynaptic membrane macromolecules involved in the receptor–ionophore function of GABA. Nevertheless, unambiguous correlation between biochemical assays and *in vivo* function is difficult to obtain, especially in heterogeneous tissue such as mammalian CNS. One approach to this problem involves cloned cell lines of neuronal origin which retain in culture the differentiated function to be studied (see, for example, ref. 12). Certain cell lines cloned from rat[13] and mouse[14] nervous system possess neuronal properties such as electrical excitability, neurotransmitter synthetic enzymes[12], neurotransmitter uptake[15,16], binding of defined ligands to their appropriate neurotransmitter receptors[12,17,18], and receptor-coupled responses to neurotransmitters[17,19,20]. Several cell lines of apparent glial origin have also been described[13,21,22]. To determine whether binding sites for GABA and picrotoxinin are localised to nerve cells, a variety of clonal cell lines were assayed for their ability to bind those ligands. We report here the presence of GABA and picrotoxinin binding sites with receptor-like properties in several clonal nerve cell lines obtained from the rat CNS, and the absence of such binding sites in many other cell lines of non-neuronal origin.

Table 1 shows that GABA receptor-like binding and α-dihydropicrotoxinin (DHP) binding were present in membranes from all five rat CNS nerve lines examined, whereas no binding was seen with the non-neuronal lines. GABA binding was measured as that fraction of radioactive GABA pelleted with the membranes that was displaceable by 10^{-5}M muscimol, in sodium-free buffer, using membranes thoroughly washed with buffer and repeatedly frozen and thawed. Extensive washing is required to remove endogenous inhibitors of GABA binding that were seen in the extracts of these cells (data not shown), as previously observed in brain[8]. Binding of GABA in such conditions has been well demonstrated to reflect receptor-like specificity[6–8,23].

Binding of ^{3}H-GABA and ^{3}H-DHP to one of the nerve cell lines, B35, was studied in detail for comparison with the well characterised binding of these ligands to rat brain homogenates. Figure 1 shows a Scatchard plot of sodium-independent GABA-displaceable binding against GABA concentration for B35 membranes. An apparent single class of affinity ($K_D = 22$ nM) was observed, with a total capacity of sites (maximal binding at saturating ligand concentration) of 250 pmol per g protein. This quantity of sites is roughly equal to the total number of sites in some of the less dense regions in CNS[23–25]. Assuming that levels of binding activity can be compared in one set of constant assay conditions, the level in the other four lines tested was slightly lower (Table 1). The absolute amount of specific GABA binding did, however, vary between different preparations of the same cell line. This is probably due to slight differences in growth state and is under investigation. The GABA binding affinity to B35 membranes was equal to that of one of the two classes of sites in mammalian brain which have K_D values of 20 and 180 nM (refs 8, 25). No low-affinity GABA binding corresponding to the brain site having a K_D of 180 nM could be detected in B35 cell membranes in three experiments. Considering only the high-affinity GABA binding sites, the number of sites in B35 cells was about the same as that for this class of sites in high-density brain regions[25].

Figure 1 (inset) shows that this high-affinity sodium-independent GABA binding to B35 cells was displaced by GABA analogues with the specificity expected of receptor sites. The receptor-specific drugs muscimol ($IC_{50} = 50$ nM in B35, 25 ± 15 nM in brain)[7] and 3-aminopropane sulphonate ($IC_{50} =$ 500 nM in B35, 85 ± 15 nM in brain)[7] were good inhibitors, with concentrations $>10^{-5}$ M displacing the same amount of ^{3}H-GABA as did 10^{-4}M nonradioactive GABA. However, the transport-specific analogue 2,4-diaminobutyrate was not active ($IC_{50} > 10^{-4}$M in both brain and cell line B35). Bicuculline was a modest inhibitor of GABA binding in B35 and picrotoxinin had no effect up to 10^{-4}M.

Table 1 Specific GABA and DHP binding to membranes from cultured cell lines

Cell line	Cell type	Ref.	DHP bound (fmol per mg protein)	GABA bound (fmol per mg protein)
B35	CNS nerve	13	850 ± 100	130 ± 20
B50	CNS nerve	13	513 ± 90	77 ± 10
B65	CNS nerve	13	378 ± 80	25 ± 3
B103	CNS nerve	13	394 ± 80	48 ± 4
B104	CNS nerve	13	252 ± 50	32 ± 4
B9	CNS glial	13	NS	NS
B12	CNS glial	13	NS	NS
B15	CNS glial	13	NS	NS
B82	CNS glial	13	NS	NS
PC12	Phaeochromocytoma exponentially dividing	27	NS	NS
PC12	Stationary phase	27	NS	NS
L6	Skeletal myoblast	28	NS	NS
S194/5	Plasmacytoma	29	NS	NS

The clonal cell lines were grown as described in the references indicated. With the exception of PC12, which was collected at both the exponential (1×10^6 cells per 100-mm diameter dish) and stationary phase of growth, all cells were collected from early stationary phase cultures, 2 days after cessation of net cell division, at a density of $4–6 \times 10^6$ cells per 100-mm diameter dish. The cells were greater than 95% viable as measured by the uptake of fluorescein dibutyrate. During preparation, the cells were washed twice in phosphate-buffered saline (150 mM NaCl, 10 mM Na phosphate, *p*H 7.3, 2 mM $CaCl_2$, 0.5 mM $MgCl_2$), frozen as a pellet (0.2–1 g) on dry ice and stored at −85°C. These were thawed in 5 ml distilled H_2O and sonicated twice for 30 s (MSE sonifier, maximum setting) at 0–4 °C separated by a 30 s cooling break. The suspension was then homogenised by hand at 0 °C with five passes of a glass–glass Dounce homogeniser, diluted to 9 ml and centrifuged for 30 min at 200,000*g* [Beckman rotor 65 (49,000 r.p.m.)]. For DHP binding studies, the pellet was rehomogenised at 0–4°C with a Potter–Elvehjem homogenising tube and motor-driven pestle, five passes at 600 r.p.m., in 0.2 M NaCl, 10 mM Na phosphate, *p*H 7.0, recentrifuged as above and rehomogenised as before in the same buffer for assay[10]. For GABA binding assays[8], the first pellet obtained after homogenisation was rehomogenised in 10 ml of 50 mM Tris buffered to *p*H 7.1 at 4 °C with citric acid (sodium-free), and frozen at least 15 h. On the day of assay, this homogenate was thawed, pelleted as before, rehomogenised in the same buffer and repelleted, then rehomogenised in the same buffer for assay. The washing procedure is suitable for the removal of endogenous inhibitors of GABA binding in brain memranes[8]; further washing of the membranes obtained from the cells did not alter GABA binding. The protein concentration was adjusted to 0.5 mg in 1 ml assay volume. Binding of both ligands was determined by centrifugation at 48,000*g* (20,000 r.p.m., Sorval rotor SM24) following incubation in triplicate at 0–4 °C for 15 min, at which time equilibrium was obtained[8,9]. ^{3}H-GABA (Amersham, 54 Ci mmol^{-1}) was included at 9.3 nM, with background (nondisplaceable radioactivity pelleted) estimated with 10^{-5}M muscimol. The nondisplaceable background was approximately 4,000 c.p.m. in each case, and the specific binding varied over 4,000–12,000 c.p.m. ^{3}H-DHP (Amersham, 26 Ci mmol^{-1}) was 63 nM, with background estimated by 10^{-4}M nonradioactive DHP. Background was generally 20,000 c.p.m., and specific binding varied over 3,000–10,000 c.p.m. After pelleting, the tubes were superficially rinsed twice, not disturbing the pellets, with 5 ml assay buffer, and the pellets were dissolved overnight at 22 °C in 0.1 ml Soluene-350 (Packard). Radioactivity was measured in a Beckman LS-100C scintillation counter with an efficiency of 40%, using a 0.5% diphenyloxazole PPO in toluene. Each value is the mean of two experiments in triplicate, ± standard deviation. NS, not significant at 90% confidence level (<100 fmol DHP bound per mg protein or <5 fmol GABA bound per mg protein at the concentrations of ligand used).

0028-0836/80/030298—02$01.00

Table 2 Drug inhibition of DHP binding to B35 clonal nerve cells

Displacing agent (M)	Per cent inhibition of specific binding				
	DHP	Picro-toxinin	DMBB	Mepho-barbital	IPTBO
10^{-7}	5 ± 5	20 ± 5	—	—	—
5×10^{-7}	42 ± 10	—	—	—	—
10^{-6}	—	—	—	—	—
2×10^{-6}	84 ± 20	—	—	—	—
10^{-5}	93 ± 20	87 ± 20	106 ± 20	—	—
10^{-4}	100 ± 20	—	—	76 ± 20	66 ± 20

Membranes were prepared from cells grown as described in Table 1, and assayed for ^{3}H-DHP binding[10] in the presence of various concentrations of the drugs indicated. DHP, nonradioactive α-dihydropicrotoxinin; DMBB, 1,3-dimethylbutylbarbiturate; IPTBO, isopropylbicyclophosphate. ^{3}H-DHP was 63 nM, 26 ± 5 Ci mmol^{-1}; protein 0.5 mg in 1 ml assay volume. The controls gave roughly 8,000 c.p.m. bound and a background of 20,000 c.p.m. Each value is the mean of two experiments done in triplicates.

These specificity properties are similar but not identical to the properties described for rat brain[7]. The small differences may reflect the presence of fewer classes of binding site populations in the B35 cells than in brain, and/or the receptor properties in the cells may be different because of a location in membranes with incompletely differentiated synaptic characteristics. Slight modifications unique to the cell line or its growth conditions are also possible.

The DHP binding to B35 cells was also further characterised (Table 2). Properties similar to those found for the binding sites in brain were observed, with 50% displacement by about 10^{-6}M nonradioactive DHP (brain $K_D = 1.2\times10^{-6}$ M)[10], and by 10^{-6} M picrotoxinin (brain $IC_{50} = 0.4\times10^{-6}$ M)[10], and 100% displacement by 10^{-5} M 1,3-dimethylbutylbarbiturate (brain $IC_{50} = 5\times10^{-8}$ M)[11], 76% displacement by 10^{-4} M mephobarbital (brain $IC_{50} = 5\times10^{-6}$ M)[11] and 66% displacement by 10^{-4} M isopropylbicylophosphate (brain $IC_{50} = 8\times10^{-6}$ M)[10].

Thus, both GABA and DHP binding sites in B35 membranes had properties similar to those characterised in brain. The specific GABA receptor and DHP binding sites were observed only in cell lines of CNS origin which have neuronal properties, and were absent from several other types of cell. The above results open the way for further studies of this neurotransmitter using the clonal cell cultures. This system should facilitate the study of several questions regarding GABA function, such as the regulation of chloride permeability, the heterogeneity in binding sites, the function of endogenous inhibitors[8] and the interactions with barbiturates[11] and benzodiazepines[26].

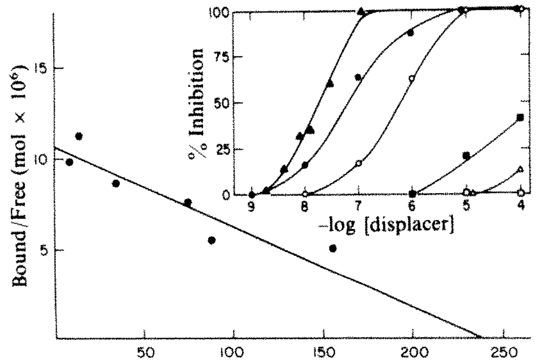

Fig. 1 Scatchard plot of GABA binding to B35 clonal nerve cells. Membranes were prepared and assayed[8] as described in Table 1 legend. Protein was 0.7 mg in 1 ml assay volume, ^{3}H-GABA (54 Ci mmol^{-1}) was varied over 0.1–10 nM, and nonradioactive GABA over 10 nM–2μM, with 10^{-4} M nonradioactive GABA used to estimate nondisplaceable background. Each point is the mean of triplicates and the experiment is typical of three. The ratio of specific binding to background varied from 3.0 (low concentrations) to 0.4 (high concentrations), with standard deviations of ≤4% in the raw data and ≤10% in the specific binding. Inset: receptor specificity of GABA binding to B35 neuroblastoma cells. ^{3}H-GABA was 9.3 nM. Control binding was about 6,000 c.p.m. with background of 4,000 c.p.m. Binding was measured in the presence of various concentrations of displacing agent. Each point is the mean of triplicates and typical of two experiments. ●, Muscimol; ○, 3-aminopropane sulphonate; △, 2,4-diaminobutyrate; ■, bicuculline; □, picrotoxinin; ▲, GABA.

This work was supported by grants from the NIH, NSF and Muscular Dystrophy Association of America. IPTBO was from Dr J. Casida, muscimol from Dr P. Krogsgaard-Larsen, 3-aminopropane sulphonate from Dr G. A. R. Johnston, DMBB from Lilly and mephobarbital from Sterling-Winthrop.

Quantitative microlocation of lithium in the brain by a (n, α) nuclear reaction

M. Thellier, J. C. Wissocq & C. Heurteaux

Biochimie et Physiologie Cellulaire, Faculté des Sciences et
Techniques, 76130 Mont-Saint-Aignan, France

Although lithium has long been used in psychiatric practice[1–4], its exact mechanism of action remains largely unknown. The reason is mainly methodological. Lithium has no radioisotope, and it is too light to be detectable by electron-probe microanalysis. To study the distribution of lithium in the brain, most authors[5] have proceeded by dissecting the brain into small fragments and determining the mean Li content of each fragment by photometric methods. However, the resolving power by this method has remained poor. Our group[6] and others[7] have recently described the possibility of using the stable isotopes of lithium as tracers for estimating unidirectional fluxes. To study Li-location, there is the theoretical possibility of using the specific nuclear reaction ^{6}Li(n, α)^{3}H. The method cannot be used as a conventional radioactivation because the induced ^{3}H has negligible radioactivity compared with the many other radioisotopes also induced in a biological sample bombarded by neutrons. The detection then consists of laying sections of the ^{6}Li-containing samples in contact with a convenient detector, and irradiating the whole arrangement with neutrons; the distribution of lithium in the sample is revealed by the tracks of the α and ^{3}H particles in the detector. Some authors have already attempted to use such methods for various biological applications[8–15]. By taking advantage of different independent technical advances[16–22], we can now give a precise quantitative picture of the distribution of lithium in the brain of a lithium-treated mouse.

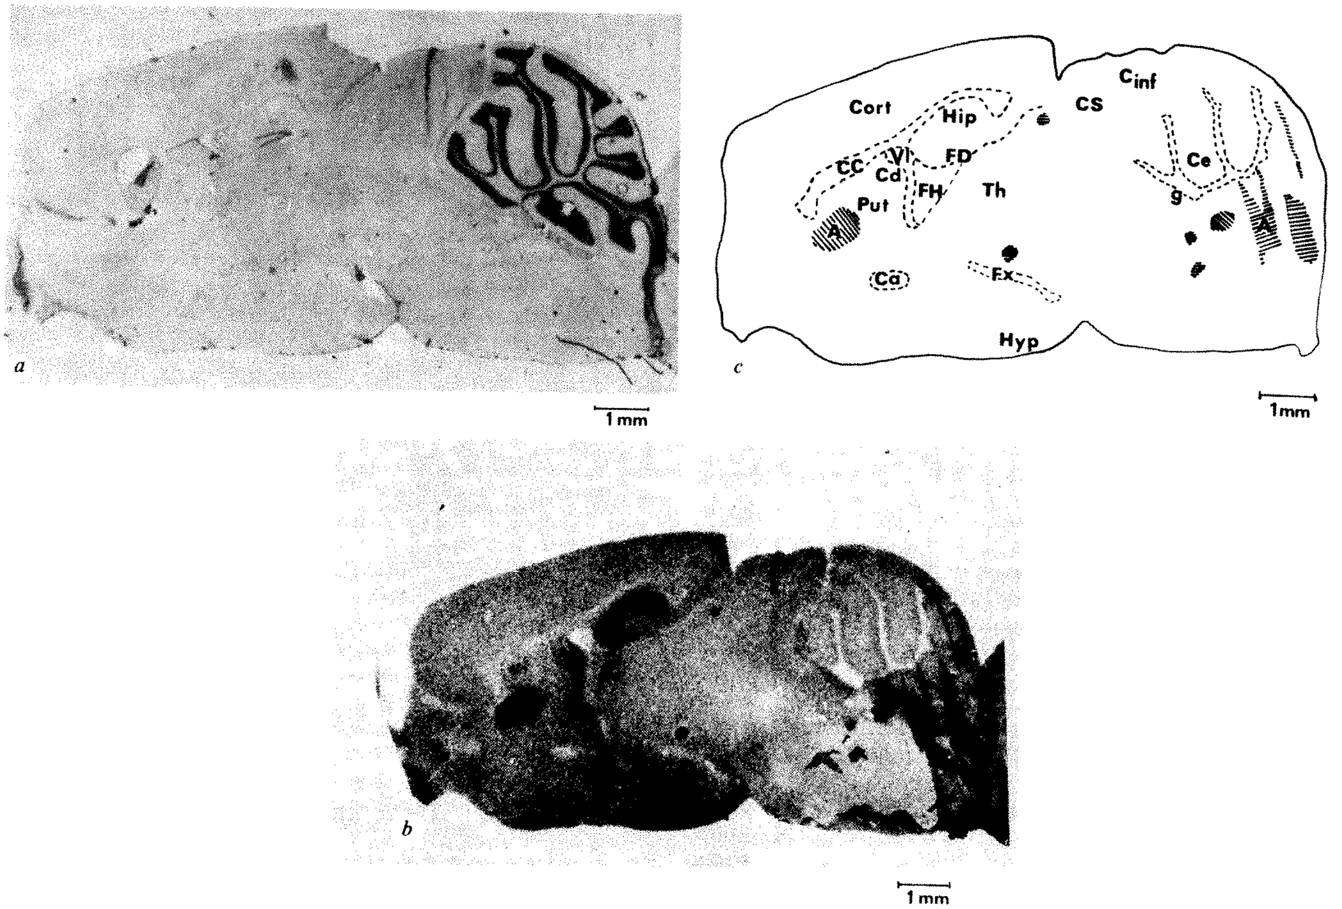

Fig. 1 Lithium distribution in a mouse brain. *a*, Histological preparation stained by Feulgen method. *b*, Photograph of the corresponding detector (each small black spot which forms the shading seen corresponds to a nuclear reaction on lithium). *c*, Schematic representation of the brain microanatomy at the level of the section. The mice had been treated with a daily dose of 12 mequiv. per kg lithium for 3 days, with the last dose 6 h before the experiment. Lithium was given as LiCl in the form of ^{6}Li-enriched isotope 96%. The mice were decapitated, and each brain was immediately removed and immersed in liquid isopentane cooled by liquid nitrogen. Sagittal sections (10 μm thick) of the frozen brains were made with a Jung microtome placed in a WKF chamber cooled to −35 °C. The sections were deposited on quartz supports, lyophilised, tightly pressed against Kodak LR 115 cellulose nitrate detectors, and neutron irradiated. A, Mechanical defects on the detector (dashed areas on *c*); Ca, Commissura anterior; CC, corpus callosum; Cd, nucleus caudatus; Ce, cerebellum; Cinf, inferior colliculus; Cort, neocrotex; CS, superior colliculus; FD, fascia dentata; FH, fimbria hippocampi; Fx, columna fornicis; Hip, hippocampus; Hyp, hypothalamus; g, grana; Put, putamen; Th, thalamus; Vl, ventriculus lateralis.

Figure 1 shows our results. The detectors show a certain number of defects seen as dark spots (especially at the level of the midbrain) or scratches (on the cerebellum); however, the different brain substructures are easily recognisable. The hippocampus, fascia dentata, nucleus caudatus, hypothalamus and neocortex are the substructures most heavily loaded with lithium. The cerebellum is also rich in lithium, except for the white matter inside the lobes. At the level of the putamen, careful observation shows lithium-rich striae corresponding approximately to the striae of grey matter. The fimbria hippocampi, superior colliculus and inferior colliculus have moderate lithium concentrations, whereas the thalamus has a rather small lithium content. Even smaller lithium concentrations are found in the corpus callosum, commissura anterior, columna fornicis and the cavity of the ventriculus lateralis. Clearly, the areas which achieve the most integrated operations for the control of motricity, behaviour and emotional attitudes are also those with the highest lithium concentrations. Therefore, in future work, it might be interesting to compare the relative distribution of lithium in the brain of control animals with that in the brain of animals subjected to various stresses, drugs or surgical operations known to affect sensory representation, motricity or behaviour. The resolving power of our method is already good enough to attempt such studies at the histological level. Moreover, as the theoretical limit of the resolving power is estimated[23] to be about 20 Å, further progress in the technology of track detection should eventually allow us to extend the use of the method to the cytological level.

The accumulation of lithium by the hypothalamus can be discussed in relation to the neuroendocrine properties of that area. We have indicated previously[20] that another endocrine gland, the hypophysis, also exhibited a high lithium concentration after treatment of the animals with lithium. Moreover, recent data obtained with Vaudry and Tonon (unpublished) indicate that the release of α-melanocyte-stimulating hormone by frog hypophysis is severely inhibited by lithium. This interference with neuroendocrine regulation might have significance in the whole-body effects of lithium.

Figures 2 and 3 are enlarged from Fig. 1, at the level of the cerebellum and the hippocampus. Although there is not a direct law of proportionality, the areas which accumulate much lithium are most generally those with the largest densities of neurone bodies. The reason is perhaps that the distribution of lithium is determined by cell water content at the various areas of the brain; thus, the nerve trunks, being highly lipid, would fail to reveal much lithium uptake. Whatever the reason, this result at least indicates that lithium effects on the brain might originate from the perturbation of the metabolism of some nerve cells, rather than from a direct effect on the process of nervous conduction. For instance, lithium could interact with the biosynthesis of some important proteins in the nervous system. Indeed, in a variety of other cases (sea-urchin embryology[24], aging processes[25,26], growth [27] and bud precedence[28] in plants), lithium affects the biosynthesis of some specific proteins, probably at the level of transcription[24], without necessarily modifying the bulk of the other protein biosynthesis[26,27].

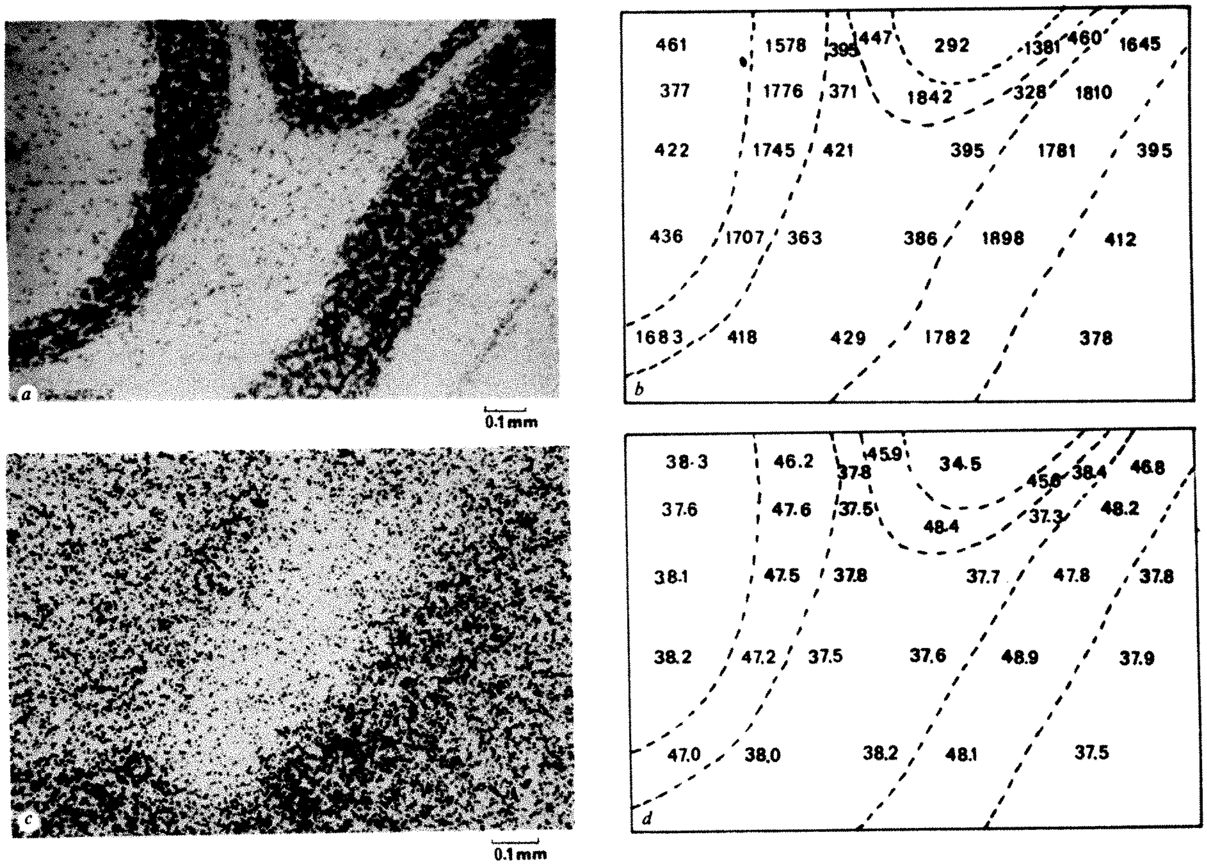

Fig. 2 Enlargement of Fig. 1, at the level of the cerebellum. *a*, Histological preparation; *b*, corresponding estimation of the local densities of cellular nuclei (nuclei per μg); *c*, photograph of the corresponding detector; *d*, estimation of the corresponding local concentrations of lithium (pequiv. per μg).

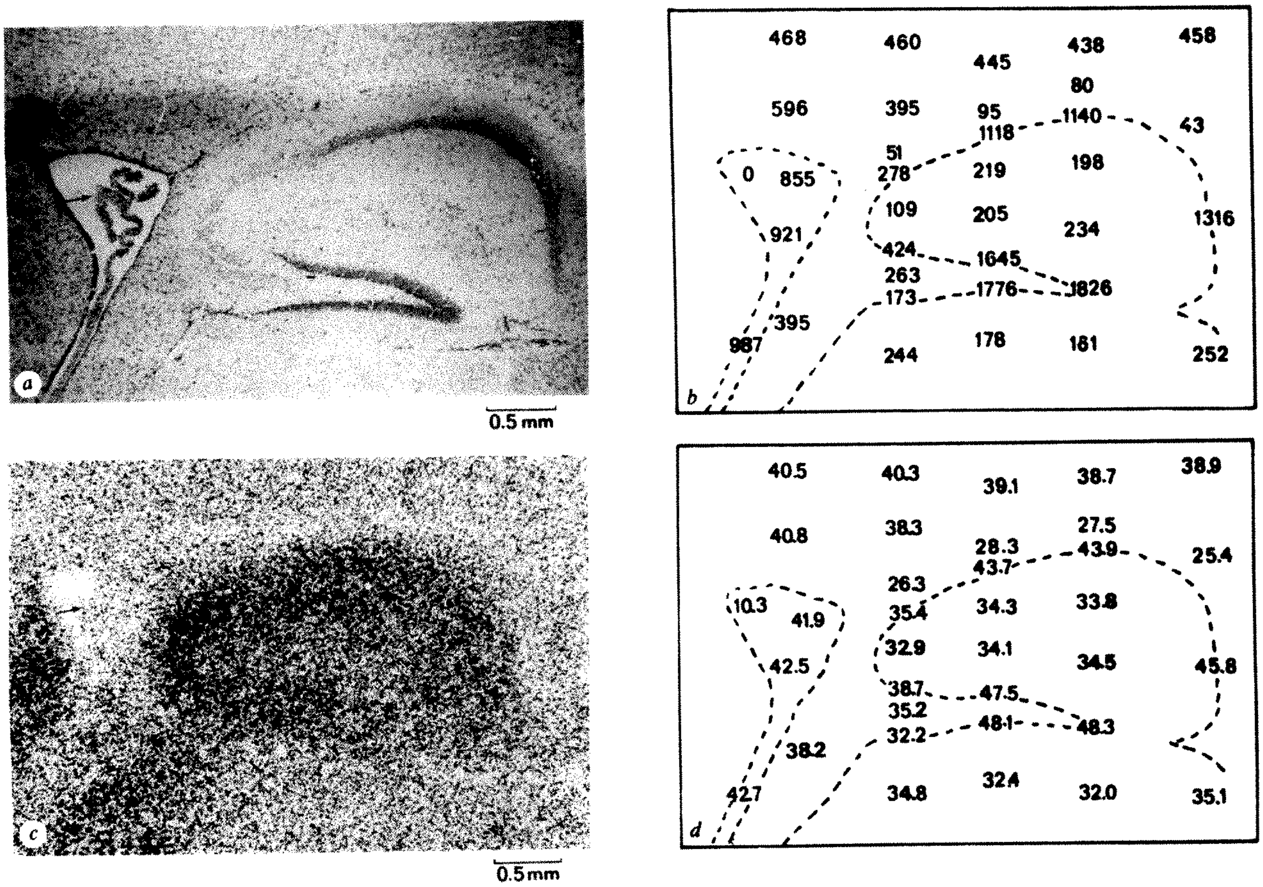

Fig. 3 Enlargement of Fig. 1, at the level of the hippocampus. Same significance of *a*–*d* as in Fig. 2. To appreciate the resolving power of the method, note the correspondence between the histological structures on the section and the distribution of tracks on the detector, especially at the level of the black arrow.

The nuclear track technique can be extended to study the distribution of elements other than lithium. Our group and others have already begun to use it for studying the distribution of boron in plants[29,30] or in semiconducting alloys[31], and the labelling of oxygen[32] by stable isotope ^{17}O for the location of catecholamines in the rat brain[33].

This work was supported by grants from the CNRS (L.A. 203 and A.T.P. 'Temps' and 'Petits mammifères') and from the DGRST (77 7 1272). The irradiations were carried out by Dr Stampfler at the reactor of the University Louis Pasteur, Strasbourg, France. We acknowledge the help of Dr Durham in the final preparation of the manuscript.

Parasite-induced 'nonspecific' IgE does not protect against allergic reactions

Ellen Jarrett & Susan Mackenzie

Department of Veterinary Parasitology,
University of Glasgow Veterinary School, Bearsden, Glasgow, UK

Hans Bennich

Biomedical Center, Uppsala University, Uppsala, Sweden

High levels of immunoglobulin E (IgE) are produced in animals, including man, infected with helminth parasites[1,2]. Such infection results not only in the production of parasite-specific IgE but also, through polyclonal stimulation of IgE-B cells, in the production of a large excess of parasitic nonspecific IgE[3]. IgE antibodies mediate allergic reactions by binding to receptors on the plasma membrane of mast cells, which are then said to be sensitised; subsequent attachment of antigen to the membrane-bound antibody causes cross-linking of the receptors leading to the release of histamine and other active substances[4]. Mast cells can be passively sensitised both *in vivo* and *in vitro* and passive sensitisation with a specific IgE antibody may be inhibited by prior saturation of IgE receptors with an excess of 'nonspecific' IgE[5,6]. In this way, helminth-infected animals become refractory to passive sensitisation, as do animals bearing IgE myelomas, because of the pre-emption of mast-cell receptors by endogenous IgE[7,8]. These findings gave rise to two related ideas: first, that it might be possible to ameliorate allergic diseases by passively administering, or by actively stimulating the production of a large amount of 'irrelevant' IgE; and second, that a high parasite-induced IgE level might protect against unrelated allergies by means of competition for mast cell receptors[6,7,9]. However, searches for epidemiological evidence of such a protective effect have had conflicting results[10–21]. We have examined this question using egg-albumin (EA)-hypersensitive rats infected with *Nippostrongylus brasiliensis* and now show that 'nonspecific' IgE induced by helminth infection, although having the capacity to block passive sensitisation, does not inhibit hypersensitivity reactions mediated by an actively produced IgE antibody.

Hooded Lister rats immunised with 10 μg of EA and the adjuvant *Bordetella pertussis*, produce IgE antibodies to EA from day 10 after immunisation. Immediate hypersensitivity reactions can then be induced in these rats by an antigen challenge; intradermal injection of EA causes an immediate wheal and flare skin reaction and intravenous injection of the antigen leads to anaphylactic shock. This state of hypersensitivity persists, as does IgE antibody production, for at least 80 days after immunisation[22]. Although, in theory, other immunological mechanisms can have a role in such allergic reactions, their contribution in the present model is likely to be minimal. IgG2a (short-term sensitising) antibodies cannot be detected in rats immunised with EA by this technique and the level of other antibodies also remains very low.

In a preliminary experiment we attempted to displace actively produced IgE from mast cells by infusing EA-immunised rats with serum from *N. brasiliensis*-infected rats having a very high IgE level: thus, rats were injected daily for 1 week with 5 ml serum containing 140 μg ml^{-1} total IgE which can be estimated to yield a serum level of 30–40 μg ml^{-1} in the recipient. The severity of allergic reactions to antigen challenge was not diminished by this treatment.

To create optimum conditions for the demonstration of an allergy-protective effect, we carried out an experiment in which EA-hypersensitive rats were infected with *N. brasiliensis* to stimulate prolonged active synthesis of high levels of irrelevant IgE. In rats infected with this parasite the level of total serum IgE rises from less than 1 μg ml^{-1} before infection to up to 400 μg ml^{-1} by the 12th day after infection[3]. The level remains elevated for many weeks and can be boosted by re-infection[22].

The design of the experiment outlined in Table 1 was based on the supposition that an observable blocking effect of nonspecific over specific IgE, in an animal actively producing both, might depend not only on the relative proportions but also on the order of production of the two. Groups of rats were therefore infected with *N. brasiliensis* 20 days before, simultaneously with or 20 days after immunisation with EA. Control groups were immunised but not infected. On various occasions after these treatments the total and antibody IgE status of the rats were assessed and susceptibility to hypersensitivity reactions was determined by antigen challenge.

Table 1 shows the results obtained on the first of these occasions, which is also representative of results obtained later in the experiment. Essentially, we were unable to induce any observable protection either in terms of skin test reactivity or susceptibility to anaphylactic shock by arranging for the occupation of mast-cell receptors with 'nonspecific' IgE whether before, during or after the synthesis of EA-specific IgE. That mast-cell receptors were indeed saturated or otherwise unavailable in the infected animals was confirmed by the finding that these animals, unlike uninfected control rats, could not be effectively sensitised for a passive cutaneous anaphylaxis (PCA)

* Outbred female hooded Lister rats (Animal Suppliers) were immunised with EA by intraperitoneal injection of 10 μg EA (Sigma grade V) in 0.15 M NaCl, together with a suspension of 10^{10} heat-killed *B. pertussis*. *N. brasiliensis*, infection was by subcutaneous inoculation of 4,000 infective larvae. The method of culture of the parasite has been described previously[29]. On various occasions after the indicated treatments, eight rats from each group were bled to obtain serum for the determination of total and antibody IgE and 2 days later were challenged with EA and the resulting hypersensitivity reactions assessed. This sequence of bleeding and challenge was carried out on days 32–34, 56–58 and 78–80. The rats of group 3 were re-infected on days 43 and 63.

† Total serum IgE was estimated by a paper radioimmunosorbent test (PRIST)[30]. Results shown are the mean ±s.e. of values from eight rats. Specific IgE antibodies to EA were estimated by the passive cutaneous anaphylaxis (PCA) technique[31] as previously described[3]. Results shown are the geometric mean PCA titre of animals with a detectable response. To detect IgE antibody in the sera of group 5, the assays were subsequently repeated using the PRAST[25] technique the results of which, in units ml^{-1}, are shown in parentheses. The reason for the use of this technique is described in the text.

‡ Hypersensitivity reactions were elicited as follows. Each of four rats received four intradermal injections of 1 μg EA (in 0.05 ml 0.15 M NaCl) on the shaved back followed immediately by intravenous injection of 0.5 ml 1% Evans blue. After 20 min the rats were killed, and the skin test reactions were measured on the inner surface of the skin. The reaction diameters shown are the mean ±s.e. of the mean values from the four rats. Small reactions only (<5 mm) occurred in unsensitised rats. Anaphylaxis was induced, in an additional four rats per group, by the intravenous injection of 250 μg EA in 0.5 ml of 0.15 NaCl. Symptoms of shock occurred within seconds and were graded on a scale of severity from 1 to 4 with the latter denoting almost instantaneous death. This does of antigen caused no reaction in unsensitised rats. The amounts of antigen used were arrived at in a previous dose–effect experiment and were chosen as being sufficiently large to elicit clearly evident reactions in the majority of sensitised animals with minimal or no reactions in normal rats. The object was to operate the system at moderate antigen excess so that the occurrence and size or severity of reactions would be determined by the amount of specific IgE on the mast cell rather than by the amount of antigen injected.

reaction with IgE antibodies to keyhole-limpet haemocyanin.

Note that *N. brasiliensis* infection, in addition to stimulating nonspecific IgE, may enhance or inhibit the EA-IgE response depending on the time between immunisation with EA and infection. A pre-established EA-IgE response is briefly potentiated by the infection[22,23] as was evident in the rats of group 3 on the first occasion of testing (Table 1), but not later in the experiment. We have previously considered whether this increment in the level of EA-IgE might actually increase the degree of hypersensitivity of the animal to EA but have found that it had no noticeable effect[24]. In the context of the present experiment, even when the EA-IgE response is potentiated it still comprises a very small proportion of the total IgE[3]. In rats immunised with EA and simultaneously infected with *N. brasiliensis* (group 5), the production of EA-IgE was inhibited by comparison with rats immunised with EA alone, a phenomenon previously described by Orr and Blair[23] and presumably reflecting a form of antigenic competition. Nevertheless, most of these rats showed marked immediate hypersensitivity to EA, suggesting that EA-IgE antibodies were produced but at levels too low to be detected by the PCA technique in the face of competition by nonspecific IgE for the mast-cell receptors. The subsequent development of a radioimmunoassay for rat IgE antibodies[25] (which is not influenced by the presence of irrelevant IgE in the test serum) enabled us to retest these sera and low levels of EA-IgE were indeed detected in them all, as indicated in parentheses.

Our results suggest that as far as the actively sensitised animal is concerned, parasite-induced IgE does not have an appreciable allergy-protective effect. We now believe that the prediction of such an effect has been based on a misleading interpretation of previous passive sensitisation experiments which has failed to consider the turnover of IgE on the mast cell in active sensitisation and the relative proportions of specific and nonspecific IgE which might be expected in helminth infection.

The binding of IgE to its receptor, although of high affinity, is a reversible process (reviewed in ref. 4) and mast-cell-bound and free IgE are in dynamic equilibrium; EA-IgE therefore becomes part of a serum pool of which the constituent molecules are in constant exchange with cell-bound IgE. Therefore, assuming a similar affinity of the molecules for the receptors, EA-IgE, whether produced before, simultaneously with or after nonspecific IgE, will eventually come to be represented on the mast-cell membrane in the same relative proportion as it is found in the serum. Estimates from radioimmunoassay show that in sera from EA-immunised rats infected with *N. brasiliensis* the amount of EA-IgE produced is of the order of 1–100 ng ml^{-1}, with nonspecific IgE forming up to a 10^4-fold excess. There are approximately 3×10^5 IgE receptors on normal rat mast cells[26]. Clearly, only a small proportion of these require to be occupied by EA-specific IgE to procure effective sensitisation, as in the parasitised animal most of the receptors will be occupied by IgE molecules with specificity for other antigens. Degranulation studies with the leukocytes of allergic humans show that only a few IgE cross-links, induced either by combination with antigen or anti-IgE antibodies, are required to cause histamine release[27,28], and evidently in our system the number of specific IgE molecules bound to the mast cells is such that they are in sufficient proximity to allow the requisite cross-links to be formed.

Thus, the ratio of nonspecific to specific IgE necessary to cause effective 'desensitisation' of mast cells is simply not achieved in helminth infection. Only perhaps in IgE myeloma will concentrations of nonspecific IgE be sufficient to ablate allergic reactions mediated by a normal IgE-antibody response. If allergies are found on balance to be less frequent in helminth-parasitised individuals, the reason is more likely to be found in other mechanisms.

Antibody response to Moloney type C virus-induced tumours

Nancy Hogg & Diana Wallace

Animals infected with RNA tumour viruses show an immune response to new virus-induced antigens present on the tumour cell surface. In tumours induced by murine leukaemia virus (MuLV), serologically detected cell membrane antigens have been placed into two major groups; the Gross cell-surface antigen(s), GCSA and G_{IX}, are associated with Gross leukaemia virus infection[1] and the FMR antigen(s), associated with infection by Friend, Moloney or Rauscher type C viruses[2]. There is good evidence that some of these antigens are related to the structural proteins of the virus. The G_{IX} antigen is found on the viral envelope protein, gp70 (refs 3–5) and the GCSA antigen is on the p30 protein which is present in the membrane as part of the glycosylated 'gag' polyprotein(s)[6–8]. It is not certain whether the FMR antigen(s) is found on membrane-located viral structural precursors or polyproteins, or whether it is present on a tumour-associated protein. Several antigens of this latter type have been described. For example, the Moloney leukaemia virus-induced cell-surface antigen (MCSA) is thought to be a non-viral protein associated with 'gag' products, p30, p15 and p12 on the membranes of Moloney lymphoma cells[9,10]. MCSA and the antigens on cells infected by Abelson MuLV[11] may be very specific cellular antigens associated with Moloney MuLV infection. There has also been much interest in whether the *src* gene product is present in the membrane of sarcoma virus-induced tumours, although it is thought not to be present on the external membrane surface[12]. A more controversial point is whether there are other virus-induced cell-surface antigens (CSA) which may serve as targets for an effective immune response to viral tumours[13]. We have previously found[14] that serum from BALB/c mice with regressed Moloney virus-induced fibrosarcomas contained specificities only for Moloney viral proteins and not for any tumour-associated protein like MCSA. We have now identified the viral proteins with which the Moloney MuSV antisera react. Using a syngeneic system of immunisation with freshly induced Moloney sarcoma tumours, we show that the antibody response is directed only at viral structural antigens and that the major part of the response is to antigens on p30 protein probably present as part of a precursor polyprotein on the tumour cell surface.

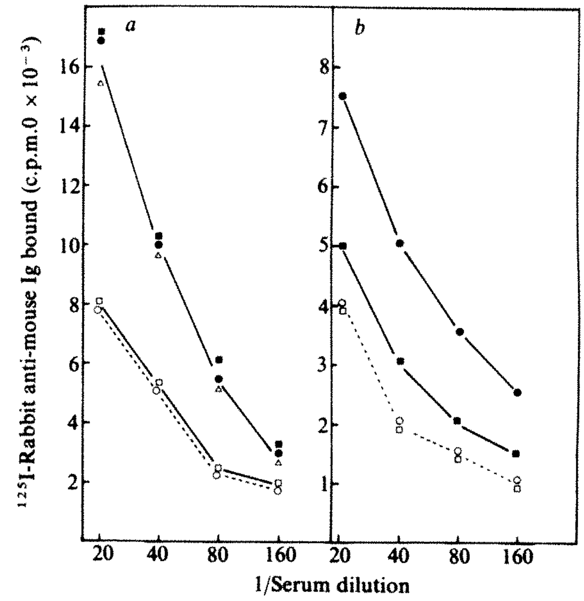

Fig. 1 Specificity of Moloney MuSV serum for type C virus-infected cells using cell monolayer radioimmunoassay. *a*, Moloney MuSV serum was reacted with secondary cultures of fibroblasts from Taylors Own (ICRF) mice, TO cells (□—□); MSC cells (●—●); TO cells infected 7 days previously with Moloney MuSV/MuLV virus contained in MSC supernatants (△—△); TO cells infected with sucrose banded Moloney MuSV/MuLV virus (■). Control BALB/c serum reacted with all cell preparations in a similar way (○---○). *b*, Comparison of binding of Moloney MuSV serum with MSC cells (●—●) and AKR-N3T3 cells (■—■) and of binding control BALB/c serum with MSC cells (○···○) and AKR.N3T3 cells (□···□). Samples were done in triplicate and standard deviations were always less than 10%.

The antisera used to describe several of the previously mentioned antigens have been obtained after an intensive immunisation schedule. By examining the response of BALB/c mice to regressing Moloney tumours which were induced by Moloney MuSV/MuLV virus rather than by tumour cells maintained in tissue culture, we hoped to obtain a closer approximation of immune responsiveness to a natural infection with virus. Thus, tumours raised in newborn mice by injection of purified Moloney MuSV/MuLV virus were subsequently injected intramuscularly into the flank of each of 20, 4-week-old BALB/c male mice. The resulting tumours regressed within 2 weeks. The serum used in this study, which will be called 'Moloney MuSV serum', represents pooled sera collected at the peak of the antibody response to tumour cells that occurred 18 days after tumour inoculation. A control group of sibling mice was maintained and bled coincidently with the tumour-bearing mice. The sera were adsorbed with BALB/c embryo fibroblasts before use.

In a cell monolayer radioimmunoassay[14], the Moloney MuSV serum binds to murine TO fibroblasts infected 1 week previously with Moloney virus from two different sources but does not bind

to any significant degree to uninfected fibroblasts (Fig. 1*a*). Control serum showed low levels of binding to both virus-infected and uninfected cells. Similarly, the Moloney MuSV serum bound to rat fibroblasts infected with Moloney virus, but not to uninfected rat fibroblasts (data not shown). As shown in Fig. 1*b*, the Moloney MuSV serum reacts with the MSC cell line[15], which is derived from a Moloney virus-induced sarcoma, and only to a small degree with Gross virus-infected N3T3 cells, called AKR-N3T3 cells[16]; this suggests that the Moloney MSV serum reacts chiefly with type-specific determinants induced by virus on Moloney virus-infected cells.

We have previously shown that the activity of this type of serum can be completely removed by adsorption of the serum with sucrose gradient Moloney MuSV/MuLV virus purified by sucrose gradient banding[14]. This has been confirmed in the present study and suggests that the major specificities in the Moloney MuSV serum are directed against antigens present on viral polypeptides expressed on the cell membrane. To assess which viral proteins were being recognised, disrupted ^{3}H-leucine-labelled Moloney MuSV/MuLV virus shed by the MSC cell line was precipitated with the Moloney MuSV serum. The Moloney MuSV serum precipitated predominantly p30 and gp70 proteins (Fig. 2*a*). Proteins coincident with p15(E) and p10/p12/p12(E) are precipitated to a minor degree and are therefore only faintly apparent in Fig. 2*a*. When the Moloney MuSV serum was adsorbed with Gross virus-infected AKR-N3T3 cells, the titre of antibodies reacting with p30 or gp70 was only slightly reduced (Fig. 2*b*), but when a similar adsorption was done with Moloney virus-infected MSC cells these specificities were completely removed (Fig. 2*c*). Control serum from unimmunised mice did not precipitate any viral proteins (data not shown). Therefore, we conclude that Moloney MuSV-induced fibrosarcomas induce antibody with specificities for Moloney type-specific determinants on p30 and gp70 proteins and that both are candidates for FMR antigens.

Adsorption of Moloney MuSV serum with Gross virus-infected AKR-N3T3 cells did remove some anti-p30 antibody and low titre antibodies reacting with the lower molecular weight viral proteins (Fig. 2*b*). These antibodies, as has been suggested by others[17–19], may be responsible for the cross-reactive or group specificity shared between the Moloney and Gross infected cells (Fig. 1*b*).

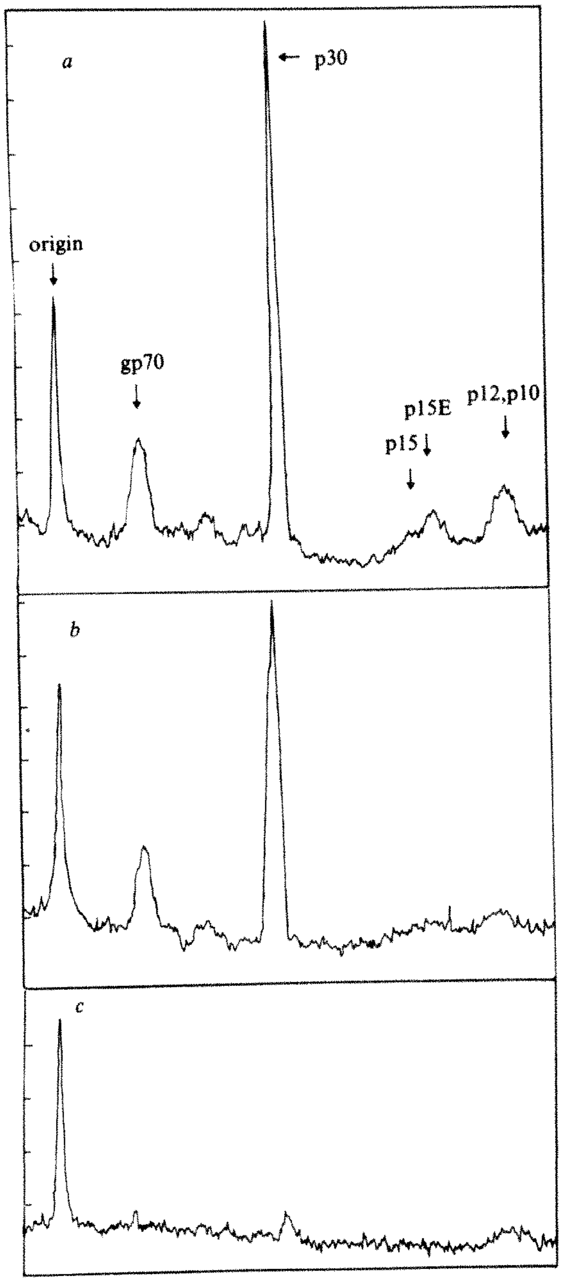

Fig. 2 Scanning densitometer tracings of an autoradiogram of 12% SDS-polyacrylamide gel analysis of proteins immunoprecipitated from ^{3}H-leucine-labelled Moloney MuSV/MuLV. MSC cells were labelled overnight with radio-labelled virus purified from the supernatant by double banding in a sucrose density gradient and disrupted by freeze-thawing 10 times. Samples of virus containing 50,000 c.p.m. were reacted for 3 h with the appropriate antisera on ice. NP-40 was then added to a final concentration of 1% and the incubation was continued at 4 °C for 16 h. *Staphylococcus aureus* (formaldehyde fixed)[29] was then added and the incubation was continued for 1 h at 4 °C. The *Staphylococcus* A–IgG–antigen complexes were removed by low-speed centrifugation, the resulting pellets were then washed (resuspended and centrifuged) with 0.01 M Tris, *p*H 7.4, followed by 1% sodium deoxycholate, and finally 0.01 M Tris, *pH* 7.4. The samples were dissolved in SDS–sample buffer and applied to an SDS gel as previously described[30]. Adsorption of Moloney MuSV serum with cells was done by incubation of serum and cells at a ratio of 1:4 for 30 min on ice. Samples of ^{3}H-leucine-labelled Moloney MuSV/MuLV were precipitated by Moloney MuSV serum (*a*), antiserum adsorbed with AKR-N3T3 cells (*b*) and antiserum adsorbed with MSC cells (*c*). Standards used for calculating molecular weight were a sample of ^{3}H-leucine-labelled Moloney MuSV/MuLV and β-galactosidase (130,000), phosphorylase *a* (94,000), lactoperoxidase (80,000), catalase (60,000), alcohol dehydrogenase (41,000), carbonic anhydrase (29,000) and myoglobin (17,200) (not shown).

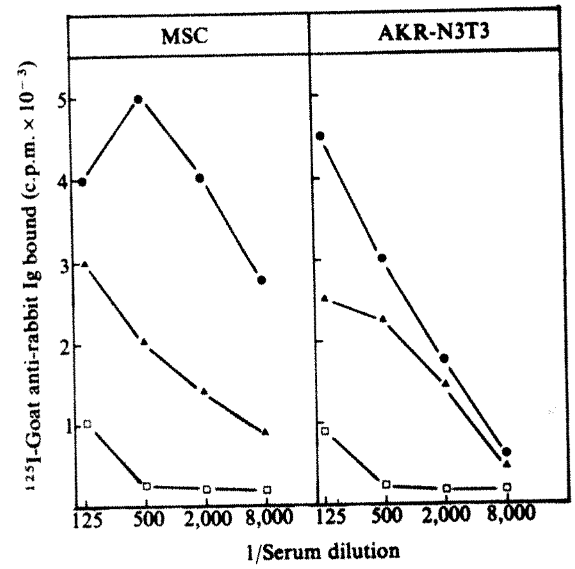

Fig. 3 Moloney MuSV/MuLV shedding MSC cells and the Gross MuLV shedding AKR-N3T3 cells were examined for expression of membrane type C viral antigens using a cell monolayer radioimmunoassay[14]. The cells were reacted with the following antisera to type C viral proteins[14]: rabbit anti-gp70 (●), rabbit anti-p30 (▲) and a control normal rabbit serum (□).

It was possible that AKR-N3T3 cells failed to adsorb p30 and gp70 antibodies from the Moloney MuSV serum because very little of these proteins were present on the membranes of the cells. To investigate this, rabbit anti-p30 and anti-gp70 reacting chiefly with shared or group-specific antigens[14] were titrated on both MSC cells and AKR-N3T3 cells. The titration profiles (Fig. 3*a*, *b*) show that both cell types have easily detectable amounts of both gp70 and p30 on their membranes. It is proposed that AKR-N3T3 cells fail to adsorb antiviral specificities from Moloney MuSV serum (Fig. 2*b*) because these antibodies are directed against Moloney virus type-specific determinants on both gp70 and p30 proteins.

FMR antisera have been shown to exhibit virus-neutralising activity and to contain antibodies which are cytotoxic for FMR-infected cells.[20] It has been reported that the cytotoxicity can be removed by adsorption of the antisera with an internal virion protein thought to be p15 (ref. 21). More recently, Nowinski and coworkers have provided evidence associating FMR antigenicity with the envelope protein, gp70 (ref. 22). In the present study, we have also found type-specific responses to gp70 protein but, in addition, we found higher titres of antibody directed against type-specific antigens on p30 protein. The finding of an immunogenic type-specific p30 antigen(s) as a possible component of the FMR antigen(s), suggests that this antigen is analogous to GCSA antigen induced by Gross virus infection, which is present on p30 as part of membrane bound 'gag' polyprotein. We do not know the molecular nature of the Moloney virus cell membrane p30. Many other species such as rats, cats, hamsters, rabbits and higher primates make antibody to p30 (refs 19, 23, 24) in response to type C virus infection. Mice have formerly been thought to be tolerant to p30 protein[25–27] unless immunised across strain barriers, as was done to raise the GSCA antisera[1]. Our study indicates for the first time that mice can mount a good response to p30 when immunised syngeneically and that the responses to G_{IX} and GCSA antigens on Gross virus tumours[1,28] and the FMR antigen on Friend, Moloney and Rauscher virus tumours are very similar in that both are type-specific responses to gp70 and p30, and not, in general, to other tumour-associated proteins.

We thank Dr Jennifer Harvey for Moloney MuSV/MuLV virus and for her help in inducing Moloney tumours, Ms Susan Crowhurst for technical assistance, and Mike Fried, Dick Knight and N. A. Mitchison for reading the manuscript. N.H. is supported by the Leukaemia Research Fund.

Anti-idiotypic antibodies in a patient with a functioning renal graft

Tetsuya Miyajima*, Reiko Higuchi*,

‡ Laboratories for Immunology, School of Medicine, Chiba University, Chiba, Japan

A central problem in improving the success of renal transplantation in humans is to discover how to induce in the recipient an active immunological unresponsiveness to the donor's alloantigens[1–3]. There is increasing evidence that immunological unresponsiveness can be induced by either suppressor T cells[4,5] or antibodies directed against the T-cell receptor, that is, anti-idiotypic antibodies[6,7]. In our institutes, there are now six successful renal recipients. One of these, CD-S5, is a 32 year old man, HLA tissue-typed as Aw31, Bw39, Bw54 and DRw4. He received a second kidney transplant from a cadaveric donor having HLA-A2 and B5 on 21 August, 1975, after the first transplant from his brother with Aw26 and Bw40 had been rejected. The stimulation index of the mixed lymphocyte reaction (MLR) between patient and first donor was 11.9 but MLR could not be tested in the second grafting. One year after the second graft, immunosuppressive treatment with azathioprine was withdrawn because of drug toxic hepatitis. In spite of the administration of only prednisolone at 10 mg per day for the past 3 yr, the patient's creatinine clearance has remained at 70 ml min^{-1}. We proposed that the long survival of the renal graft might be due to an immunological unresponsiveness induced by the host immunoregulatory mechanism of this patient. To test this possibility, we have investigated the patient's serum for factor(s) capable of suppressing the host immune response. We report here our finding that the patient's serum contained an antibody against a T-cell receptor for a certain MLR, which was capable of specifically inhibiting a certain MLR.

First, we carried out an MLR inhibition test between recipient and donor using the recipient's serum. However, the recipient had received his graft from a cadaveric donor and the responsiveness of his lymphocytes in the MLR was found to be very weak, probably because they had already been inactivated, either by the host regulatory mechanism or by the immunosuppressive drug. A similar HLA-mismatched combination from a third individual was then attempted. As the HLA-B locus is more closely linked to the HLA-D locus (the MLR locus) than HLA-A, a combination of responder T.M. (A2, A11) (Bw15,) (DRw4,) and stimulator R.H. (A2, Aw26) (B5,) (DRw2,) cells was selected from healthy individuals who had the same mismatched HLA-B antigen B5 as was found between recipient and cadaveric donor. B5 antigen has recently been split into two antigens, Bw51 and Bw52, and B5 of the stimulator R.H. was later defined as Bw52. Using this combination, the patient's serum was subjected to the MLR inhibition test by its addition to the mixed lymphocyte culture. As shown in Table 1, the patient's serum clearly inhibited the MLR of this combination. The characteristics of the inhibitory factor in the patient's serum were then investigated to determine whether or not it was an antibody. For this, the patient's serum was fractionated by Sephadex G-200 column chromatography with borate-buffered saline, *p*H 8.0. Fractions of 19S, 7S, 4S and <4S, after being concentrated to the original volume by negative pressure dialysis, were each tested for their inhibitory activity in the MLR. Inhibitory activity was found mainly in the 7S fraction, and was

0028–0836/80/030306—03$01.00

Table 1 The effect of the renal recipient's serum fraction on the MLR of the selected third-party combination

Serum fraction added to the MLR	^{3}H-Thymidine incorporation by T.M. cells against R.H. (mean c.p.m. ± s.d.)
—	1,384 ± 252*
Not added	16,856 ± 1,234
Whole serum	1,480 ± 396
19S fraction	11,799 ± 1,099
7S fraction	3,371 ± 469
4S fraction	5,900 ± 899
<4S fraction	15,170 ± 769
7S fraction absorbed with rabbit anti-human IgG ab.	15,822 ± 1,177

The serum of the renal recipient was fractionated by elution on Sephadex G-200 column chromatography (2.6 × 100 cm) with borate-buffered saline, *p*H 8.0. As the inhibitory activity was mainly found in the 7S fraction, it was absorbed with purified rabbit antibodies directed against human IgG at room temperature for 1 h and then at 4 °C overnight at optimal ratio. Ten per cent of unabsorbed 7S fraction or absorbed 7S fraction was added to the culture medium of the selected MLR which had the same mismatched HLA-B antigen, B5, as found between recipient and cadaveric donor. Phenotype of responder T.M. is (A2, A11) (B15,) (DRw4,) and that or stimulator R.H. is (A2, Aw26) (Bw52,) (DRw2,). For MLR, 1×10^5 lymphocytes, prepared from defibrinated peripheral blood, were cultured with 1×10^5 2,000-rad irradiated stimulating cells for 5 days in microtissue culture plates (Nunclon N-1182, Roskilde) using RPMI-1640 medium (GIBCO) with 10% heat-inactivated human serum. Sixteen hours before collection, 0.5 μCi of ^{3}H-thymidine was added to each well and its incorporation measured with a liquid scintillation counter. Values are expressed as mean c.p.m. ± s.d. of triplicate samples.

* The value shows ^{3}H-thymidine incorporation by responding cells without stimulating cells.

completely removed by the absorption of IgG from the fraction using purified rabbit antibodies against human IgG at an optimal ratio (Table 1). This indicated that the inhibitory effect on the MLR is mediated by IgG antibodies. The serum IgG fraction was then isolated on DEAE-cellulose column chromatography by elution with 0.005 M phosphate buffer, *p*H 8.0, and tested for specificity of the MLR inhibition using various responder–stimulator cell combinations (Table 2). Treatment of responder cells (2×10^6 cells) with 0.5 ml of the antibody fraction (3 μg ml^{-1}) selectively inhibited the MLR of only those combinations with the same mismatched HLA-B antigen B5 as found in the combination of recipient and cadaveric donor. Also, the IgG fraction did not inhibit the MLR of the responder cell S.S., which differs from T.M., against any stimulating cells. Furthermore, the treatment of the stimulating cell R.H. with the antibody fraction had no effect on the response of untreated responder T.M. cell against the treated R.H. cell (Table 2), indicating that the inhibition is specific for very restricted combinations and is not mediated by antibody directed against common surface antigens of either the responder or the stimulator cell. In addition, the inhibitory effect on the MLR was directed against the responder cells, not against the stimulator cells.

The specificity of the inhibition by the antibody fraction was confirmed by an absorption study. When the antibody fraction (3 μg protein ml^{-1}) was absorbed three times with the responding cell T.M. (1×10^7) the inhibitory activity was markedly reduced, whereas absorption with an equal number of stimulator cell I.M. failed to remove the inhibitory activity (Table 3). Therefore, this restricted inhibitory effect on the MLR of specific pairs indicates that the antibody found in the patient's serum is directed against the T-cell receptor initiating MLR of the responding cell.

The nature of the T-cell receptor has been investigated in several laboratories[8,9]. Studies using anti-idiotypic antibody provide evidence that the T cell has receptors sharing idiotypes with the B cell for T-cell mediated immune reactions. Binz *et al.*[10] have already reported that the MLR, which is thought to be a T-cell mediated immune reaction[11], can be inhibited by an anti-idiotypic antibody directed against alloantibodies or T-cell receptors for alloantigens. An anti-idiotypic antibody has also been shown to compete with the corresponding alloantigen for binding to MLR-activated T-cell blasts[12], indicating that the inhibition of the MLR is mediated by the binding of anti-idiotypic antibodies to the antigen binding site of the T-cell receptor. The present finding that the inhibitory activity of the MLR in the recipient's serum is completely removed by absorption with purified rabbit antibodies directed against human IgG shows that the activity is associated with IgG antibody and directed against responder cells, but not stimulator cells. Moreover, the treatment of responder cell T.M. with the IgG antibody completely inhibited only the response against two types of stimulator cells, those which share Bw52 and DRw2,

The IgG fraction was isolated from the patient's serum by DEAE-cellulose column chromatography using 0.005 M phosphate buffer at *p*H 8.0. 3×10^6 cells of either responder T.M. or stimulator R.H. were treated with 0.2 ml of the IgG antibody fraction (3 μg ml^{-1}) for 30 min at 37 °C and then washed three times with RPMI-1640 medium. After treatment, the responder cells were mixed with 12 different irradiated stimulator cells. In another experiment, R.H. stimulator cells were mixed with untreated responder cells T.M.

The IgG antibody fraction had an inhibitory effect on the MLR even at a concentration of 3 μg ml^{-1}. Therefore, 0.5 ml of 3 μg ml^{-1} of the IgG antibody fraction was absorbed with either 1×10^7 I.M. stimulator cells or 1×10^7 T.M. responder cells for 30 min at 37 °C. The absorption was repeated three times with the same number of fresh cells each time. After absorption, the IgG fraction was tested for its inhibitory effect on the MLR, treating the responder cells T.M. with either unabsorbed or absorbed IgG antibody fraction.

* The first parenthesis is for *A* locus, the second for *B* locus and the third for *DR* locus antigens.

but did not inhibit the response against 11 other types of stimulating cells. This suggests that the antibody is directed against a restricted clone of T cells bearing the MLR antigen of the stimulating cells R.H. and I.M. From this, and observations reported by others, we consider that the patient's serum contains antibody against a T-cell receptor for an MLR antigen, that is, an anti-idiotypic antibody. Genotype for the responder cell T.M. is *A2, /A11, Bw15, DRw4*; for the stimulating cell R.H., *A2, /Aw26, Bw52, DRw2*; and for the stimulator cell I.M., *Aw24, Bw15, /Aw24, Bw52, DRw2*. Phenotype of the cadaveric donor of the patient was (A2,) (B5,). From these combinations, because one haplotype of stimulator R.H. or I.M. is in parts identical to that of the responder T.M., we suggest that this antibody could bind an idiotype of the receptor specific for DRw2-associated MLR determinants.

In contrast to our findings, it has been reported that in experimental animals, idiotypes of T cells usually differ between strains, although intrastrain idiotypic cross-reactions of T-cell receptors are extremely strong[13]. However, it has been observed that idiotypes are shared in immunoglobulins from genetically different individuals[14]. Furthermore, T-cell receptors are generally idiotypically more homogeneous than antibodies[15,16]. These findings suggest that certain idiotypes are shared by a T-cell clone of T.M. and the renal recipient, which can be activated with DRw2-associated MLR antigen.

As presented by Jerne, the immune network theory claims that the autoimmune response to self-idiotypes can basically act as an immunoregulatory system[17]. The passive immunisation with an anti-idiotypic antibody or active immunisation with parental cells of F_1 hybrids induces immunological unresponsiveness in animals against the relevant antigen[6,18]. This idea seems attractive for clinical transplantation, and it is conceivable that anti-idiotypic antibodies directed against autologous idiotypes on T cells are at least partly responsible for the successful graft survival in the patient not receiving azathioprine.

Stimulation of cytolytic T cells by isolated viral peptides and HN protein coupled to agarose beads

Daniel P. Guertin & David P. Fan

Department of Genetics and Cell Biology, University of Minnesota,
1445 Gortner Avenue, St Paul, Minnesota 55108

Sendai virus-infected mouse cells can be lysed by mouse cytolytic thymus-dependent lymphocytes (CTL) directed specifically against the infected cells. The CTL is known to recognise the H–2 antigens on the target cells together with structure(s) including at least the two viral surface glycoproteins also found on purified virus[1–8]. We report here that anti-Sendai CTL can be stimulated *in vitro* by detergent-solubilised viral haemagglutinin–neuraminidase (HN)[9], either as the isolated protein or coupled to agarose beads. We further show stimulation by the hydrophilic portion of a protein removed from the virus by the protease subtilisin BPN′, and we demonstrate that cyanogen bromide- (CNBr-) cleaved viral peptides also produce such stimulation.

For studies with the detergent-solubilised Sendai glycoproteins we made three preparations: (1) a mixture of HN and the fusion protein (F)[9,10], denoted HNF, contaminated by a small amount of nucleoprotein (NP)[9], or a breakdown product of HN[19]. (2) cleanly purified F, and (3) HN fraction separated completely from the F but retaining a trace amount of NP or HN breakdown material (Fig. 1). Since the NP is normally associated with the nucleic acid at the interior of the virus[9], we assume that this protein is not likely to be a CTL antigen. Thus any small amount of NP in the HN and HNF preparations should not affect their properties in CTL stimulation.

The preparations of HNF, F and HN were either: (1) left untreated, (2) dialysed to remove detergent, or (3) coupled covalently to *N*-hydroxysuccinimide-activated agarose beads at initial concentrations ranging from 25 to 60 μg protein per 0.5–6.5 ml packed beads in a total volume of 3–15 ml. In preliminary experiments, the HNF and HN, either free or bound to beads, were consistently able to stimulate H–2-restricted anti-Sendai CTL *in vitro* from spleen cells of BALB/c(H-2^{d}) and C57BL/6(H – 2^{b}) mice previously exposed to Sendai virus. The BALB/c CTL were typically able to lyse P815(H-2^{d}) mastocytoma cells only after Sendai infection and were unable to lyse EL4(H – 2^{b}) leukaemia cells either with or without Sendai infection. In contrast, HNF- and HN-stimulated C57BL/6(H-2^{b}) CTL specifically lysed infected EL4(H-2^{b}) but not P815(H-2^{d}) cells either with or without infection. There did

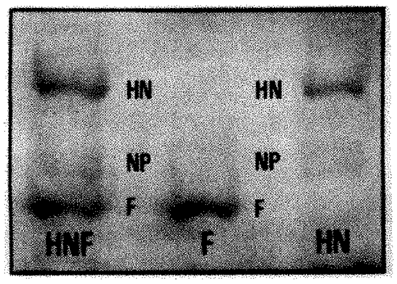

Fig. 1 Preparation of Sendai F, HN and HNF and their presentation to mouse spleen cells for CTL stimulation *in vitro*. SDS-polyacrylamide gel electrophoresis of Sendai protein fractions. Purified Sendai virus was extracted with 0.25% Triton X-100 in 0.01 M sodium phosphate buffer, *pH* 7.2, at 6.4 mg protein ml^{-1} for 30 min at room temperature with repeated mixing in a homogeniser. After centrifugation at 200,000*g* for 1 h (ref. 9), the HNF was contained in the supernatant of the extracted proteins. The yield of HN was 20% as measured by neuraminidase enzyme assay. The HN fraction was HNF material which did not absorb to a diethylaminoethyl-agarose (DEAE-BioGel A, BioRad) column equilibrated with 0.1% Triton X-100 in 0.01 M sodium phosphate buffer, *pH* 7.2 (ref. 16). The F fraction was HNF material which did not absorb to a hydroxyapatite (BioGel HTP, BioRad) column equilibrated with the same buffer. The yield of both F and HN was over 80% from the two columns. The purified HN had 460 units neuraminidase per μg protein. Aliquots of 15 μg HNF, 6 μg F and 9 μg HN were loaded onto the 7% gel[17].

tend to be some stimulation of C57BL/6 CTL against uninfected EL4 cells although this stimulation was always less marked than that for the infected cells. These characterisation experiments showed that the fact that the BALB/c CTL did not lyse the Sendai infected EL4 cells was not due to the inability of the infected EL4 cells to act as targets for anti-Sendai CTL. On the contrary, the CTL stimulated by the isolated viral proteins gave the typical H-2 restriction seen for anti-Sendai CTL[1-8]. In view of the more clearcut viral dependence with the BALB/c CTL, further experiments were performed with this system.

Results with the isolated F protein, either free or on agarose beads, were inconsistent, at best showing marginal stimulation; so experiments with the F protein were not pursued further. However, F is in fact an antigen recognised by anti-Sendai CTL since the F and H-2 proteins inserted together into lipsomes can stimulate these CTL although the antigenicity seems to be lower than that for HN[8].

The extent of stimulation by the HN and HNF preparations was closely correlated to the amount of neuraminidase and hence HN in the preparations regardless of whether the antigen was free in a detergent-containing solution, had been removed from the detergent by dialysis, or had been coupled to agarose beads (Fig. 2). The same maximum stimulation was observed with 0.04–0.80 units neuraminidase per well and 130–16,000 beads per well. The minimum amount of HN needed to give maximum stimulation represented enzyme from 30 virus particles per cell. The presence of the extra F in the HNF preparations did not increase stimulation beyond that of HN alone, confirming that the F had little if any stimulatory activity. The

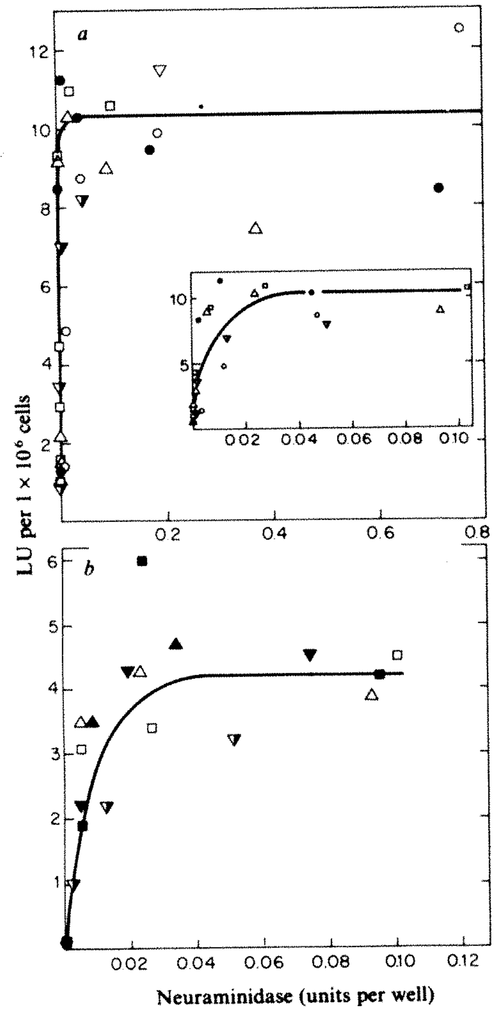

Fig. 2 Dependence of anti-Sendai CTL stimulation on HN concentration. The HNF and HN preparations of Fig. 1 were shaken gently overnight in the cold with *N*-hydroxysuccinimide-activated agarose beads (2×10^6 packed beads ml^{-1}, bead diameter 50–200 μm, Affigel-10, BioRad) in 0.1 M HEPES buffer, *pH* 6.5. The covalently coupled beads were then washed with 0.1% Triton X-100 in 0.01 M sodium phosphate buffer to remove unattached protein, and unreacted *N*-hydroxysuccinimide groups were blocked by further shaking in 0.1 M glycine ethyl ester, *pH* 8.0 in 0.1% Triton X-100 for 1 h. The beads were finally washed repeatedly and suspended in TD buffer (8g NaCl, 0.38g KCl, 0.1 g Na_2HPO_4, 3.0 g Tris-HCl per litre, *pH* 7.4). (In the descriptions below involving the coupled beads, the concentrations at the begining of the coupling are indicated in brackets in μg ml^{-1} for protein and beads per ml $\times 10^5$ for the Affigel.) From neuraminidase enzyme measurements, the binding of HN to beads for HN(12)–Affigel(3) was 12% to give 4.5 units neuraminidase per 10^5 beads. The corresponding values for HN(5)–Affigel(6) were 29% and 2.8 units, for HN(2)–Affigel(7) were 43% and 1.3 units, for HNF(20)–Affigel(3) were 14% and 6.6 units, for HNF(10)–Affigel(6) were 20% and 2.4 units, and for HNF(4)–Affigel(7) were 51% and 1.9 units. For the stimulation of anti-Sendai CTL, spleen cells ($3–4 \times 10^6$) from BALB/c (H-2^d) mice immunised intraperitoneally several weeks previously with live Sendai virus were added to 16-mm diameter tissue culture wells (Linbro Scientific) together with the additions indicated in 0.5 ml serum-free medium. After 30 min at 37 °C, serum containing medium was added to give 2.5 ml per well at the final composition used previously[18]. The CTL in the wells were assayed as described[18] for the ability to release radioactivity from ^{51}Cr-labelled P815 (H-2^d) cells exposed to an excess of UV-inactivated Sendai virus in a small volume of serum-free medium for 1 h. The lytic units per 10^6 cultured cells (LU per 10^6) were as defined previously[18], except that lysis was measured after 6 h instead of 3 h. *a*, The inset has the same data plotted on an expanded scale. The antigens added to the wells were: the HN preparation as in Fig. 1 in detergent solution (○), the same preparation dialysed extensively against TD buffer to remove the Triton X-100 (●), HN(12)–Affigel(3) (△), HN(5)–Affigel(6) (□), and HN(2)–Affigel(7) (▼). Two control cultures stimulated with an excess of UV-inactivated Sendai virus gave 94 and 176 LU per 10^6 respectively. The inset shows the same data plotted on an expanded scale. The antigen added to these wells were the same HN–Affigel preparations used above (same symbols), plus: HNF(20)–Affigel(3) (▲), HNF(10)–Affigel(6) (■), and HNF(4)–Affigel(7) (▼). Two control cultures similar to the ones used in *a* gave 70 and 119 LU per 10^6 respectively.

anti-Sendai CTL were indeed thymus-dependent because lysis could be reduced more than 99% by treatment with anti-Thy 1.2 antibody and rabbit complement.

Since the haemagglutinin activity of the HN will cause the protein to bind to cell surfaces, it was conceivable that the protein was acting as a lectin in the same way as concanavalin A (Con A), which is known to stimulate CTL nonspecifically[11]. This possibility was unlikely since HNF beads did not efficiently stimulate anti-H-2^d specific CTL from C57BL/6(H-2^b) mice previously immunised with H-2^d cells, while Con A on beads was able to do so (Fig. 3). Conversely, Con A on beads did stimulate these allospecific CTL but not the anti-Sendai CTL as the HNF beads had done. The ability of bead-bound Con A to stimulate at least one class of T cells is in contrast to a previous report[12] that Con A bound to surfaces could stimulate B but not T cells. It is conceivable that only a small subset of T cells could be stimulated by Con A on beads and that this subset was missed by the earlier report.

The results with the bead-bound antigen suggested that stimulatory antigen need not be presented to spleen cells in the context of a lipid membrane. The ability of antigen coupled to beads to stimulate CTL has also been demonstrated for H-2 alloantigens[13]. Next, we tested for stimulation by fragments of Sendai proteins, beginning with those cleaved from the virus by subtilisin BPN′. In the conditions used, the HN was liberated from the virus as demonstrated by mobility of the neuraminidase activity at a rate corresponding to a molecular weight smaller than bovine serum albumin (molecular weight 68,000) on an agarose gel filtration column (Fig. 4*a*).

Since our object was to determine the minimum antigenic determinant for anti-Sendai CTL stimulation, we chromatographed the subtilisin-solubilised viral proteins on a Sephadex G-75 column with an exclusion limit of molecular weight 70,000 and tested the fractions for both neuraminidase activity and CTL stimulation (Fig. 4*b*). The enzyme activity appeared almost in the excluded volume, indicating that the solubilised HN had a larger apparent molecular weight on this column than on the agarose column. Anti-Sendai CTL stimulatory material was found in the region where the HN protein and smaller materials ran.

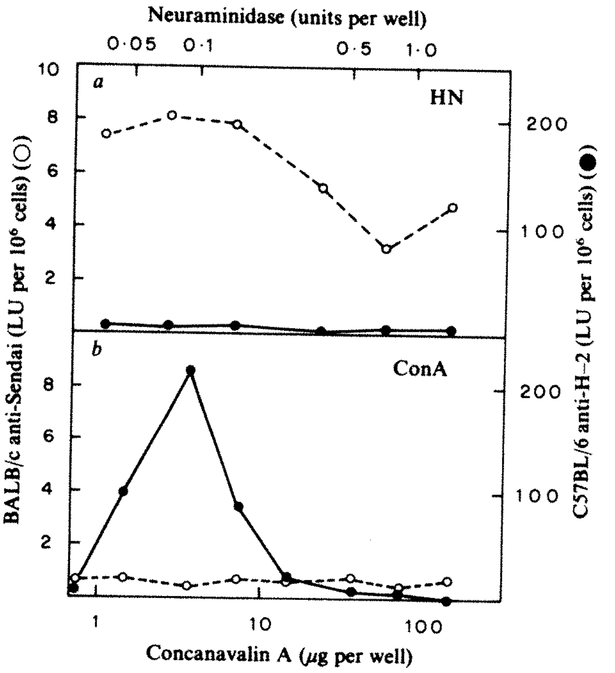

Fig. 3 Specificity of HNF stimulation of CTL. *a*, BALB/c(H-2^d) spleen cells were stimulated with HNF(4)–Affigel(14) at various concentrations and assayed for anti-Sendai CTL using Sendai-infected P815(H-2^d) target cells as described in Fig. 2. Spleen cells from C57BL/6(H-2^b) mice immunised intraperitoneally several weeks previously with 30×10^6 P815(H-2^d) cells were also stimulated *in vitro* as above with HNF(4)–Affigel(14) and were assayed for anti-H-2^d CTL using the same Sendai-infected P815 target cells. The assay was for 3 h instead of 6 h. The results were essentially the same when non-infected P815 target cells were used. *b*, The same conditions were used in the stimulation and assay except that concanavalin A covalently coupled to agarose beads at 15 mg ml^{-1} beads (Miles Labs) was used in place of the HNF(4)–Affigel(14).

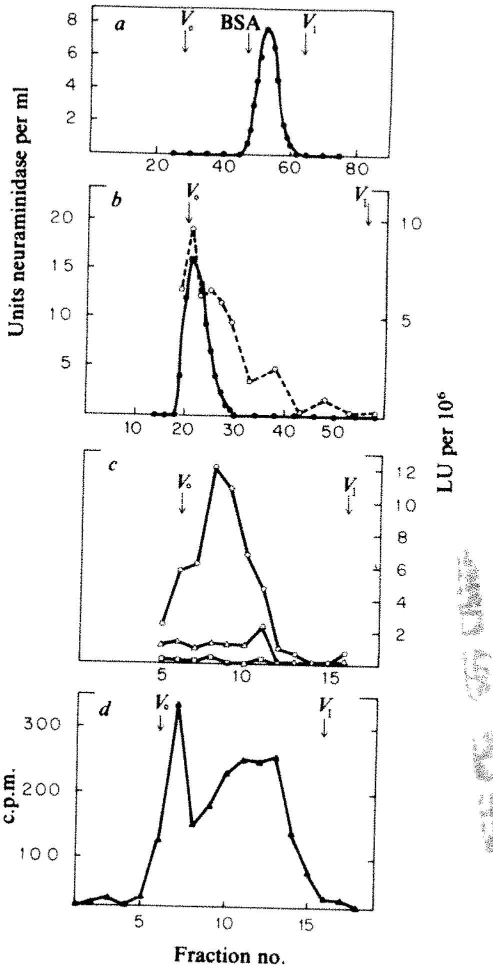

Fig. 4 Characterisation of subtilisin and CNBr-cleaved fragments of Sendai viral proteins. Purified Sendai virus was digested for 60 min at 37 °C with 100 μg subtilisin BPN′ (Sigma) (100 μg per 30 mg viral protein per ml) in 0.005 M sodium phosphate buffer, *p*H 7.4. After digestion, the sample was centrifuged at 200,000*g* for 60 min, and the supernatant solution containing approximately 10% of the neuraminidase activity in the original virus preparation was chromatographed on a Biogel A-5 m (BioRad, 11 mm × 110 cm) gel filtration column packed with 6 mm diameter glass beads (*a*) and on a Sephadex G-75 (Pharmacia, 21 mm × 55 cm) gel filtration column (*b*) using 0.005 M sodium phosphate buffer, *p*H 7.2. The subtilisin-solubilised material was also mixed with one-half volume of formic acid and CNBr equivalent to 100 times the estimated mass of the solubilised protein. After overnight cleavage at room temperature, the sample was lyophilised, resuspended in 0.2 M acetic acid chromatographed on a Sephadex G-25 (Pharmacia, 6 mm × 25 cm) gel filtration column in 0.2 M acetic acid (*c*). A separate virus sample (*d*) was subtilisin- and CNBr-digested and then chromatographed on a G-25 column as in *c* except that the starting virus was labelled radioactively using ^{3}H-D,L-alanine injected into the allantoic cavity of the egg used for viral growth. The void (V_0) and included (V_I) volumes of the column are indicated for each chromatogram. The samples from the columns were analysed for neuraminidase activity (●), radioactivity (▲), and the ability to stimulate CTL. The column fractions were lyophilised, resuspended in TD buffer, and added directly to the cultures for the *in vitro* stimulation as described for Fig. 2. The assays were also as in Fig. 2 except that the target cells included P815(H-2^d) non-infected cells (△), and EL4(H-2^b) Sendai-infected cells (□) in addition to the P815 Sendai-infected cells (○).

Thus it was conceivable that fragments of the HN too small to have neuraminidase activity could still stimulate CTL. After subtilisin-solubilised viral proteins were further cleaved with CNBr, over 99% of the neuraminidase activity was abolished. The cleavage products from radioactively labelled virus were found to have molecular weights ranging from 1,000 (the inclusion limit of Sephadex G-25) to over 5,000 (the exclusion limit of the same gel filtration beads) (Fig. 4*d*). Fractions from the G-25 column corresponding to proteins smaller than the excluded volume were still able to stimulate BALB/c anti-Sendai CTL (Fig. 4*c*). Furthermore, these CTL were Sendai-specific and H-2-restricted, lysing H-2^{d} but not H-2^{b} cells only after Sendai infection (Fig. 4*c*).

The material from fractions 19–30 from the column of Fig. 4*b* was also pooled, cleaved with CNBr and chromatographed on the G-25 column used in Fig. 4*c*. The same pattern of stimulatory material was observed indicating that compounds of small molecular weight could indeed be generated by CNBr cleavage of larger molecules and retain the stimulatory capacity. When the starting material for the CNBr cleavage from the pooled fractions was analysed by sodium dodecyl sulphate–polyacrylamide gel electrophoresis as described in Fig. 1*a*, only two bands were seen at molecular weights of approximately 55,000 and 61,000. Because of their large sizes, neither could have been derived from the F glycoprotein. Furthermore, protein corresponding to the smallest detergent-solubilised F peptide (F$_1$)[10] at molecular weight 51,000 or less was not seen suggesting that no material from the F protein was represented in these G-75 column fractions. However, at least one of the new bands was likely to have been derived from the larger HN by proteolytic cleavage, since neuraminidase activity was still present and the band corresponding to detergent-solubilised HN at molecular weight 69,000 was missing.

In a comparison experiment, the maximum stimulations by the subtilisin-solubilised viral peptides for Sendai-infected P815 target cells, non-infected P815 targets, and Sendai-infected EL4 targets from five independent samples in the plateau region of saturating antigen were 8.4 ± 1.9, 2.4 ± 0.5 and 0.7 ± 0.2 LU per 10^{6} cells, respectively. The corresponding values for the CNBr cleaved material were 5.6 ± 1.7, 1.6 ± 0.3 and 0.6 ± 0.2 LU per 10^{6} cells, respectively, again for five samples in the plateau region. Antigen from fraction 9 of Fig. 4*c* of molecular weight less than 5,000 was also able to stimulate with corresponding values of 7.3 ± 0.8, 1.4 ± 0.2 and 0.4 ± 0.1 LU per 10^{6} cells, respectively. In all cases, the maximum stimulation was similar to that for the detergent-solubilised HN that is, in the range of 5–10% of the stimulation found for UV-inactivated Sendai virus. Within the limits of sample loss, the CTL stimulation was as efficient using CNBr fragments as it was with the subtilisin-cleaved HN. Therefore, it does not seem that any of the antigenic determinants for this low level of stimulation were destroyed by the subtilisin and CNBr treatments. It is possible that this low level of stimulation corresponds to that found by Finberg, Mescher and Burakoff[2] using liposomes containing viral proteins in the absence of any H-2 products and probably derives from a special subset of all anti-Sendai CTL precursors. The ability to use isolated viral proteins to stimulate anti-viral CTL has also been reported for influenza virus[14,15].

The advantage of using bead-bound antigens stems from the fact that the beads are large and can be removed easily and quantitatively from the *in vitro* stimulation mixture so that the time course of the stimulation can be studied precisely. In initial experiments, the beads lost all their ability to stimulate fresh cells after overnight incubation with responder cells. Therefore, it is conceivable that the antigen bound to the beads was cleaved from them during the incubation and that antigen fragments constituted the actual stimulatory material. Alternatively, the bead-associated antigen could have been processed for the stimulation in some other way. Also, a variety of cells, including macrophages, can be exposed to the beads to determine which cells process the added antigen first. The use of protein fragments in the stimulation tests should permit the biochemical characterisation of the minimum antigenic determinants for CTL stimulation. As a working hypothesis, we are assuming that one or more cleavage products of HN are responsible for the stimulation since stimulation by the purified detergent-solubilised proteins correlated most closely with the presence of this protein, and, also, analysis of the G-75 column made it unlikely that the F protein was present in fractions which gave rise to stimulatory fragments.

We thank Dr R. Zinkernagel for the hospitality of his laboratory during initial stages of this work and Mrs O. M. Hurlburt for technical assistance. These studies were supported by a PHS research grant.

Viral pathogenesis and resistance to defective interfering particles

Steven Jacobson & Charles J. Pfau

Department of Biology, Rensselaer Polytechnic Institute, Troy, New York 12181

Recently presented evidence indicates that synthesis of defective interfering (DI) particles following infection of cultured cells with lymphocytic choriomeningitis (LCM) virus may result in self-curing[1]. The genesis of DI particles can occur in cells infected with virtually any animal virus[2], and seems to be a host-controlled function[3]. Thus, these particles may represent a third line of defence—with the immune response and interferon—against virus invasion[3,4]. LCM virus infection causes the rapid appearance of DI particles in tissue culture cells[5,6]. Nevertheless, persistent infections can be easily established with LCM and other arenaviruses[7–9]. The LCM-persistent infections are apparently maintained in these cultures by the genesis of DI-resistant viruses[1]. This latter finding prompted us to determine whether such DI-resistant viruses occur in nature. Vertical transmission of LCM virus in the house mouse or neonatal infection of laboratory mice takes the form of a life-long inapparent infection. These mice lack functional virus-specific T lymphocytes, but may make an antibody response against the invasion. It is known that LCM virus injected into a neonatal mouse can change during the course of the infection so that at least two different viral populations coexist in the same mouse[10]. DI particles are produced in abundance shortly after neonatal infection and this precedes the appearance of a virus population that, by plaque morphology, differs from the one originally inoculated[11]. We report here the isolation of an LCM virus from persistently infected mice that is resistant not only to the DI particles which were produced shortly after neonatal infection with heterotypic virus but also to the DI particles that this virus itself induces in neonates. We know of no other report of viruses which can replicate normally in the presence of the DI particles they induce.

0028-0836/80/030311—03$01.00

A recently isolated clone of the UBC strain of LCM, designated substrain T, was injected into outbred (ICR) mice less than 24 h old. This virus strain had a long history of tissue culture passage in our laboratory[12]. Ten months later, the blood of these mice exclusively contained two virus types which were easily distinguishable from substrain T (Table 1). These cloned viruses were called substrains A and D because the disease syndromes they produced in mice infected as adults were similar (Table 1) to two previously described substrains of LCM-UBC designated 'aggressive' and 'docile' (ref. 13). All three virus types: (1) were neutralised by heat-inactivated (56 °C for 30 min) filtered ascites fluid taken from a patient infected with the MP strain of LCM; (2) induced patching and capping on living MDCK cell membranes after a fluorescein isothiocyanate indirect staining sequence using sera from a substrain T hyperimmunised hamster; (3) initiated life-long (>9 months) persistent infections when injected into neonatal ICR mice. DI particles for each of the three substrains, designated DI_T, DI_A and DI_D, were generated in neonatal mice by previously described methods[11]. Each newborn mouse in a litter (usually 15) was injected intraperitoneally with 100 LD_{50} of one of the substrains. Eight days later the mice were killed and kidneys from the littermates were pooled and homogenised. After resuspension in 10 ml of tissue culture medium and clarification by low-speed centrifugation, the putative DI particle stocks were stored at −70 °C until use. DI particle activity was measured in MDCK cells. These cells are killed with single hit kinetics by infection with standard virus. However, co-infection with a single DI particle not only spares the cell but also inhibits the replication of standard virus[14]. Our test was to infect a series of MDCK monolayers with one type of DI particle and then challenge them individually with each of the three virus substrains shown in Table 1 (which by themselves would cause almost complete destruction of the monolayer). DI particle activity was determined visually and by reduction of the amount of infectious challenge virus synthesised.

In each case, all three putative DI particle preparations completely inhibited any observable cytopathic effect (CPE) caused by standard virus substrains T and D (Table 2). Synthesis of these challenge standard viruses in the above conditions varied from 13% to 43% of normal (we have previously shown[14] that suppression of CPE and inhibition of standard virus synthesis by DI_T particles are separable functions). However, none of the DI preparations protected cultures challenged with substrain A (Table 2). Thus, substrain A seems to be relatively resistant to DI particles in general, even to those that it induced.

The results presented in Table 2 were judged to be due to DI particles for the following reasons. (1) Kidneys taken from normal mice had no sparing ability on cultures challenged with any of the three standard viruses. (2) UV treatment of the DI particle-containing kidney extracts in conditions which lowered the infectivity of standard virus 100-fold (multiplicity of infection (MOI) reduced from 0.7 to 0.007) had little or no effect on the cell-sparing phenomenon or the inability of these cells to support the replication of challenge virus (Table 2). This agrees with the previous observations of the relative UV resistance of LCM DI particles[15,16]. Furthermore, UV treatment did not increase the interference phenomenon, thus eliminating the possibility that it was an artefact created by irradiation of standard virus. (3) LCM-specific antiserum treatment of the kidney extracts taken from mice infected with substrain T lowered the standard virus titres (and supposedly the DI particle titres, as its polypeptide composition is not recognisably different from that of standard virus[17]) by 90% and effectively eliminated the cell-sparing and virus inhibitory properties. These results, combined with the unique properties of the DI_A particles, eliminated interferon as an explanation of the results. (4) Organ extract addition immediately after a 1.5-h adsorption period with 'challenge' virus still exerted its inhibitory effect on the virus, albeit somewhat less effectively[14]. This eliminated the possibility that the observed effects were due to blocking of receptor sites for the challenge virus or neutralising antibody in the kidney extracts. All these results are consistent with the general properties of DI particles[2]. When it becomes possible to separate LCM DI particles from standard virus effectively by physical means, purification of the DI particles from the kidney extracts can be undertaken.

Table 1 Plaque morphology and mortality pattern as a function of LCM virus substrain

Virus designation	MDCK plaque type* (diameter)	Murine characteristics† Appearance at death	% Dead	Mean day of death ± s.d. (range)
T	Clear (3–4 mm)	Convulsive	100	9.7 ± 1.4 (7–11)
A	Pinpoint (1-2 mm)	Convulsive	100	6.75 ± 0.5 (6–7)
D	Clear (3–4 mm)	Wasting	75	12.3 ± 5.8 (9–19)

* Monolayers were stained with neutral red on the fourth day after infection and plaques were scored within 24 h.

† Groups of 12 ICR mice, 14–21 days old, were injected intracerebrally with 100 LD_{50} of virus stock in a volume of 0.02 ml. Although a clear LD_{50} end point was obtained with substrain D, it was routinely observed that mortality fell as the dose of the inoculum increased.

Table 2 Ability of DI particles to interfere with the synthesis of different standard LCM viruses

Standard challenge virus subtype	% Of control challenge virus yield after pretreatment of MDCK cells with: DI_T*	DI_T	DI_A	DI_D
A†	95	90	94	94
D‡	13	32	23	26
T‡	25	30	43	37

Kidney extracts, which were found to contain the highest amount of DI particles after neonatal infection[11], were diluted so that 3 ml of tissue culture fluid contained the equivalent amount of virus extractable from one organ. Aliquots of 1 ml of the virus were then used to infect a 25-cm^2 monolayer of MDCK cells as described previously[14], or first subjected to the UV irradiation from two 30-W GE UV lamps giving an incident energy dose at the surface of the fluid of 6×10^4 erg. After a 1.5-h adsorption period the cells were repeatedly washed and then challenged with standard virus at an MOI of 0.1. The cultures were observed under the microscope at intervals over a 72-h period. DI particle-treated cultures were always compared with those that had either no pretreatment or pretreatment with organ extracts from normal mice. All tissue culture fluids were changed at 40 h post-infection and saved for future plaque assay titration. Control challenge virus yields were: substrain A, 1.3×10^8 plaque forming units (PFU) per ml; substrain D, 4.6×10^8 PFU per ml; substrain T, 3.0×10^8 PFU per ml.

* This preparation was not UV irradiated.

† All DI particle-pretreated cultures challenged with substrain A developed cytopathology to the same extent as cultures infected with substrain A alone.

‡ All DI particle-pretreated cultures challenged with substrains D or T developed little, if any, cytopathology.

Tissue culture models[1,5] of LCM persistent infections continue to have predictive value when applied to *in vivo* situations. The present finding of a DI-resistant virus offers an explanation for one of the plaque morphology changes in the virus as life-long infection progresses. The virus–cell interactions in these mice are obviously complex. The role of LCM substrain D is unclear; the time course of its appearance with regard to substrain A is under investigation. An LCM virus which changes slightly, if at all, in plaque morphology has also been observed in persistently infected mice[18]. This virus may initially have been resistant to DI particles, or evolved to this state without other striking signs of change. Our studies suggest that it may be worthwhile to determine whether DI-resistant viruses have arisen through natural selection in other persistent infections, especially those in which mutant viruses have appeared.

It has been proposed that cells budding LCM virus in the choroid plexus, ependyma and meninges are specifically recognised and damaged by sensitised T cells[19,20]. As DI particles suppress surface antigen expression in LCM-infected cells[21,22], the pathogenetic mechanisms of various LCM viruses in the adult mouse may be linked to their resistance to DI particles.

^{1}H NMR study of valinomycin conformation in a phospholipid bilayer

G. W. Feigenson & P. R. Meers

Section of Biochemistry, Molecular and Cell Biology,
Clark Hall, Cornell University, Ithaca, New York 14853

Our understanding of how ions pass across biological membranes has been greatly advanced by the study of small molecules which are capable of enhancing ion transport. The concepts of ion movement through channels or via mobile ion carriers have arisen from studies of model systems[1–4]. However, direct probing at the molecular level of the process of ion movement in a membrane system has proved difficult. The electrical properties of black lipid membrane model systems do not provide information about the details of ionophore location or conformation. Spectroscopic methods which are suited for probing the details of ionophore conformation and the stoichometry of ion binding have been confined largely to organic solvent systems which are limited as models for biological membranes. We report here proton magnetic resonance (^{1}H NMR) spectroscopic studies which investigate valinomycin conformation and ion binding in small bilayer vesicles.

Valinomycin is a cyclic 12-membered depsipeptide composed of D-valine, L-lactic acid, L-valine and D-hydroxyisovaleric acid with the structure [D-Val-L-Lac-L-Val-D-HyIv]$_3$. It is an interesting ionophore because of its ion binding selectivity. It is particularly suitable for the work reported here because its conformational states are now well understood, largely owing to extensive NMR[5–8], circular dichroism[6,9], and infrared[6,9] studies in solvents, X-ray diffraction studies of crystals[10,11], and conformational energy calculations[12,13]. The present studies in phospholipid bilayers were made possible by our recent synthesis of a perdeuterated phospholipid, dimyristoyl phosphatidylcholine (DMPC-d$_{72}$) (ref. 14). DMPC-d$_{72}$ has 99.0–99.7% replacement of ^{1}H by ^{2}H throughout the molecule. The corresponding reduction in the ^{1}H NMR background signal makes it possible to observe ^{1}H NMR spectra from small molecules which are incorporated into bilayer vesicles of the perdeuterated lipid[15].

DMPC-d$_{72}$ was synthesised according to Kingsley and Feigenson[14]. Valinomycin was dissolved in chloroform together with the phospholipid, and solvent removed under high vacuum. Small bilayer vesicles were prepared by sonication in ^2H_2O, or in a NaSCN solution in ^2H_2O having ionic activity of 2.25 M. Alkali cation titrations were performed by adding the thiocyanate salts to the vesicle samples. The exclusive location of the valinomycin within the bilayer and not in the water was determined by chromatography with Sepharose 4B. The valinomycin profile followed the phospholipid profile in both 50 mM NaHPO$_4$ buffer, *p*H 7, and in 3 M KSCN.

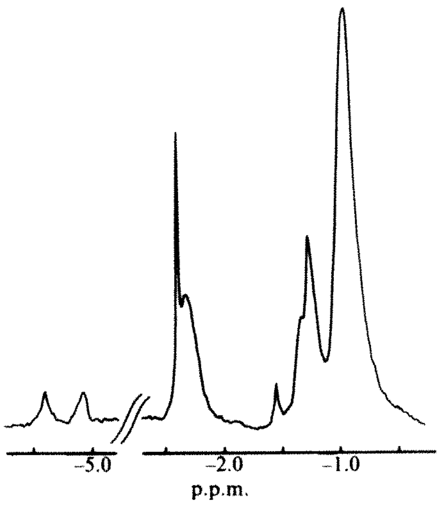

Fig. 1 360-MHz proton magnetic resonance spectrum of 3.1 mol % valinomycin in 11 mg ml^{-1} small sonicated bilayer vesicles of DMPC-d$_{72}$ with 50 mM NaHPO$_4$, *p*H 7, at 50 °C. Transients (48) were collected and a sensitivity enhancement corresponding to a 5-Hz linebroadening was applied. The peak assignments are as follows: −5.39 p.p.m., L-Lac $C_\alpha H$; −5.07 p.p.m., D-HyIv $C_\alpha H$; −2.38 p.p.m., CH_3 from trace tosylate impurity; −2.32 p.p.m., $C_\beta H$ from valinomycin plus residual lipid acyl $C^2_\alpha HH$; −1.55 p.p.m., residual lipid acyl $C^2_\beta HH$; −1.33 p.p.m., L-Lac CH_3; −1.27 p.p.m., residual lipid acyl $(C^2HH)_n$; −0.93 p.p.m., D-HyIv and D,L-Val CH_3.

Resonances from L-Lac and D-HyIv $C_\alpha H$ and CH_3, from D, L-Val CH_3 and from D, L-Val and D-HyIv $C_\beta H$ groups are well-resolved at 360 MHz for valinomycin incorporated into DMPC-d$_{72}$ vesicles in the absence of alkali cations (Fig. 1). Assignments are according to Ohnishi and Urry[5]. Chemical shifts are given in Table 1. The linewidths of 20–40 Hz for the valinomycin resonances, similar to the linewidths for the phospholipids or for other small molecules incorporated into small bilayer vesicles[15], imply considerable local molecular motion. The chemical shift values observed and the temperature dependence of these shifts are close to the values observed in non-polar organic solvents (see Table 1 and refs 8, 16). Spin–spin splitting could not be measured because of the linewidths of 20–40 Hz. This is unfortunate, as the Karplus-type relationship between the coupling constants and the molecular conformation is well-established for many peptides and for valinomycin in particular[8]. Instead, we used the empirical relationship between the observed chemical shifts for valinomycin and its molecular conformation[7,8,16]. Thus, the conformation of uncomplexed valinomycin in bilayer vesicles is the 'A$_2$ bracelet', with quasi-axial carbonyl groups, previously described for valinomycin in cyclohexane and in chloroform[8]. Because of this assignment of the conformation of uncomplexed valinomycin, it is reasonable

Table 1 Proton chemical shifts for valinomycin and its alkali cation complex at 50 °C

		Chemical shift				
Proton	Residue	Vesicles, uncomplexed	Vesicles, Rb^+ complex*	Cyclohexane, uncomplexed	Dimethysulphoxide, uncomplexed	Chloroform, K^+ complex†
$C_\alpha H$	L-Lac	5.34	5.04	5.31	5.09	4.90
	D-Hylv	5.04	4.61	5.03	4.82	4.55
	D-Val	4.16		4.03	4.26	3.74
	L-Val	4.03	3.72	3.91	4.36	3.85
$C_\beta H$	D, L-Val, D-Hylv	2.32	2.22	2.34	2.18	2.16
CH_3	L-Lac	1.36	1.55	1.36	1.28	1.51
CH_3	D, L-Val, D-Hylv	0.96	0.96	1.00	0.91	1.02

* Extrapolated values.
† Data from ref. 8.

to infer that the location of uncomplexed valinomycin is in a largely non-polar environment. Support for the inference that the predominant location of uncomplexed valinomycin is in the hydrocarbon region of the bilayer must await further investigation.

The chemical shifts of the L-Lac, L-Val, and D-Hylv $C_\alpha H$ and the L-Lac CH_3 can be followed up to high concentrations of added alkali salts, thereby describing a complete ion binding isotherm. The ion binding curves for Rb^+ are shown in Fig. 2. Similar results were obtained for K^+. Addition of up to 3M NaSCN caused no significant chemical shifts, in accordance with the extremely weak binding by valinomycin for this ion in aqueous systems[9,17]. The values for the limiting chemical shifts of L-Lac, L-Val, and D-Hylv $C_\alpha H$ and of L-Lac CH_3 resonances at high concentrations of K^+ or Rb^+ are very similar to the shifts observed in a variety of organic solvents for the fully complexed ionophore[8]. Thus we conclude that the solvent and the bilayer conformations of the fully alkali cation-complexed valinomycin are both of the 'bracelet' type, with carbonyl groups directed inward.

During the course of these titrations each resonance remains as a single peak, up to a shift of as much as 150 Hz for the D-Hylv $C_\alpha H$. Thus, complexed and uncomplexed valinomycin are in fast exchange on this time scale. Any steps in the mechanism of K^+ or Rb^+ binding or release by valinomycin must be significantly faster than $150\ s^{-1}$. Fast exchange for cation complexation has previously been measured for valinomycin in black lipid membranes[18]. This rate must apply to the transfer of the monovalent cations between water and valinomycin, a necessary step in the association. If the ion binding mechanism should also involve a change in the location of the uncomplexed valinomycin, for example from a position in the bilayer interior to a position near the aqueous interface, then this process too must be fast on this time scale. Note that for valinomycin in organic solvents the exchange rate between complexed and uncomplexed forms is slow on this time scale[19].

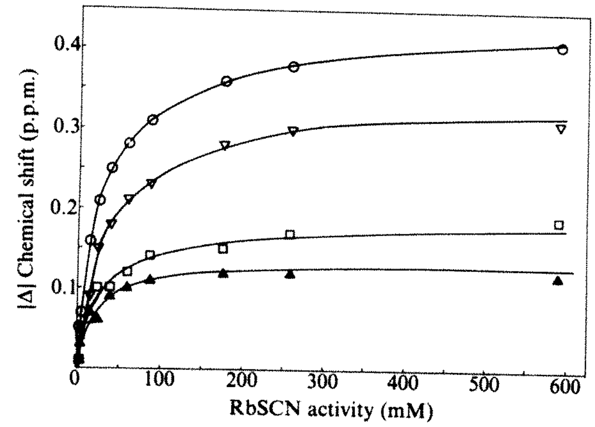

Fig. 2 Rb^+ binding curves for 3.1 mol % valinomycin in DMPC-d_{72} vesicles at 50 °C. The change in chemical shift is plotted against the activity of RbSCN. The activity coefficients used were those for KSCN (ref. 22). ○, D-Hylv $C_\alpha H$; ▽, L-Val $C_\alpha H$; □, L-Lac $C_\alpha H$; ▲, L-Lac CH_3. The sample contained the appropriate concentrations of NaSCN to keep the ionic activity constant throughout the titration.

The titration curves shown in Fig. 2 are hyperbolic, as would be expected for 1/1 binding. Thus this experiment shows no evidence of the formation of complexes of other stoichiometries[20]. When titration of valinomycin is performed by simply adding Rb^+ or K^+ salts to the vesicle suspension with no added NaSCN, thus allowing the cation activity to vary from 0.03 to 0.60 M, the observed chemical shifts were significantly smaller over the first half of the titration than are the shifts shown in Fig. 2. Therefore, any positive charge contributed to the vesicle surface by cation–valinomycin complexes must be more than offset by the adsorption of lipophilic thiocyanate anions in the experiments shown[21].

In conclusion, we have presented the first ^{1}HNMR studies of the conformations of valinomycin within a phospholipid bilayer. We find that uncomplexed valinomycin has a similar conformation in the bilayer and in non-polar organic solvents. Thus, the uncomplexed valinomycin molecule could be located predominantly in the interior of the bilayer. This conformation shifts on K^+ or Rb^+ binding to a structure which is characteristic of fully complexed valinomycin in many different solvents. Complexed and uncomplexed valinomycin are in fast exchange (rate $> 150\ s^{-1}$) throughought the observed range of alkali cation activities of 0.5–600 mM. Further work with this system is now directed toward determining the location and the dynamics of valinomycin in the phospholipid bilayer.

This research was supported by NIH grants HL 18255 and GM 25675. P.R.M. received support from NIH Research Service Award 5 T32 GMO7273. This work was carried out, in part, at Brookhaven National Laboratory under the auspices of the United States Department of Energy.

Elementary particle theory

R.H. Dalitz

An Introduction to Quarks and Partons. By F.E. Close. Pp.481. (Academic: London, New York and San Francisco, 1979.) £26.40; $54.50.

EVEN a decade ago, it was apparent that the proton and neutron, previously regarded as elementary constituents of the atomic nuclei, were actually composite. Very many excited states were known for them and many also for the hyperons and the mesons. The quantum numbers of these excited hadronic states formed definite patterns, recognised to correspond to a 'molecular model' for the hadrons, each baryon consisting of three of the quarks hypothesised by Gell-Mann and Zweig some years before, each meson consisting of a quark and an antiquark. Each pattern corresponded to a definite excitation of their internal spin and orbital motions. Independently, the data on deep-inelastic electron–nucleon scattering had shown rather directly that nucleons contained point-like particles, which Feynman termed 'partons'. With later experiments on deep-inelastic $\nu \rightarrow \mu^-$ and $\bar{\nu} \rightarrow \mu^+$ reactions on nucleons, these data showed that partons and quarks appeared to be identical, having the same spin, baryon number and charge values ($\frac{2}{3}$ and $-\frac{1}{3}$ times the proton charge). This quark–parton picture of the hadrons is now generally accepted.

The quarks are 'point-like' for distances down to 10^{-16} cm, at least, so that they are our present-day candidates for the title 'elementary particles'. However, quarks come in a number of kinds, with differing attributes, known as 'flavours'. There are $N = 5$ flavours established today, the corresponding quarks being labelled u,d,s,c and b, in order of mass, and the discovery of further flavours is expected. The experiments also showed that nucleons contain neutral objects; these are now believed to be the quanta of a 'gluon field' which binds the quarks and antiquarks into the hadron. Finally, in order to give the patterns observed, the Pauli principle required that each quark have three possible states, each now labelled by a colour, and each indistinguishable through the hadronic, electromagnetic and weak interactions we know. This corresponds to an exact 'colour symmetry' and we now believe that the gluon field may be the gauge field for 'colour', just as the photon field is the gauge field for charge. This gauge theory is now known as quantum chromodynamics (QCD). It is a tightly constrained theory, almost unique in form, and it is the theory at the centre of attention today.

Following QCD, elementary particle theory is now undergoing rapid changes and our views today differ greatly from those when this book was finalised. Nevertheless, the book will be much welcomed, especially by students, for it is the only recent introduction available at book length. It does not proceed to expound the subject deductively, from basic principles, but is better described as a discursive review surveying the state of the art in this field of physics in mid-1978. It tends to give results without derivation, although then analysing the result to give some intuitive understanding of its origin and meaning, a procedure having great value for any isolated reader.

Following a brief introduction to set the scene, the book consists of three parts. The first part begins with SU(N) symmetries for N quark flavours, initially for $N = 2$ and then for $N = 3$. This SU(3) symmetry is then extended to an SU(6) symmetry in the space $SU(3) \times SU(2)_\delta$, where δ denotes Pauli spin. In this framework the quark model classifies hadrons according to the product group $SU(6) \times O(3)$. Since Pauli spin is nonrelativistic, this classification cannot refer to a fundamental symmetry; its use today is motivated only by the quark model and is for convenience, allowing the systematic procedures of group theory to be used for economic calculation and tabulation. In general, the observed hadrons correspond to mixed representations of $SU(6) \times O(3)$. The matrix-elements, for the most important transitions, are shown to correspond to the group $SU(6)_W$, so its algebra is discussed in considerable detail, making the usual distinction between SU(6) for currents and SU(6) for hadron constituents and leading to the general Melosh expression for electromagnetic transition amplitudes. Various selection rules are noted, compared with the data and analysed to show how they work. For hadronic decay processes, the transition 'Vacuum $\rightarrow$ $^3P_0(\bar{q}q)$' is introduced, and the resulting amplitudes are related with $SU(6)_W$. Some review is given of attempts to include relativistic effects in quark-model calculations.

The second part is devoted to partons and their phenomenology. The notion of levels of scaling is introduced, and traced (for inelastic electron scattering) from the nuclear to the quark–parton level. The parton distributions in nucleons are deduced from the various leptonic deep-inelastic reaction data and discussed in considerable detail, bringing out their connection with simple field theories. There are brief discussions of scale invariance in electron–positron annihilation at high energies, of neutral currents appropriate to the unified electromagnetic-weak interaction, and of the observed scaling violations, now believed to reflect asymptotic freedom for the underlying field theory. The parton model is extended by introducing quark fragmentation functions, used to analyse and predict hadron spectra and their angular dependence in various high-energy reactions. This leads on to a discussion of large momentum-transfer phenomena in hadron–hadron collisions and to quark counting rules for their asymptotic forms. Specific models such as 'Drell-Yan' and 'constituent-interchange', are introduced and compared with the data.

The third part first sketches briefly the electromagnetic-weak and QCD gauge theories, analysing the qualitative features of the one-gluon-exchange potential between quarks. The major topic is the charmed quark c and its role in the 'new particles', such as the ψ/J and ψ' mesons discovered in 1974, and the D and F mesons established subsequently. Quite a detailed discussion is given of the bound states of Charmonium (c-$\bar{c}$), the 'hydrogen atom' of the 'new particle' physics; all of its properties are well accounted for by QCD, assuming that this can be shown to imply confinement. The heaviness of the c quark (about 1.5 proton masses) justifies a nonrelativistic Schrodinger treatment and the hyperfine structure of the spectrum arises from the one-gluon-exchange potential. Electric dipole γ-transitions occur between its S and P states with rates in accord with these Schrodinger calculations. The long lifetimes of the ψ/J and ψ' states are due to the asymptotic freedom of QCD. The one-gluon-exchange potential and the quark masses are then used to account for all of the mass splittings between and within the various charge multiplets observed within particular $SU(6) \times O(3)$ mesonic and baryonic supermultiplets. There are also chapters dealing with the 'bag model' for hadrons and the possibility of bound multiquark systems. The former is entitled "Quarks confined to a sphere"; despite its very general formulation, the bag model program has been implemented to date only for the case with a rigid spherical bag. The book closes with gauge theories for 'grand unification', where quarks and leptons are assigned to common multiplets and the lepto-quark gauge fields are extraordinarily heavy, with masses of the order of 10^{-10}g. These theories mostly imply that the proton should decay spontaneously (for example, to $e^+ + \pi^0$) and have led to a number of experimental proposals to push up the present limit ($\gtrsim 10^{30}$ years) on the proton lifetime.

This is a book for the quark-model practitioner. It gives all the prescriptions and rules; they are analysed thoroughly but are not always derived (nor even necessarily all consistent). It says something about every idea current today, although some in much more detail than others. The book is somewhat uneven in its treatment, being strongest and most detailed in the areas where the author's own contributions lie (photo-excitation of excited baryons and polarised lepton–hadron interactions). It also has a somewhat dated air, since our picture of elementary particle physics has been changing rapidly. It is now a general belief that the quarks (u,d) are almost massless, whereas most hadron spectroscopy still assumes non-relativistic motion for the quarks in hadrons. The SU(N) symmetries discussed here are now considered accidental, the true symmetry being the flavour independence of quark–gluon interactions, violated only by the quark mass values. Little is said about 'confinement', the central unresolved question for QCD; indeed, the book says rather little about QCD, beyond implications of the one-gluon-exchange potentials. The book has come too soon to include the recent developments in baryon spectroscopy due to Isgur and Karl, which have brought much order concerning Λ^* and Σ^* states. It would have greater value for students today if it had more about the fundamentals and applications of gauge theories, especially for QCD, since the book would then have appeared forward-looking; its present emphasis is on theoretical aspects from the past, which may be expected to change in the near future. But this is perhaps the fate of any book in this field of physics, where exploration is moving fast; it is easy and unfair to make this judgement in retrospect. There is no doubt that every physics library should possess this book, for there is much to be found on its pages which it is not easy to find elsewhere. ☐

Chondrocytes and their matrix

F.N. Ghadially

Biology of Cartilage Cells. By R.A. Stockwell. Pp.329. (Cambridge University Press: London, New York and Melbourne, 1979.) £25.

THIS book is a welcome addition to the literature on cartilage. It is not a book about the chondrocyte only, as the title might lead one to believe; quite detailed accounts of the morphology and chemistry of various components of the matrix are included as well as other topics such as the nutrition and permeability of cartilage and the nature of the articular surface. All this is successfully accomplished in what the author modestly refers to as a "short book", but the concise style of writing has permitted the inclusion of a volume of factual data which one usually associates with much larger works. The well selected references and a carefully prepared index enhance the value of this work.

It is difficult to fault the text in any major respect. The photomicrographs are rather small in size but of good quality; the same, however, cannot be said of the electron micrographs, which are of a variable quality. In contrast to this the line drawings are superb, and the graphs and tables are well planned and informative.

The book begins (chapter 1) with a brief description of the morphological and chemical differences between various types of cartilage. Chapter 2 gives an adequate account of the ultrastructural morphology of the chondrocyte, the effect of hormones on the chondrocyte and the antigenicity of chondrocytes. Chapter 3 deals with the morphology and chemistry of the matrix components. In this excellent chapter we are treated to quite a detailed account of collagen structure and synthesis, elastic fibres and elastogenesis, and the structure of proteoglycans. However, the morphology of proteoglycans (that is, matrix particles) is barely discernible in the electron micrographs presented. Chapters 4 and 5 deal with the metabolism and nutrition of chondrocytes. Chapters 6 and 7 deal with chrondrocyte differentiation and proliferation. The book ends (chapter 8) with a discourse on degenerative changes, age — associated changes, and a section on calcification in which an up-to-date account of matrix vesicles and their role in cartilage calcification is presented.

In summary, this book provides a brief review of existing knowledge about the chondrocyte and surrounding matrix. It is up to date, well written and packed with factual data. In my opinion this book should be of value not only to research workers as suggested by the author, but also to rheumatologists, orthopaedic surgeons and postgraduate students (residents) interested in cartilage.

Primary energy resources

D.O. Hall

Biological Energy Resources. By M. Slesser and C. Lewis. Pp.192. (E. & F. N.Spon: London, 1979.) £8.50.

TODAY about one-seventh (or possibly more) of the world's primary energy is derived from biomass — this is equivalent to 19 million barrels of oil a day (which is twice the Saudi Arabian oil production and equal to the US daily oil use). However, because most of this biomass energy use occurs in the developing countries (and there predominantly in rural areas) and because it seldom enters the official statistics, it has, until recently, been virtually ignored by planners, politicians and aid agencies alike. A combination of the "energy crisis" and desertification problems has focussed the attention of both developing and developed countries on the importance and potential of 'biological energy resources'.

This aptly titled book is a must for anyone interested in the basics of bioenergy and its conversion, and more especially in the energetics and economics of biomass systems. The concepts of energy ratios, net energy yield, net utilisable energy production, and gross energy requirement are well presented, and a number of case studies are thoroughly discussed. It is clearly pointed out that intensification of natural ecosystems for biomass energy requires both capital inputs and better management — but local industry, skills and energy self-reliance can be built up. Such energy systems are applicable to varying extents in diverse conditions around the world and must be tailored to suit local conditions.

The chapter on economics of biomass systems touches on net present value, energy payback times, and economic costings. It considers some specific examples like ethanol production and biogas generation, and compares costs with other energy sources. These costs are changing so rapidly it seems imperative to update one's analyses and comparisons annually to take account of accelerating costs.

It is a good book and very timely. But please could authors and/or publishers try to list references that can be traced — conference proceedings references are useless unless the accurate source is given and organizations who publish booklets, and so on, have their addresses given. In such a rapidly developing field with wide sources of interest it is important to be able to trace the information. ☐

Grassland ecology

Peter D. Moore

Grassland Ecosystems of the World. (International Biological Programme, 18.) Edited by R.T. Coupland. Pp. 401. (Cambridge University Press: Cambridge, 1979.) £25. *Perspectives in Grassland Ecology: Results and Applications of the US/IBP Grassland Biome Study.* Edited by Norman R. French. Pp. 204. (Springer: New York, Heidelberg and Berlin, 1979.) DM54; $29.70.

SOME thirteen years after the initiation of the International Biological Programme for the collection of information concerning the productivity of the world's biomes, the publication of the accumulated data is gaining momentum. The book books reviewed here are concerned with grassland ecosystems; the first (edited by Coupland) is a condensed comparative synthesis of information from various sites around the world, and the second (edited by French) is a more detailed set of papers from the United States IBP grassland team.

In some areas of the world grassland is believed to represent the climax vegetation type, existing as a response to climate, soil, natural grazing or fire. In other regions, grasslands have developed as a result of human management practices. Often it is difficult to distinguish the two with certainty. In Coupland's book, grasslands are divided initially into climatically determined types and those actually sown and managed by man. Then, within the climatic subdivision, natural and semi-natural grasslands are distinguished — the latter being exploited by man either for hay crops or for grazing.

Each type is dealt with in a separate section subdivided into chapters concerning primary production, consumer organisms, microorganisms, ecosystem synthesis and modelling, nutrient cycling, and the exploitation, management and conservation of grassland systems. This arrangement is particularly valuable, as it permits an easy cross-reference from one section to another. It makes it simple, for example, to check back from tabulations of the efficiency of energy capture in Indian grasslands to equivalent data in a similarly constructed table for prairie systems in the United States.

This facility reflects creditably upon those responsible for the design of the volume and upon the editor, who has ensured a uniformity of expression and presentation which greatly aids those who wish to obtain comparative figures with ease. This must be regarded as the primary function of a book like this one, which seeks to present a global collation of IBP grassland data.

Perhaps a surprising inclusion in the book is a section on croplands, reviewing gramineous agroecosystems. Sadly, this is the least informative section, containing many casual pieces of information in a generally uncoordinated manner. It is largely derived from data emerging from the Polish Agroecological Station at Turew, Poland, but really a wider synthesis of world literature is necessary if this were to be a useful discussion.

Coupland concludes the volume by attempting to make generalisations concerning the structure and production of grasslands. This is a formidable task and tends to take the form of a summary of the range of variation found within grasslands of different types. It is useful mainly in that it identifies those areas of study which need further attention, such as the role of fire in grassland management.

Perspectives in Grassland Ecology, edited by N. French, is more limited in its geographical coverage, being solely concerned with the US grasslands, but it is far more diverse in its structure. It is essentially a series of independant papers concerning grassland studies in North America. Some, such as Lauenroth's paper on grassland primary production, are attempts to review areas of grassland study and to place them in their wider context. Others are concerned with very specific research topics, such as Detling's study of the factors controlling the productivity of the C4 grass ***Bouteloua gracilis*** in mixed grassland in Colorado.

The collection of papers deals with a range of topics, many of which will be of interest to ecologists in general, such as the role of stress in grassland ecology (Dodd and Lauenroth), biomass trophic pyramid structure in grasslands (French, Steinhorst and Swift) and nitrogen input and output (Woodmansee). Finally there is a series of papers concerning ecosystem modelling in grasslands and its value in management studies.

The two books are thus very different in approach. Both supply valuable sources of information and current ideas in the field of grassland ecology. ☐

Particle transport processes

W.A. Wakeham

Transport Theory. By J.J. Duderstadt and W.R. Martin. Pp.613. (Wiley: New York and Chichester, UK, 1979.) £24.

THE study of particle transport processes in a wide variety of fields has been a growing area of activity for a number of years. Inevitably, the developments in the various fields have been largely independent and the underlying similarity of the governing equations for particle transport has been somewhat neglected. This book continues and enhances the modern trend of providing a common basis and methodology for the study of all transport processes and brings together an armoury of techniques for the solution of transport problems.

The fundamental proposition of the book is that transport theory is the mathematical discipline associated with the solution of transport equations. This restricted, but valid, view leads to a volume which is more suited to applied mathematicians than to physicists or engineers. The essential physics of any transport problem is the derivation of a kinetic equation for the problem, the evaluation of the various scattering cross-sections and a statement of the boundary conditions. Of these, only the derivation of kinetic equations is given significant attention in this book. However, the familiar Boltzmann, Fokker–Planck and Vlasov transport equations are obtained with minimum fuss and a short description of the projection operator methods for the derivation of more general transport equations is included. The relationships between the kinetic equations, continuum theory and non-equilibrium statistical mechanics are given a careful and useful exposition.

The elegant mathematical techniques for the solution of transport equations in the integro-differential or integral form, which make up the essence of the book, are well presented. First the simplest transport equations for idealised non-scattering single energy systems are solved and then several more complicated problems are attacked. The necessary mathematical tools are generally developed as required, but a potential reader should already be well versed in integral transforms, boundary value problems and complex variable analysis before attempting the book. Otherwise the treatment of integral equations will be insufficient and the "Child's Primer on the Spectral Theory of Operators", provided in an appendix, will remain obscure. The tool kit for the solution of transport problems is completed by a discussion of numerical methods including finite element techniques and the Monte Carlo simulation methods.

The full battery of mathematical tools is unfortunately applied to very few practical examples in a few problems surprisingly included at the end of every chapter. It is rather as if, when training a mechanic, the theory of a screwdriver was carefully explained but he was never required to use the device to undo a screw. As a practical scientist I found this aspect of the book disappointing since the fields to which transport theory can be applied range from the important subject of neutron distributions in nuclear reactors through light propagation in stellar atmospheres to vehicular traffic flow.

However, the book is written with sufficient humour and insight to lift it above the level of a mere compendium of mathematical methods. In any event, no scientist interested in more than a phenomenological description of particle transport should be without this volume.

W.A. Wakeham is a Lecturer in the Chemical Physics of Transport Processes in the Department of Chemical Engineering, Imperial College, London, UK.

Signal processing

P.W. Hawkes

An Introduction to Statistical Signal Processing, with Applications. By M.D. Srinath and P.K. Rajasekaran. Pp.499. (Wiley: New York and Chichester, UK, 1979.) £18.30. *Digital Signal Processing and Control and Estimation Theory: Points of Tangency, Areas of Intersection, and Parallel Directions.* By A.S. Willsky. Pp.256. (MIT Press: Cambridge, Massachusetts, and London, 1979.) $22.50; £13.50.

THERE are already numerous introductory textbooks on signal processing but the temptation to turn their lecture notes into a textbook continues to be found irresistible by some university lectures. Furthermore, in such a subject, which is expanding into new areas, there is always some fresh application to mention that was not covered in earlier texts. The first of these two volumes is just such a book; it arose from various courses of lectures in the Southern Methodist University (Dallas) and two Indian institutes, and covers detection and estimation theory in commucations, radar, pattern recognition and system identification. It is a competent if uninspired work, clearly written for the most part though rather pedestrian in tone, and contains many worked examples, for which students will be grateful. Although it is described by the authors as a graduate text, much of the material is taught at undergraduate level in British universities, and for this audience, the book is probably too detailed: lecturers and students alike will probably find that their preferred text on signal processing, supplemented by a volume on two-dimensional questions in general (pattern recognition, image processing and the like), is more suitable.

Willsky's book is a very different matter. The author is a control theorist who was struck by the fact that work in digital processing and in control and estimation theory has a great deal in common, as well as certain clear differences that are themselves illuminating. There is no doubt that these two groups of subjects have much to offer one another and the author explores a range of topics from both points of view.

This kind of book is in the best sense a piece of self-indulgence on the part of the author, a leisurely examination of difficult problems and unsolved questions by a wide-ranging mind, not under any immediate compulsion to provide solutions. The result is an enjoyable and stimulating book, easy to read despite the advanced nature of the contents although the reader is expected to be familiar with the vocabulary, verbal and mathematical, of the subject. There are five main chapters, concerned with (1) the analysis of stability, (2) parameter identification and related topics, (3) synthesis, realization and implementation, (4) multiparameter systems, distributed processes and random fields, and (5) nonlinear system analysis.

The flavour of the text is well illustrated by the opening remarks of the chapter on multiparameter systems, which is much concerned with image processing: "This area is rich in both potential applications and challenging theoretical problems . . . How does one process distributed data efficiently? What properties do recursive techniques have when the recursion is in more than one dimension? Do causality and state make any sense here? What about stability? What are the tools for analyzing stochastic processes? How do we "predict" when time is not the independent variable? What role do recursive estimation techniques play? What are recursive estimation techniques? Which concepts concerning signals and systems in one independent variable carry over to the multiparameter case? Which do not, and why don't they?". Altogether an interesting and provocative book.

P. W. Hawkes is Maître de Recherche in the Laboratoire d'Optique Electronique du CNRS, Toulouse, France.

Curing Europe's biological death-wish

LAST WEEK an apparently European firm, Biogen, incorporated in Luxembourg and with a laboratory in Geneva, announced that it has successfully engineered *Escherichia coli* to produce interferon — currently touted both as an anti-viral and as an anti-cancer agent, after some small trials have shown remissions; larger trials are on the way. So does Europe rejoice at its technological breakthrough?

Unfortunately not, for Biogen stockholdings are held almost exclusively in North America. The major exceptions are the seven European scientists involved; with two Americans, the scientists hold one third of the stock. The largest individual stockholder is International Nickel, a Canadian-based mineral company, with the drug firm Schering-Plough — which has bought the international licence to exploit the Biogen creation — in second place. A handful of other bodies have holdings of under 10%. Hence the remark of Charles Weissman, who co-engineered the interferon-producing bug, quoted in this issue (page 323), that it was a shame that European industry had not taken greater interest in Biogen. Apparently those who were forming the company approached a number of firms in Europe, particulary in Switzerland and West Germany — but none was interested in a share in the business.

The fault, then, was doubly Europe's: first, it was a fault not to attempt to draw on its own potential bioengineers through its own 'Biogen' — noone was adventurous enough to set it up, though many had the idea; and second, it was a fault to ignore a ready-made opportunity — Biogen itself — when it was offered.

Furthermore in the UK a number of scientists have been attempting for three years to interest venture capital and the government in a British contract research organisation, akin to Biogen, to no avail. Some who were active in that attempt are now members of Biogen. The National Research Development Corporation, which might be expected to take a lead in such matters, seems content merely to exploit. Whereas four of six major revenue-earners are biotechnical, its past and present biological development projects are outnumbered by the non-biological 10:1.

Neither do European politicians have much to praise each other about. When it began to be possible to make high fructose syrup economically from maize starch using immobilised enzymes, the Council of Ministers of the European Community — the highest and most political authority — slapped a punitive levy on the process, killing its development (which was already underway in Britain), in the name of protecting beet growers.

No wonder that a draft version of the forthcoming Royal Society report on biotechnology recommends that Europe puts its house in order. Biotechnology must not invite penal levies, says the draft, merely because Community policy is in the grip of interests which "resist the cheaper and better products of this new technology, particularly where these threaten to perturb existing patterns of agriculture". Common Agricultural Policy legislation which threatens biotechnology must be revised; and arrangements reached whereby agricultural surpluses can be turned to good use as biotechnical feedstocks.

In this and other ways the report is a strong blast of good sense which the British government — and the Community — would do well to respect. Recession, when individual firms are without the funds to invest, is exactly the moment when governments can move in legitimately to pick up the bill for long-term, strategic research. This also happens to be exactly the moment when technology is finding a new lease of life, through microcircuits and now biotechnology. The nations which will dominate the economics of the 21st century will be the ones that have invested in the new ideas — the ones that have the new processes underway and the new talent in their industries. Engineered bugs and microchips will be the coalfields of the next century: and they are not to be found, but created.

Two great opportunities are shortly to be forthcoming in biotechnology: the £16 million research programme proposed for the EEC which the European Commission should not foolhardily reject; and the recommendations of what will, we hope, be a not too diluted version of the draft report we describe this week (page 324). Europe and the UK must embrace both of them. □

United States

Regulators loosen up on carcinogen standards

Labour unions and the chemical industry have locked the US Occupational Safety and Health Administration in a dispute over translating carcinogenicity data into appropriate regulatory controls. **David Dickson** reports

LAST week Dr Eula Bingham, head of the US Department of Labour's Occupational Safety and Health Administration (OSHA), unveiled the final version of the agency's new scheme to identify and regulate carcinogens in the industrial workplace.

The scheme was orginally proposed more than two years ago as a way of streamlining the regulation of cancer-causing substances. The intention was to set out broad criteria for deciding how to deal with certain types of data in determining whether a substance is carcinogenic. Mr Ray Marshall, Secretary for Labour, has hailed it as a "landmark policy" and a "tremendous step forward" in protecting workers from cancer.

But in attempting to find a position that fulfils OSHA's congressional mandate while also minimising its vulnerability to the inevitable legal challenges, the agency has loosened some of its original proposals, adding the criticism of labour unions to that of the chemical industry.

The industry, while pleased with some of the new flexibility, remains unhappy with the scheme. And the American Industrial Health Council (AIHC) , representing a number of leading chemical companies such as Dow Chemical and Monsanto, has already asked a federal appeal court to review the regulations, claiming that they "lack scientific validity" and impose an unreasonable economic burden.

But OSHA is now facing opposition from one of its previous supporters, the American Federation of Labour — Conference of Industrial Organisations (AFL-CIO), which has filed its own suit in the District of Columbia, claiming that by relaxing some "cornerstone" provisions the agency has weakened the scheme's effectiveness.

In broad outline, OSHA's new policy for regulating potential suspected carcinogens (see box for definition) is comparable with that first suggested in 1977. In particular, the agency has stuck to its proposal to place suspected carcinogens in two principal categories. The first contains substances for which there is good scientific evidence of carcinogenicity; exposure to such substances is to be reduced to lowest feasible levels, or eliminated if substitutes can be found. The second category contains substances for which there is "suggestive" evidence of carcinogenicity.

As previously, OSHA states that, in evaluating claims of carcinogenicity, it will not accept a 'threshold' hypothesis, and will still give greater weight to positive animal studies showing evidence of carcinogenicity than to 'non-positive' human studies showing no such evidence.

However the agency has shifted from laying down strict, formal criteria for making such assessments, to relying more on the judgment of scientists, in particular through the use of scientific review panels.

Thus several alterations have been made in the criteria used to classify a substance as belonging to category 1. For example, it was originally proposed that a substance could be included in this category if it was shown to be carcinogenic in one animal bioassay, the results of which were subsequently replicated.

OSHA received various objections to this criterion, some claiming that at least two animal tests were necessary, others that a single, well-conducted test should suffice, and that to require replication or confirmation would unreasonably delay regulatory action.

Responding to these criticisms, OSHA has agreed to amend its criteria so that now a substance can meet the definition of a potential term bioassay "where the results are in concordance with some other scientifically evaluated evidence of a potential carcinogenic hazard" or in a single mammalian species "in which the secretary determines the requirement for concordance evidence is not necessary".

A 'potential suspected carcinogen':

Any substance, or combination or mixture of substances, which causes an increased incidence of benign and/or malignant neoplasms in humans or in one or more experimental mammalian species, or a substantial decrease in the latency period between exposure and onset of neoplasms in humans or in one or more experimental mammalian species as the result of any oral, respiratory or dermal exposure, or any other exposure which results in the induction of a tumour at a site other than the site of administration.

A positive result in a short-term test would be:

Positive results in assays for two or more of the following type of effect:

- The induction of DNA damage and/or repair
- Mutagenesis in bacteria, yeast, *Neurospora* or *Drosophila melangaster*
- Mutagensis in mammalian somatic cells
- Mutagenesis in mammalian germinal cells
- Neoplastic transformation of mammalian cells in culture.

Evidence of 'concordance' may include positive results from testing in the same or other species; or positive results in short-term tests (OSHA has reaffirmed its previous position that such tests can be used to confirm, but not to substitute for, bioassay data, claiming much of the criticism of these tests to be "unsubstantiated"); or the induction of tumours at injection or implantation sites (despite protests from industry, OSHA has again refused to distinguish between malignant and non-malignant tumours as evidence).

In contrast to its earlier proposal, OSHA has decided to drop two further classificatory proposals, one covering substances for which there was a suspicion, but no hard evidence, of carcinogenicity, and the other for substances not occuring in US workplaces.

More controversially, the agency has also decided that preliminary classification in category 1 will not, as previously proposed, automatically require the Secretary of Labour to issue an 'emergency temporary standard' requiring companies using the substance in question to reduce exposure to lowest feasible levels, at least until firm regulations have been established.

Rather, OSHA will publish at the beginning of each year a list of potential candidates for each category. Preliminary estimates indicate that there could be about 150 chemicals in category 1 and 350 in category 2. Every six months OSHA will then select about ten substances from each category for priority attention, with the Secretary of Labour having the power to impose emergency standards if he felt that the chemical poses a "grave danger" and that such a standard is needed.

This added flexibility has angered the labour unions, strong supportors of automatic standards for category 1 substances. OSHA points out that it may lack the legal powers to carry out such a policy — and officials add that if OSHA did introduce such a rigid ruling, there might be a reluctance to place substances into this category because of legal challenges.

But the AFL-CIO is disputing this, complaining that by dropping what it calls "indispensable provision", OSHA has removed the "cornerstone" of its cancer policy, in conflict with the requirements of the Occupational Safety and Health Act of 1970 requiring it to take all steps necessary

0028-0836/80/04320-02$01.00

to protect the health of US workers.

The chemical industry has, in general, welcomed the new flexibility in the rules — although it still considers them to be too harsh. For example industry rejects OSHA's criteria for accepting epidemiological evidence of non-carcinogenicity.

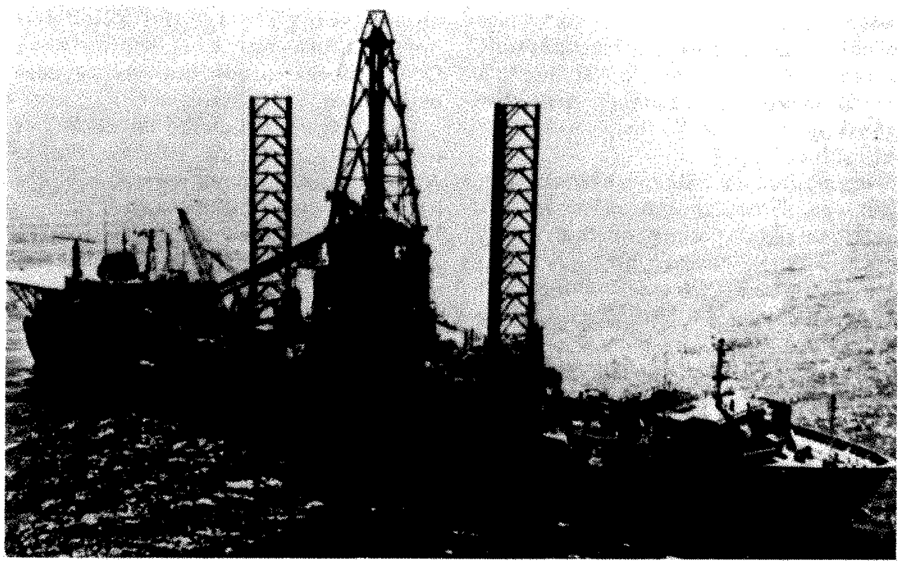
And the industry remains critical of the costs. Dr Bingham, in presenting the new scheme — scheduled to be published this week in the *Federal Register* — said that some studies now showed that the costs of cancer exceeded $15 billion a year.

But she repeated the agency's opposition to using cost-benefit analysis in its rulemaking rather than restricting itself to calculations of economic feasibility. Allegations that OSHA was trying to create a "risk-free" environment, regardless of cost, "conveniently overlook that Congress charged OSHA with protecting workers to the extent feasible" she said.

But the industry is not convinced. Significantly the AIHC has chosen to file a suit requesting federal review of the new regulations with the fifth circuit court of appeals in New Orleans. It was this court which, two years ago, rejected OSHA's proposed new benzene exposure standards on the grounds that the agency had used cost-benefit techniques in reaching its conclusions. The case is now before the Supreme Court for final arbitration. A decision against OSHA could have a devastating effect on OSHA's effectiveness. □

US to announce $700 million ocean-drilling research programme

In a unique experiment in cooperation with private industry, writes **David Dickson**, the US government and leading oil companies are about to announce plans for sharing the costs of a 10-year research programme to investigate the Earth's continent margins



Glomar Explorer: to be made use of in the new programme

WHEN President Carter presents his 1981 budget proposals to the US Congress next Monday, he is expected to include plans for one of the biggest and most ambitious research projects ever sponsored by the National Science Foundation: a 10-year programme to investigate the geology of the ocean floor.

The programme offers potential payoffs both in terms of increasing understanding of the history and dynamics of the Earth's crust, and of assessing the exploitable resources — in particular ore and hydrocarbon deposits — which the crust contains.

And in a unique arrangement largely credited to the President's science adviser, Dr Frank Press, the estimated $700 million costs of the programme are to be shared equally by the federal government and private oil companies.

Final details of the agreements are yet to be reached. But it is understood that at least eight companies have agreed in principle to participate in the scheme. Several others have indicated their interest.

At a later stage, it is also intended that the programme will include the participation of research teams from other countries. Britain, France, West Germany, Japan and the Soviet Union each contribute $1 million to the NSF's current deep-sea mining programmes, and several have expressed interest in participation in the new project, as have Canada, Mexico and Australia.

Speaking at the Woods Hole Oceanographic Institution in Boston, Massachusetts, last week, Dr Press said that the administration intends to make use of the ship Glomar Explorer for the ocean drilling project. Originally built by the Central Intelligence Agency to attempt to retrieve a Soviet submarine from the Pacific floor, the vessel has more recently been used by private corporations for investigating the potential of sea-bed minerals. It is considered almost ideal for the type of operation currently envisaged.

The idea of using the Glomar Explorer for ocean-floor drilling has been actively discussed in the geological research community for several years, especially since interest has focused on the ocean margins, the zone between the continental shelf and the deep ocean basin.

For the past 12 years, the NSF has supported a major deep-sea drilling project from the smaller Glomar Challenger. But although the 'challenger' has produced much important science, leading to increased understanding of plate tectonics and other geological processes, it has been limited in its scope.

In particular, the Challenger lacks the equipment to prevent a blow-out should it hit a pocket of pressurised oil or natural gas during experimental drilling. This has restricted its ability to investigate the continental margins, since it is in these regions that such pockets are likely to occur, rather than in the central ocean basin.

To explore such regions, while at the same time minimising the potential danger resulting from a blow-out, drilling will have to be carried out with the aid of a 'riser' — a protective shell surrounding the drill — as well as other appropriate preventitive equipment.

The general desirability of a large-scale programme of ocean drilling has been supported by various groups who have studied the idea, in particular by a special committee of the Joint Oceanographic Institutions for Deep Earth Sampling (JOIDES) whose report on the matter was issued in 1977.

Further reports prepared for the NSF endorsed the scientific importance of a deep-sea drilling project, designed to reach the ocean floor at a depth up to 4,000 metres and drill 7,000 metres below that, and indicated that such a programme was technically feasible, with the use of the Glomar Explorer as the most promising platform to drill from.

In order to study the overall importance of the programme in the context of national scientific priorities — a move requested by Congress in reviewing the Foundation's 1979 budget request — the NSF established a top-level committee under Dr Guyford Stever which recommended last summer that ocean

0028-0836/80/04321-02$01.00

margin drilling "should be given high priority consideration for approval" in the NSF's 1981 budget.

The report also supported moves to gain support from private corporations in the US. This strategy has been actively canvassed by the Office of Science and Technology Policy, which Dr Press directs. And although corporate involvement had been objected to by some scientists on the grounds that it could steer the project away from basic research priorities, it soon became clear that the financial climate would not support the project on federal funds alone.

Last autumn both Dr Press and Dr Richard Atkinson, Director of the NSF, spent considerable time and effort talking to the heads of major US oil companies soliciting their support. The reactions were generally favourable, and in response to a formal approach, a number have now agreed in principle to help match the federal funding.

Negotiations have at times been delicate, given in particular the price sector's traditional reluctance to cooperate directly with the federal government, rather than on a contract basis. And various measures have been discussed to make the deal more attractive.

For example, it is expected that companies will not, at this stage, be required to commit themselves for the full ten years, but will have the option of pulling out after one year or after five years. It is also likely that the first location chosen for investigation will be off the North Atlantic coast of the US, an area of interest to the petroleum companies.

Details of how the scientific programme will be organised are also under discussion. One likely arrangement is that the scientific efforts will be coordinated by the Joint Oceanographic Institutions Inc, a consortium of nine institutions involved in oceanographic research. There would also be three policy review boards, one established by the National Academy of Sciences, one by the Department of Defense, and one by various private institutions and corporations.

Total funding request for the next financial year is expected to be about $20 million, half coming from the NSF — whose total deep-sea drilling budget would increase from $18 million to about $32 million, and half from the oil companies.

So far, despite some reservations about the corporate involvement, the reaction of most geologists to the scientific opportunities has been enthusiastic. Congressional reaction, however, has been more mixed.

Representative Edward Boland, for example, Chairman of the House Appropriations Committee responsible for the NSF budget, has already written to President Carter urging full support for the project. But others are more sceptical, one congressional staff member pointing out that the cost per hole will be at least an order of magnitude greater than with the Challenger.

But the administration is convinced that it is sufficiently important to merit substantial support. "This will be an important scientific venture with possible implications for future resource discovery" said Dr Press. "We believe it is also a good example of government-industry cooperation, the kind of cooperation that we must see more of, in more fields, in the coming years". ☐

Laser fusion project to be halted?

PRESIDENT Carter is expected to recommend to Congress next week a halt to construction work on the $200 million Nova laser fusion project, which began last year at the University of California's Lawrence Livermore Laboratory as a successor to the Shiva system first operated in 1978.

Administration officials in Washington confirmed last week a story appearing in the *Washington Post* which claimed that the Office of Management and Budget had recommended that funding for Nova be dropped from the President's budget request for the fiscal year 1981.

The agency is said to have been concerned partly about the cost of the project, and partly about growing uncertainties about whether glass laser technology can meet the efficiency of a commercially viable source of power.

Congress authorised $23 million for Nova in 1979 — and a further $56 million for 1980. The foundations for the new machine are currently being laid near Shiva.

A number of recent reports, however, have indicated that the project should be slowed until more is known of the physics of laser/pellet interaction, and of the engineering problems involved.

Officials at Lawrence Livermore are making no public comment until the final budget is published next week. But if funding for Nova is dropped, this is likely to be firmly resisted by the armed services committees in both houses of Congress, which support laser fusion research on account of its potential military applications.

Soviet Union

Science planners and the Press tackle the 'two cultures'

SOVIET science planners have taken up the "two cultures" controversy of CP Snow. A new Press "discussion", launched last week by the prestigious *Literatunaya Gazeta* will deal with the falling popularity of the applied sciences and its possible effect on the Soviet economy.

The new campaign, which will include expert articles and readers comments, is entitled "Applied science; prestige and people". It is intended to look into the factors hindering the implementation in production practice of new scientific results. This is not a new theme — the slow rate of implementation of R&D into industry has for some years been a recurrent complaint of planners and Party leaders alike.

Recently, however, the problem has been seen in a somewhat wider context. In December 1979, Moscow radio put out a Press-round up on the dirft of Soviet school-leavers away from science. Instead of the "infatuation" with science and technology, which had characterised university applications for the past two decades, there was now, said the commentator, a significant increase in applications for medicine, economics and teacher-training and journalism courses. So long as this drift from science reflected a genuine response of young people to "spiritual values", he concluded, it was, on the whole, a good thing.

Literaturnaya Gazeta, however, is less approving of the drift. In the course of creation of a scientific society, it observes, a "certain stereotype mode of thinking" has grown up, which considers that "applied research in the interests of this or that branch" is "second-rank and non-prestigious". The two opening articles of this discussion set out to contradict this assumption. The first, by A Savelev, a sector-chief of the Central Scientific Research Institute of the Sewing Industry, cites C P Snow to the effect that many "pure" scientists fail to grasp the fact that many engineering problems are in no way inferior as regards explicitness and strictness to those with which they (the scientists) are concerned. And Boris Smagin, a leading science writer says that many Soviet scientists including Vernadskii, Bardin and Kurchatov "always placed the interests of science on the same level as the interests of the national economy".

The problem of prestige, however, is, as Smagin admits, a "mysterious" one. More precisely, in the words of an editorial footnote, the "prestige of the profession of applied-scientist is a social-psychological concept." The Press discussion of the role of prestige, explain the editors, is intended to focus attention on this. **Vera Rich**

Switzerland

Engineered *E. coli* produce interferon

THE announcement, last week, by Professor Charles Weissmann of the University of Zurich that his laboratory, on behalf of Biogen, had managed to recover biologically active interferon from bacteria containing human interferon DNA, establishes Biogen as a company that means business. Although the yield of interferon so far obtained from the genetically engineered bacteria is far too low for commercial production, Professor Weissmann thinks that "if things work out as hoped, we should have a high yielding strain within six to twelve months and we could then move relatively fast".

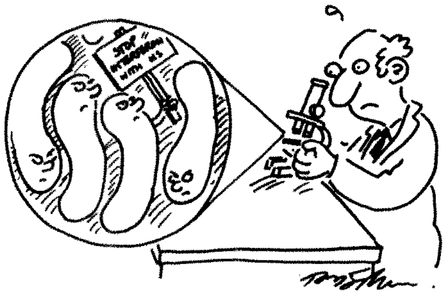
Until recently interferon has only been available in very small quantities with a purity of less than 1%. It has been produced by laboriously purifying human lymphocytes taken from blood donated for transfusion in Finland. A number of very small scale clinical trials have suggested that interferon is effective not only as an antiviral agent but also in the treatment of neoplastic disease. Because of the success of the initial trials there is now a tremendous demand for sufficient interferon to set up bigger trials.

The man behind the Finnish programme is Dr Kari Cantell. He provided Biogen with the human lymphocytes from which its genetic engineering approach started. The first step in that approach was to prepare complementary single stranded DNA from a crude mixture of messenger RNA extracted from virus-stimulated human lymphocytes.

Since there was no way to isolate the sequences corresponding to the interferon gene from the DNA, it was necessary to clone the DNA at random (using the plasmid pBR322 as vector and *Escherichia coli* as the bacterial host) and then to screen the resultant bacteria for any that contained the interferon gene.

Five thousand bacterial clones were screened by extracting their plasmid DNA. The plasmids containing interferon DNA were determined from their ability to direct the production of biologically active interferon when injected into oocytes of a frog. Having identified individual bacterial clones containing interferon genes, Professor Weissmann's team established that the bacteria were producing interferon with much the same biological and chemical characteristics as authentic human lymphocyte interferon.

It remains to be seen whether the bacteria can be further manipulated to increase their yield of interferon, currently running at one thousand fold less than that produced from an equivalent culture volume of human lymphocytes. Professor Weissmann is confident that that can be done. He is somewhat more concerned about the potential clinical activity of bacterially produced interferon, since it is unlikely that bacteria can add the carbohydrate chains that are naturally present on the protein molecule. Current indications, however, are that this will not matter clinically.



If the carbohydrate groups do turn out to improve clinical activity, genetic engineering will probably be a less profitable route to interferon than the alternative approach of cell culture, which is already producing enough interferon for some clinical trials. For example, the Wellcome Research Laboratory in Beckenham, UK already extracts interferon from virus-transformed lymphoblastoid cells in sufficient quantities to satisfy a UK Medical Research Council sponsored trial in myelomatosis. Many, perhaps dozens, of other laboratories are undertaking a similar approach although some of them, such as Searle Laboratories in High Wycombe, UK, use fibroblasts rather than lymphoblastoid cells.

Biogen is not alone in its genetic engineering approach to interferon. Amongst other industrial concerns, some of them with an undeclared stake in the business, Searle Laboratories and the Dupont Chemical Co (in Wilmington, Delaware) are thought to be particularly close on Biogen's tail. Dupont in collaboration with the California Institute of Technology has recently sequenced one end of interferon. They will now probably synthesise the complementary DNA sequence and use it to fish out bacterial clones that contain interferon genes.

What must already concern Biogen's industrial competitors is the patents that Schering-Plough have applied for on behalf of Biogen in which they hold 15% of the shares. Professor Weissmann says that the patents are connected with the plasmid rather than the process and no one knows whether they will be granted. In any case, most of the eventual profits that accrue from interferon or any other Biogen product will finish up in the US, a fact which does not please Professor Wiessmann, himself a shareholder.

It is a great pity, he told *Nature*, that none of the Swiss or German companies that were originally approached was willing to take a major share in Biogen. The more the pity because several eminent European scientists are attached to the company and because its own laboratories are in Geneva. These are already occupied by the first recruits and a director of research is being sought. The interferon work has been carried out during the last 18 months in Professor Weissmann's own laboratory but was paid for by Biogen.

Peter Newmark

United States

Registration proposed for private DNA research

A bill that would require companies to register details of their research and production activitities involving the use of recombinant DNA techniques is to be introduced into the US Senate by Senator Adlai Stevenson, chairman of the Science, Technology and Space Subcommittee.

The proposed bill, which Senator Stevenson refers to as a "reasonable alternative" to comprehensive regulation, would cover individuals and institutions not presently required to observe the National Institutes of Health's safety guidelines. The Secretary of Health, Education and Welfare would have to be notified of all research, development and production activities using these techniques — including the source of the DNA, the type of hostvector system used, and the volume of growth media — with a civil penalty for non-compliance.

The bill also includes procedures to guarantee the protection of trade secrets. And to provide an opportunity to evaluate claims of voluntary compliance with the NIH guidelines, it would also require the secretary of HEW to report annually to Congress on the adequacy of safety precuations reported to have been taken.

Senator Stevenson is proposing to schedule hearings within the near future on the status of current regulation and development of recombinant DNA research. How far the bill goes, however, will depend partly on the support that it gets from Senator Edward Kennedy's Human Resources Subcommittee, which has jurisdiction over medical research — and with the presidential campaign now in full swing, the subcommittee is not expected to give the bill high priority.

United Kingdom

Biotechnology report urges £10 million programme "to match competitors"

A MAJOR report on biotechnology in Britain — not yet published but made available to *Nature* — calls for a rapid increase in investment to build a competitive industry. It says the "customer-contractor" principle should be scrapped for biotechnology, where the border-lines between basic and applied research are grey. The report is a first draft — though unlikely to be substantially altered — from a seven-man working party set up early last year under Dr Alfred Spinks, a former research director of Imperial Chemical Industries. **Robert Walgate** reviews its hard-hitting and interventionist recommendations.

THE working party was drawn from the Royal Society, the Advisory Board for the Research Councils and the Advisory Committee for Applied Research and Development. It was set up under the previous Labour administration; during its deliberations a Conservative government, committed to non-interference in industrial affairs, has taken office, but this has not restrained its far-reaching proposals.

It says the whole foundation of biotechnological research in Britain should be changed:

"Since 1972, the UK has unlike other countries adopted a very rigorous customer-contractor principle for all its applied R&D funded by government. This approach is well-adapted to short-term or tactical applied work with clear objectives which can be defined by a single customer.

But biotechnology epitomises a field in which scientific knowledge and technical expertise are evolving rapidly, where definite customers have yet to develop in any number; where the research of government departments is divided; where the research will be of interest to a wide range of private industry, public services, etc.; and where the principle need for growth is in strategic applied research much of which will not yield results of immediate commercial benefit for perhaps a decade.

"For such a field the customer-contractor principle has serious shortcomings, and may exacerbate the situation by emphasising an arbitrary and unreal division between fundamental and applied research." Nevertheless the ultimate objective should be to make British industry competitive with the best of its foreign rivals.

Among its recommendations are:

- That the research councils and the ABRC should set up a Joint Committee for Biotechnology to develop a coherent programme of biotechnology research and to coordinate spending of not less than £3million annually (including existing research council initiatives). The Joint Committee would aim to set up new projects in universities and elsewhere, and "should encourage collaboration between experimenters of different disciplines, in different departments and institutions". Applied biologists currently working in medical or agricultural studies should be encouraged to take up biotechnology. A condition might be applied to applicants for grants that they should show evidence of industrial interest in their project.

- That an Interdepartmental Steering Group should be sent up to coordinate the actions of ministries and develop a programme of industrial R&D. The Department of Industry might take a lead in this, setting up cooperative programmes with industry (funded 50:50), research associations, government research establishments, universities, and inventors amounting to £2.5million annually (including existing projects).

- The Steering Group should consider setting up a Support Unit, like the Department of Energy's Energy Technology Support Unit, to do desk studies and build up a list of potential projects for which applications would be sought.

- The Joint Committee and Steering Group should have overlapping membership to avoid a division between basic and applied work, and in any case should review the position in 4-5 years' time.

- There should be no new establishments specifically to pursue research in biotechnology; these can stagnate and exacerbate interdisciplinary divisions. But the Department of Industry should co-sponsor the Centre for Applied Microbiological Research at Porton Down (it is presently sponsored by the Public Health Laboratory Service); CAMR expertise could be well-applied to biotechnology.

- The University Grants Committee and the Committee of Vice-Chancellors and Principals should support the expansion of a limited number of centres of excellence in biotechnology from the best existing in universities. A minimum of 20 new teaching and research post should be established over the next five years with a capital investment of around £2million to provide additional laboratory facilities.

- Urgent provision must be made for training a work-force to match the expected growth of biotechnology; greater interaction should be encouraged between departments and undergraduate courses in the biological, chemical and engineering sciences.

- The Science Research Council's Cooperative Awards In Science and Engineering, which funds research students in joint projects between university and industry, should be extended to the Agricultural and Medical Research Councils; and there should be analogous post-doctoral awards.

"Government should not impede the rapid development of biotechnology by inappropriate or unfounded concern for existing industries or the conjectural hazards apparently presented by some aspects of the new technology."

0028-0836/80/04324-02$01.00

Dr Spinks: he chaired the working party.

- The National Research Development Corporation, one of whose roles is to patent and license appropriate inventions made in universities, "should play a more entrepreneurial role in this area, where inventions are often not readily patentable. The NRDC should expand its staff in biotechnology and review existing financial incentive for academic inventors. The NRDC should be at least as concerned with the development of new business as with obtaining and licensing industrial property.

- The NRDC should continue to pursue with the Patents Office the patenting of microorganisms and press for arrangements, as in the US, which do not require the microorganism to be made available until the patent is granted.

- As new research defines the hazards of genetic manipulation, the UK in consultation with others from abroad should modify regulations appropriately. The Genetic Manipulation Advisory Group and the Health and Safety Executive should continue to reduce constraints while maintaining an adequate level of safety and introduce procedures to ease industrial application.

- The National Enterprise Board and the NRDC should investigate the use of public funds to set up a research oriented biotechnology company (akin to the American Biogen and Cetus). £2million a year for five years should be sufficient to establish if it could be profitable, the report suggests.

- The Ministry of Agriculture, Fisheries and Food and the Department of Industry should jointly investigate the use of agricultural products as feedstocks for biotechnology.

- The Department of Health and Social Security should adjust its purchasing policy to encourage small biotechnological firms.

- The Department of the Environment together with the Department of Industry and the Natural Environment Research Council should consider the use of biotechnology for waste disposal and materials recovery.

- If the European Economic Community decides to pursue its research programme in biotechnology, the UK should seek maximum return from it.

- Government should seek fiscal regulation within the EEC which will allow the use of agricultural feedstocks for industrial biotechnology "and not impede the introduction of new processes based on biotechnology". The report here criticises "the strong lobbies of established industry and agriculture which tend to exert a disproportionate weight in resisting the cheaper and better products of new technology, particularly where these threaten to perturb existing patterns of agriculture". There should be assurances that processes "will not invite penal levies . . . We are concerned that this appears to be the present case."

- Addressing itself to the European Community, the report recommends that "all member states should consider the value of biotechnology in transforming agricultural surpluses, and should seek to amend the Common Agricultural Policy legislation that threatens this end". Further, the EEC directive on the control of genetic manipulation is outdated and should be "reconsidered".

- The report "supports" the SRC in a £1.5million capital, £1million annual expenditure on biotechnology; commends the ARC's initiatives in genetic manipulation, and makes a mild and indirect criticism of the MRC: "The MRC and research councils should review their roles in relation to industrial development based on biological processes so that their staff are aware of the desirability of creating, where possible, a national return for their efforts through industrial development."

Despite the case of cephalosporins (antibiotics emerging from MRC research which are now the NRDC's single greatest revenue earner) "the take-up of discoveries by UK industry is not encouraging". Extra facilities might be provided to researchers for applied work in their own laboratories, or a special development unit might be established. However, the MRC was not set up with industrial development as an objective, and any moves along these lines would require extra resources.

National Collection of Yeast Cultures threatened

THE UK National Collection of Yeast Cultures, one of the most used in Europe, faces closure at the end of this year — unless the Agricultural Research Council can find a meagre £20,000 per annum to support it. "I don't see how biotechnology can carry on without a repository of cultures from which one can select strains" said a yeast microbiologist last week.

The collection has been looking for a home since early 1979, when one of its present co-sponsors, the Brewing Research Foundation, announced that it would withdraw its one-third contribution to the costs of the collection from January 1981. The major sponsor, the Ministry of Agriculture, Fisheries and Food, also decided to withdraw at the same date. The collection must also move from its present location at the BRF, in Nutfield, Surrey.

All would be well, say microbiologists, if there was some firm promise of new funds and a new place for the collection. But despite detailed recommendations to the Agricultural Research Council — who it is widely believed should support the collection — from the UK Federation for Culture Collections, no decision has been reached on either location or funding.

"Individual collections are not sufficient" said one microbiologist. "We keep our own small collections but we do not have time, competence or staff to do routine testing or distribute samples. It would be very serious if we sent the wrong organism".

The UKFCC has recommended that the collection and its four staff be established at the ARC Food Research Institute in Norwich, on a site where the John Innes Institute and the University of East Anglia are already established.

MAFF has placed the problem firmly with the Advisory Board for the Research Council's, which in turn has passed the problem to the ARC. But it would appear that the ARC is not prepared to fund the collection unless it receives extra finance.

Barbara Kirsop, the curator of the collection, told *Nature* that the collection has been in financial difficulty for four years. A number of agencies picked up the bill for short periods in the past, including the ARC which paid 50% of the bill for one year in 1976. "The BRF" said Kirsop "no longer wishes to support the collection because its emphasis has changed over the past ten years. People are using yeasts a lot more and we have constructed a very physiological collection which means we have a great number of yeasts with many interesting and useful properties". The collection holds 10-15 patented strains among a collection of 2000 varieties. "We need to start moving the collection in June, if we are to be out by December," says Kirsop. □

0028-0836/80/04325-01$01.00

NEWS IN BRIEF

Europe's biotechnology programme one step nearer

THE European Commission has approved the £16 million, five-year research programme on biotechnology described recently in *Nature* (10 January, page 125). But the programme still has one hurdle to jump before it can be implemented: the Council of Ministers, where the nine EEC member states take final control over Commission proposals.

The Council will take advice from CREST, the Commission's official joint consultative committee for science and technology, in February; and from the European Parliament early in March. If there were no national objections, the programme could be approved in April.

IAEA to hold closed nuclear safety conference

THE International Atomic Energy Agency in Vienna has organised an international conference on current nuclear plant safety issues to be held in Stockholm 20-24 October 1980. Reinhard Schmidt, scientific coordinator of the conference describes it as being within "the framework of those who want and need nuclear power". The conference hopes to address four main issues: assessment of current safety issues, improvements in safety, information exchanges, and development of increased national cooperation. Plenary sessions will be held with "exclusively invited papers" and conference participation "whether or not a paper will be presented must be through designation by the government of a member state of the IAEA". The meeting is expected to be open to the Press although a final decision has not been taken on this yet.

Academy report calls for orderly energy transition

A panel of the US National Academy of Sciences stated last week that both a significant increase in energy efficiency, and the development of new sources of energy — including the fast breeder nuclear reactor — were necessary to make an "orderly and smooth" transition to a coming era of energy scarcity.

The report, prepared by an *ad hoc* Committee on Nuclear and Alternative Energy Systems (CONAES) under a commission from the Department of Energy, emphasised in particular the importance of energy demand considerations in planning future energy supplies.

In a covering letter submitting the report to the department, the two co-chairman, Dr Harvey Brooks of Harvard University and Dr Edward L Ginzton of Varian Associated, emphasise the importance of remembering that the energy problem does not arise from an overall physical shortage of resources.

"The problem is effecting a socially acceptable and smooth transition from gradually depleting resources of oil and natural gas to new technologies whose potential are not now fully developed and whose costs are generally unpredictable", they say.

The report also warns that current uncertainty about the problem associated with the development of nuclear fusion as a source of power means that it cannot be relied upon as a source of energy, at least not until well into the next century.

New head for US Atmospheric Research Center

DR Robert M White, for many years head of the US National Oceanic and Atmospheric Administration and its predecessor organisations, has been appointed president of the University Corporation for Atmospheric Research, responsible for operating the National Center for Atmospheric Research in Boulder, Colorado, under the sponsorship of the National Science Foundation.

Dr White, who will succeed Dr Francis Bretherton as the full-time chief executive of UCAR, is currently administrator of the National Academy of Sciences' National Research Council. He has served as the US permanent representative to the World Meteorological Organisation since 1963, and was chairman of the WMO's world climate conference, held in Geneva in February last year. Dr Bretherton has relinquished his position in order to return full-time to scientific research.

Defector details NATO first nuclear strike plans

THE former senior secretary to the director of war games at NATO's Brussels headquarters said last week that NATO leadership planned to make first use of nuclear weapons in the event of a conflict with Eastern Europe. Ursel Lorenzen, who defected to East Germany last year, told a press conference in Berlin that NATO also had detailed plans to start a war by provoking major incidents such as blocking Eastern European shipping lanes or activating remote controlled mines in international waters. Ms Lorenzen, aged 41, said that for 11 years she had watched the planning and development of strategies to start a war with a rapid nuclear strike against East European nuclear targets. "I was present countless times when high NATO officials and military men confirmed that NATO most certainly in every case would use atomic weapons first" she said. In addition she said that NATO carried out occupation and invasion exercises under simulated Russian winter conditions and that NATO officials had told her that they were drawing on the World War II experience of the Germans. Small NATO member states such as Norway and Denmark who objected to the nuclear strike plans were overruled by the bigger countries, she said.

French police break up researchers protest

A 24 hour occupation of the headquarters of the French national institute of health and medical research (INSERM) by medical researchers was broken up by police at the request of the directors of INSERM last week. Four hundred members of the trade unions representing French medical researchers occupied the headquarters to protest about the government's changes in the status of researchers in INSERM and the Centre Nationale de la Recherche Scientifique (CNRS). The unions called recourse to police action an "illustration of the determination of the institute's director as well as the minister of health and the secretary of state for research not to negotiate". The sensitive points in the new statutes include introduction of a new four year probationary period, a lowering of the maximum age for entry into the profession to 27 years old, and forced mobility at the discretion of research directors.

United Nations University delegation visits USSR

A top level delegation from the UN university visited the USSR from 6 to 11 January at the invitation of Academician D M Gvishiani, vice-Chairman of the State Committee of the USSR for Science and Technology. The purpose of the visit was to establish increased cooperation between the USSR and the university. Talks were described as "productive" but no formal agreements have been finalised. A similar visit to China last May resulted in the creation of two joint research projects in areas of the university's strength — one a study of land-water interaction in the Pearl River basin in China, the other a remote sensing project in the Netherlands — as well as the placing of Chinese scientists for limited periods in western research institutes and universities. "I think we can expect a similar outcome of this visit" a UN official said.

Middle East brain drain switches back from the West

The brain drain of scientists from the poorer countries of the Middle East has switched from the industrialised West to the oil-rich countries of the region. And some countries are running successful schemes to attract expatriate scientists back.

Ziauddin Sardar reports

THE pattern of the brain drain from the Muslim countries of the Middle East and Pakistan has changed considerably in the past few years. In the sixties and early seventies the flow of scientific and technical expertise was almost exclusively from the Muslim world to the developed countries. As science could not be "consumed" at home or bring adequate financial rewards, the only satisfying career for the up and coming Muslim scientists was in the universities and industries of the West.

This South-North flow of scientific manpower has now given way to a South-South flow: scientists from Muslim countries such as Pakistan are now going to the Middle East. Moreover, many Muslim scientists who had settled in the West or who had trained there are persuaded by the prospect of greater prestige or simply better salaries to return home. Those who have just trained are also finding difficulty in settling in the West because of tighter immigration laws.

The changing pattern of the brain drain is welcomed by scientists and science policy makers in the countries involved. Although no figures are available, the brain drain from Pakistan to the oil-rich states of the Middle East, for example, is thought to be considerably higher than the drain to the West has ever been. But, according to Ghulam Mirza Galani, Secretary of Pakistan's Science Council, "this does not worry Pakistan for two reasons. Firstly, it is not a permanent brain drain. Pakistani scientists working in the Middle East always return home after four or five years, once they have made their money. This contrasts sharply with our brain drain to the West where Pakistani expatriates have tended to settle down. Secondly, while working in the Middle East Pakistani scientists send home much needed foreign exchange so they are not completely cut off from us".

In certain Arab countries the brain drain to oil-rich countries is actually encouraged by the government. Egypt, for example, educates its graduates for the technical-manpower market of oil-rich states. Most Egyptian universities have courses on petrochemicals, desalination and high technology agriculture. Some of these special education programmes are recognised only in the Arab world and a few particular qualifications are only recognised in specific countries. Certain Egyptian medical degrees and doctorates, for example, are valid outside only in Saudi Arabia.

Syria, unlike Egypt, faces an acute shortage of scientific manpower, but it manages to provide facilities for its scientists who wish to work in other Arab states. "Once it used to be the United States, West Germany and France", says Dr Asaad Lutfi, Vice-Rector for Scientific Affairs, University of Damascus, "but now our brightest scientists wish to go to Saudi Arabia, Libya and the Gulf.

"But we do not feel bad about this. It is our responsibility to help other Arab states. We see this as our scientists making an important contribution to the development of the region." Scientists who wish to work in other Arab states are granted up to 4 years' leave of absence; in many cases the government helps them find employment in the country of their choice. According to Dr Lufti over one-third of Syria's scientific manpower is using the scheme.

As exporters of manpower, both Egypt and Syria have an advantage over the other main manpower exporter to the Arab region — Pakistan — being Arabic-speaking. Egyptian scientists seem to favour Saudi Arabia and the Gulf whereas

LEBANESE agronomists testing soil humidity: until four or five years ago, the Lebanon was a major training ground for scientists in the Middle East. The American University in Beirut, in particular, trained many scientists for the region.

0028-0836/80/04327-02$01.00

the Syrians prefer Algeria where the language of science is being changed from French to Arabic.

Rich Arab countries are also making efforts to attract the pool of Muslim scientists and technologists working in the West.

Attracting the expatriates home

For example, Libya has set up the Tripoli-based Arab Development Institute — which despite its name is an organisation devoted to scientific research in fields that range from biology to solar energy — and provides it with almost unlimited resources. Although it employs only 70 scientists, it is particularly attractive to Muslim scientists working in the West because of the high salaries — a young PhD can earn $2000 per month — and the excellent facilities. According to Dr Kamel Al Din Hassan, head of solar energy research, "when a project is approved, the scientists simply go ahead and spend what they have to. Research is what counts, budget limitations just do not apply." Publication is also guaranteed in the ADI's own quarterly research journal. The institute now runs recruiting offices in Rabat, London and Washington and is planning opening offices in every Arab capital. The Libyans consider it an outstanding success.

But not all Muslim countries have access to endless financial resources. Turkey, for example, has had to seek alternative ways of attracting back its scientists. In 1977, the Turkish government, with the help of the UN Development Programme, initiated the Project for Transfer of Know-How Through Expatriate Nationals (TOKTEN) with the aim of securing the expertise gained abroad by the many expatriate Turkish scientists and technologists. After two years in operation the TOKTEN project has proved to be ingenious and highly workable.

The main objective of TOKTEN is for specialists of Turkish origin now resident in the West to provide specific technical help. It gives preference to scientists of international standing whose services are obtained for short assignments of one week to a maximum of three months. The visiting scientist transmits his knowledge through training seminars, consultations, reports and proposals on policy issues, and other advisory services. The UNDP meets the travel costs, and living expenses, but pays no salary; the host institution pays an honorarium.

This method of consultancy by expatriates has proved far superior to traditional methods of seeking technical assistance. According to Professor Hakki Oranc, Assistant Secretary General of the Scientific and Technical Research Council of Turkey (TUBITAK), "in general a rich return on the time invested by the consultant has been achieved. There is no need for a period of adaptation, adjustment, acquaintance of the consultant with local conditions, or for the establishment of his credibility. His cultural affinity to Turkey improves his acceptance and effectiveness".

There are further reasons why TOKTEN has proved to be more successful than most multi-lateral technical cooperation programmes. The Turkish expatriates provide a faster response to an institution's problem than is possible through traditional technical cooperation. Sometimes the character and confidentiality of the desired advice requires a privileged relationship which is easier to ensure with a trusted expatriate. Often the full value of a training programme or seminar can be ensured only if it is conducted in Turkish.

Quite a number of expatriate Turkish scientists have become specialists in solar energy research. Some have been brought under the TOKTEN scheme to Turkey for various lengths of time bringing the latest know-how. This should make a significant contribution to the success of a proposed regional centre for the Mediterranean on alternative sources of energy, which the UNDP is expected to support in southern Turkey. The government also hopes to seek the help of an equally large group of expatriate nuclear scientists in its attempt to make Turkey self-sufficient in nuclear power by the turn of the century (see *Nature* **282**, 670; 1979).

"The TOKTEN project has shown that Turkish expatriate scientists are motivated by a desire to help their homeland and not by financial gain", says Professor Oranc. "Of course, we hope that some of them will get so involved with their assignments that they will prefer to work in Turkey. But until such time, scientific and technical gains to Turkey from their efforts are proving to be much higher than one would expect from traditional technical assistance provided at much higher cost", he says.

Second-class citizens

Despite considerable economic gains, Muslim scientists working in the Middle East complain bitterly about the working conditions. The most common complaint is that they are treated as second-class citizens. One Saudi scientist, Dr Raghib El Naggar, an Egyptian says: "expatriate scientists working in Saudi Arabia, the Gulf and Libya are treated viciously. They have no rights whatsoever and virtually no prospects for promotion. No wonder then that most of them leave as soon as they have gained their financial goals". Expatriate scientists in the Middle East are also facing the same problems of corruption and bureaucracy that they are running from in their native countries. "Many expatriates believe that if they have to fight corruption and bureaucracy, they would rather stage the battle back home. There they have a higher probability of success". □

Institut

THE Institut Pasteur is a monument to great men. Pasteur himself is entombed there, in a glorious mosaic sepulchre; images of Faith, Hope, Charity — and Science — gaze down on his casket, and chickens, cows and silkworms decorate the walls. His spirit, and that of the more recently deceased director, Jaques Monod, still inhabit the place.

One of Pasteur's passions was that the new biology — his discovery of the role of microorganisms in disease — should be applied to medicine and agriculture. Biology was not an end in itself but existed to help people, industry, and France. There was a certain practical socialism to his vision, and it remains with the Institut Pasteur today.

Now, François Jacob believes, there is a dual conflict with industry. People in the universities have contempt for applied work, "and industry considers that the scientists are leftist, impossible people".

The Pasteur has a factory that contributes 20% of the funds, with 50% coming from government and 30% from legacies and donations, but negotiations are going on to increase the proportion from manufacture by involving private firms.

Pasteur himself, said Jacob, was able to do all his industrial work in the laboratory, on the bench — "and this was still possible up to the last war; but after the war it didn't work like that at all, and the Institut's funds began to decline".

And despite the Pasteur's history "even here it is not easy to put the people in the factory and the people in the research laboratory together". There is financial encouragement to do applied work, but few Pasteur researchers take it up.

The division is also present in biotechnology. Jacob has recently co-authored a report on the subject with François Gros, Director of the Pasteur, and Pierre Royer, President of the administrative council; they recommend that France's principle research funding body, the DGRST (Directorate Generale pour la Recherche Scientifique et Technique), should control any initiative that France might take.

"We have a secretary of state for science, Pierre Aigrain, and of course we have a minister for industry — and there is already a debate between them over who does what and who gets the money". The DGRST is under Aigrain, and "it is better that they make moves towards industry than industry towards science. But the tendency here is to give the whole thing to industry".

But new firms, such as Biogen and Genentech in the US "are interesting: probably much of this biotechnology is small business anyway, and the small firms may be the best way to put things together . . . In our report we suggested it would be

0028-0836/80/04328-02$01.00

Pasteur seeks out industrial support

François Jacob wants industry's money for fundamental biology — but not its control. A Nobel laureate for his work on the *lac* operon (he shared the prize with Jaques Monod), he is head of the cellular genetics unit in the department of molecular biology, Institut Pasteur in Paris. He spoke with **Robert Walgate**

better to push biotechnology with small enterprises, like wine making and so on".

In the laboratory, secrecy and confidentiality were going to be a problem, but the secrecy "will really be extremely limited . . . it will concern what people are actually doing; it has nothing much to do with the basic principles. It may be some trick to get some particular messenger, or something like that; it is unpleasant, because secrecy is always unpleasant, but I don't think it is a severe problem — in this case anyway.

"To know that these guys are doing insulin is not a very big secret; what is important is to know how it works."

"What is worse is that industry is going to control a lot of basic research. Because if, as usual, a researcher has difficulty in getting money, and if he can get money only in what interests industry, industry is going to channel research in its own directions. I think this is more injurious than secrecy."

How could this be dealt with? "Well, the channelled industry money must be kept down to a certain fraction of the research budget. I have nothing against giving *free* money!"

But this would be difficult to police; "and that's exactly what we are fighting with in the Institut Pasteur. We have had troubles with industry since the war; and now there is an attempt to cooperate more narrowly with some big firms.

"We are trying to make arrangements that are not injurious to the Pasteur. The French pharmaceutical industry has done very little for basic research — except for two or three firms. Most of them have done only very narrowly directed, applied research.

"It's always unpleasant to have to negotiate with these people. What they would like to do is to give money to the Pasteur as a function of contracts; but we want the main part of the money to be completely free for basic research."

The problem is the Institut's factory, which is "either too big or too small". The factory has to make vaccines "which are used only in the case of epidemics — to avoid situations like Brazil some years ago when a lot of people died of a meninogococcal infection. The big drug companies are not interested in that. We are making stocks of these things here but there is no profit in them."

"Profit politics will not go on forever — there will be a time when you have to stop this nonsense — but probably the big drug companies cannot do it."

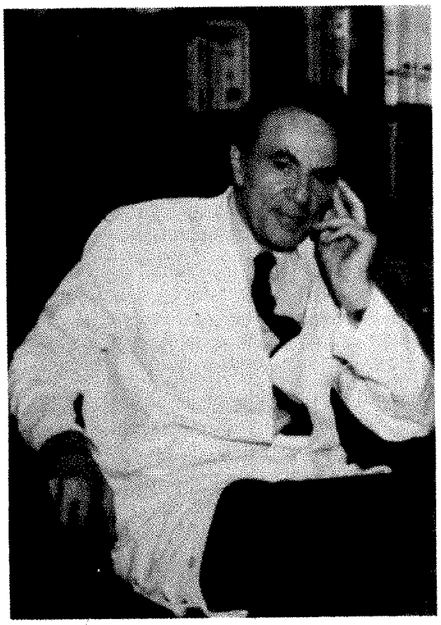
Is there a socialist ethic in the Pasteur? "Yes, that was the idea of Pasteur himself, and Monod tried to pick it up." The mood continues very strongly, "and that's exactly the difficulty of our negotiations with industry".

In the recent report on biotechnology, Jacob wrote the last and most philosophical chapter, on the possible interactions between biology and society in the next 20 years. "The problem was the following. We were asked to produce predictions of the unpredictable . . . and the most interesting thing in science is precisely what is unpredictable.

"What kind of thing could you predict? The first thing I took was the pill, and then the ability to choose a baby's sex, which would not have much impact in Western Europe."

He also predicted brain drugs: two scenarios of psychoactive drugs which would be produced in large quantities through molecular cloning techniques; in one, they would be used by governments as warfare or social control agents; in the other, as a more advanced kind of pill-popping, hyper-valium, opiates of the masses: Aldous Huxley's Brave New World.

"You take this seriously or not seriously as you wish; personally, though, I do not take it seriously."



Francis Jacob — carrying on the traditions of Pasteur.

More serious was the transformation of certain ideologies from biology into political beliefs like social Darwinism or eugenics.

Jacob allows himself one remark however: "the genetic diversity which creates the richness of animal and vegetable species also creates that of the human species," he writes in the report.

"A population composed of individuals genetically too alike would find itself at the mercy of an accident — an epidemic or a sudden shift in the conditions of life. All efforts towards a uniformity in individual biological characteristics, be it towards an 'improvement' of the race through eugenics, or towards the increase of an aptitude for mathematics or for running, would be biologically suicidal and socially absurd".

Scientists should discuss their work, with as little secrecy as possible; they should point out what is possible in five or ten years, even if they think it will not come to pass; and then there have to be enough people who are not scientists making the effort to understand.

"These questions should not be restricted to scientists and/or politicians. Reasonable people from outside must come in — but then they have to make the effort, and the scientists have to make the effort, to talk to each other and understand what is going on."

Professor Jacob proposes that the Academie des Sciences should coordinate such discussions. "I'm not sure they will, but they should". Or there could be a European forum: the European Molecular Biological Organisation could do something, for example.

However, Jacob is not hopeful that France will join in with the European programme on biotechnology presently under discussion in Brussels (*Nature* 10 January p 125).

"The French attitude will probably be nationalistic. But that is just stupid, because I think Western Europe is just going to be eaten in the next 50 years. I'm very pessimistic — aren't you? I just don't see how one can be optimistic. There are many reasons but especially because of this tremendous differential increase in population between Europe and the rest of the world . . . And then there will be the problem of food; you will have some fancy food technology in the West while the rest starve . . . it's a tremendous mess".

François Jacob, who was a Spitfire pilot in the war, and had to get up once or twice during our interview to ease his shrapnel wounds, told me "I personally am very much a European and have always been so since the war; but it's a fact that nationalism is on the increase, not more in England than in France. The whole thing is just incredible". ☐

CORRESPONDENCE

Clerk-Maxwell centenary

Sir, — It is not my intention to spoil the effect of the perfect tribute paid by Professor Domb in *Nature* (15 November, page 235) to Maxwell on the occasion of the centenary of his death. But could I be permitted to make a minor point and to mention Maxwell's ideas about the principle of relativity of motion?

Professor Domb's remark that the true quality of Maxwell's genius became apparent only with the development of twentieth century physics, might lead some to believe that his genius was lost on his immediate successors in the nineteenth century. Far from it. Perhaps, Boltzmann gave the most eloquent praise to Maxwell's equations (of electromagnetism). On reading these equations Boltzmann exclaimed, "War es ein Gott, der diese Zeichen Schrib?" (Was it a God, who wrote these signs?) (*Mensch, Physiker, Philosoph.*) Berlin 1957, page 31).

The word "relativity" was first coined by Samuel Coleridge in the year 1834 but he used it in a philosophical sense. It appears that Maxwell was the first ever to use the word relativity with reference to the doctrine of relativity of motion, and this not only for mechanical but also for electromagnetic phenomena. True, he suggested experiments to determine the putative motion of the Earth relative to the "ether" and in fact made an experiment himself to measure this motion, using a rotating spectroscope, prism and partially silvered mirrors but got a negative result (*Phil. Trans.* 1868, page 532). Therefore Maxwell was not sure whether motion relative to the ether could be observed, but he ultimately moved to a firm belief in the relativity of all phenomena.

It is not widely known that in *A Treatise on Electricity and Magnetism* published in the year 1873, Maxwell devoted two articles, to the modifications of the equations of "electromotive intensity" when referred to moving axes. Using a method which is questionable, he yet came to the conclusion that "the electromotive intensity (in the moving system) is *expressed by a formula of the same type*", and added, "In all phenomena, therefore, relating to closed circuits and the currents in them, *it is indifferent whether the axes to which we refer the system be at rest or in motion*". This was more than an intimation of things to come.

Four years later in the year 1877, Maxwell published the book *Matter and Motion*, in which he used the word 'relativity' and affirmed, "Our whole progress up to this point may be described as a gradual development of the *doctrine of relativity of all physical phenomena.*" Obviously he expected that the principle would be found to be universally valid. Penetrating deep into the future he proclaimed, "There are no landmarks in space . . . we have no log which we can cast to take a dead reckoning by . . . we may compute our motion with respect to our neighbouring bodies, but we do not know how these may be moving in space."

However, he thought as Newton before him did, that the doctrine of relativity broke down in the case of rotational motion, saying, "But though it is impossible to determine the absolute velocity of a body in space, it is possible to determine whether the direction of a line in a material system is constant or variable. For instance, it is possible by observations made on the Earth alone, without reference to the heavenly bodies, to determine whether the Earth is rotating or not". Maxwell then quoted Newton's bucket-experiment, carrying the bucket in thought to the North Pole. However, finding the calculated depression of the water-surface in the bucket too small for measurement, Maxwell remarked that the most satisfactory experimental proof was Foucault's pendulum, the rotation of which (except at the equator) establishes the absolute rotation of the Earth, although the stars and the pendulum are in no visible manner connected.

Probably Poincaré, who developed these ideas soon after, and used the phrase "Le principe de relativité," followed in Maxwell's footsteps — and, of course, travelled farther. Otherwise, how could we explain the exact transliteration of "relativity" into "relativité"?

Yours faithfully,
G. H. Keswani

Tata Institute of Fundamental Research,

Dioxin detection

Sir, — *Nature* is too important a scientific forum to leave unchallenged the inaccuracies contained in the report (8 March, 1979, page 109) of my comments about comparative laboratory measurements of 2,3,7,8-tetrachlorodibenzo-paradioxin (TCDD or dioxin).

Alastair Hay failed to provide any context to my comments and they appear to be an admission that Dow's analytical capabilities are poor in evaluating the dioxin content of environmental samples. This, of course, is not true. Dow chemists are now confident that the 2,3,7,8-TCDD molecule can be isolated from its isomers and detected at the 5 parts per trillion (10^{12}) level in environmental samples.

With that as background, let me move to the incident reported in your 8 March issue — the EPA study to evaluate the ability of the Agency's Mississippi Test Facility to "spike" and clean up samples of beef fat and human milk; and the determination of abilities of various laboratories (University of Nebraska, Harvard University, EPA's PTSEL Laboratory at Research Triangle Park, Wright State University and Dow Chemical) to measure TCDD in final extracts.

Beef fat was spiked and extracted by EPA Mississippi Test Facility using an acid/base procedure. Identical samples were shipped to Lab A and Lab B. An equivalent set was shipped to Lab C at a different time. Other extracts of beef fat were shipped to Lab D and Lab E. All the laboratories made measurements of TCDD. Of the total 20 unspiked samples measured, 10 gave false positive results. The 15 samples spiked with 0.5 to 9 ppt TCDD showed seven false positive results and zero false negative results. Lab C did not show false results below 9 ppt because its detection limit was too high to make measurements. The 94 samples spiked with 9-81 ppt TCDD showed two false negative results and one false positive.

Spiked beef fat was shipped to Lab D to evaluate its neutral extraction procedure for TCDD. These extracts were examined by Lab D and Lab C. Of six extracts of unspiked samples, one showed false positive results. The 18 spiked below 9 ppt showed six false positive results and zero false negative results. Above 9 ppt, two of 38 extracts gave false positive results and one false negative.

Extracts of human milk were shipped to Lab A and Lab B. Of 12 unspiked extracts, 11 gave false positive results. Of 12 extracts spiked with 0.5 to 9 ppt TCDD, two gave false positive results and three false negative. The 53 extracts spiked above 9 ppt TCDD gave no false positive results and no false negative results.

So the collaborators correctly concluded that the method gave acceptable results above 9 ppt but none of the laboratories was able to produce satisfactory data below 9 ppt.

These facts may be accounted for by any or all of the following reasons: the clean-up may be unsuitable for the particular mass spectrometer being used; the extracts may have stood too long before measurement; or the mass spectrometer may not have been performing properly.

The results obtained in this study in no way compromise results obtained by the various laboratories in other studies in which they did their own extractions and clean up.

Yours faithfully,
Warren B. Crummett

Dow Chemical, Michigan, US

Closed universities better than "sophistry centres"

Sir, — It was obvious that somebody would point out that the 1960s expansion of universities has overstretched resources, and now the words have come, from the mouth of Lord Todd and others. Since the resources derive from the taxpayers, one has only to persuade them that what Lord Todd says is true and it will become so — universities have little else in the way of income, at least as far as scientific research is concerned.

But is the answer to encourage low-caste universities to give up research? Lord Todd is surely as aware as anybody else how research stimulates — even positively goads — teachers into keeping ahead, delving in hidden places and generally searching out the truth. Who benefits most? — the students of course. Without research, no chemistry department is any good at all, and the outcome of Lord Todd's suggestion will be to create not teaching centres but sophistry centres.

If things are so bad we should not be aghast at the idea of closing down a few universities completely; it would be better than trying to keep alive an impotent, wishy-washy, limping sort of place in every university town.

Yours faithfully,
Roy Ballard

Norwich, UK

Iranian terrorists

Sir, — The cynical apology of the Iranian terrorists in *Nature* (29 November, page 439) reminds one of Geoffrey Dawson's infamous editorial in *The Times* of 7 September, 1938. Brutal terror will always appeal to a certain kind of intelligentsia. Let them have their fun, but please spare us the hypocrisy of preaching to the victims and not to the henchmen. Europe no longer has a Churchill to redeem a Munich.

Yours faithfully,
S. V. Vaeck SC

Islamic science

Sir,—I appreciate that the Islamic world has lived under western colonisation and oppression, particularly economic oppression, for centuries. However, I found that the article 'A revival for Islam, a boost for science?" (22 November, page 354) has a religious bias and is highly racist and chauvinistic. I do not recall any great scientist from Galileo to Einstein mentioning a religious science.

A quotation on page 354 states: ". . . The new civilisation of Islam will be capable of boosting scientific activity and scientific knowledge to heights and achievements unknown to man before". Surely boosting would have been more appropriate round. However, the simplest, scientific question that the statement begs is: why?

Your faithfully,
J. M. Goldschvartz

NEWS AND VIEWS

Dust grain orbits in the Solar System

from David W. Hughes

LONG gone are the days when interplanetary dust grains were thought to move in simple elliptical orbits around the Sun. Today three factors in addition to the gravitational field have to be taken into account in determining their orbits.

First, there is a force acting on the grain simply because it is being illuminated by solar electromagnetic radiation. This force contains a radiation pressure term which is related to the ratio between the amount of solar photon momentum intercepted by the grain and the grain mass. For certain particle sizes and materials this radiation pressure force can even exceed the solar gravitational attraction and the particle can be 'blown' out of the Solar System.

Energy absorbed from the solar radiation flux is reradiated isotropically in the frame of reference of the particle. In the rest frame of the Sun however, more momentum is radiated in the direction of motion of the particle than in other directions and this results in a dynamic drag and deceleration. This is known as the Poynting–Robertson effect. Due to this the eccentricities of the orbits of large particles slowly decrease and the particles spiral in towards the Sun in a time which is proportional to the product of radius and density.

Another, more subtle radiation drag operates due to the rotation of the Sun. Light from the advancing half is blue-shifted, increasing its momentum. Light from the retreating half is red-shifted and the resulting asymmetry in the flux of radiation momentum produces an additional force on the particle transverse to the radiation direction. This force is only significant when the particle is close to the solar surface.

A spinning particle which takes time to attain thermal equilibrium will have a skewed temperature pattern. In other words it will have an evening hemisphere that is on average slightly warmer than the morning hemisphere. The warmer hemisphere radiates more energy and momentum, and the integrated reaction force will have a transverse component somewhat analogous to the non-gravitational forces that perturb cometary orbits. This so-called Yarkovsky effect can increase or decrease the semi-major axis of the particle orbit dependent on the spin direction. The spin speed and particle composition are also important. It is only significant, though, for large particles of over a metre in size.

The second factor affecting the particle orbit is similar to the Poynting–Robertson effect but is caused by the absorption and re-emission of solar wind protons.

The relative significance of the effects mentioned above has been reviewed in a recent paper by J.A. Burns, P.L. Lamy and S. Soter in *Icarus* (**40**, 1; 1979).

The third factor leading to changes in the orbit of a particle is the electromagnetic charge. A force is exerted on a charged particle as it moves in the interplanetary electromagnetic field of the solar wind. This effect has been studied in detail by G.E. Morfill and E. Grün of the Max-Planck-Institüt für Kernphysik, Heidelberg in a recent paper in *Planetary and Space Science* (**27**, 1269; 1979). All dust particles in the heliosphere, a circular region around the Sun extending out to a distance of about 50 AU, have a potential of about 10 V. This constant value is due to the fact that the mechanism causing charging (electron emission induced by solar ultraviolet radiation) and the mechanism responsible for charge decay (electron influx and subsequent recombination) both decrease inversely with the square of the distance from the Sun.

At the Earth's orbit the interplanetary magnetic field B is about 5×10^{-5} gauss. There are strong magnetic fields on the Sun and currents are induced in the solar wind plasma as it moves through them. These currents distort the field and this field is carried away from the Sun just as if it were 'frozen-in' to the moving plasma. The Sun takes 27 days to make one complete turn on its axis and a stream of particles emitted over a period of time from an active area forms a loose spiral in space. The associated magnetic field also has a spiral shape. This magnetic spiral is divided into an even number of sectors and the magnetic field is directed in opposite senses in neighbouring sectors. The solar magnetic field reverses in polarity every 11 years and also the latitudinal extent of the sectors varies in phase with solar activity.

The force acting on the charged particle (the Lorentz force) is proportional to $R\phi$ where R is the particle radius and ϕ is the electrical potential. It is also proportional to $\mathbf{V} \times \mathbf{B}$, the vector product of the relative velocity between the particle and the solar wind magnetic field B, and that field B. Now, as a particle moves from sector to sector in its journey around the Sun the effect of the perturbing Lorentz forces are in opposite directions. However as the sectors are not exactly equal in size and strength, stochastic magnetic scattering occurs. Morfill and Grün consider the effect of this scattering on the orbital inclination of dust grains. It is strongly size dependent. For particles of 10^{-4} cm radii the upper limit is 24° and as the size increases this limit drops, being 3° for 4×10^{-4} cm radii and 0.6° for 10^{-3} cm radii. This result is of importance because it indicates that the thickness of the zodiacal dust cloud, a thickness which corresponds to a root mean square spread of inclination of the order of 20°, cannot be produced entirely by magnetic scattering but must be a characteristic of the source of the dust particles.

Systematic orbital perturbations can be induced electromagnetically due to the fact that the equatorial plane of the Sun and thus of the solar wind magnetic field is at an inclination of about 7.3° to the ecliptic (the plane of the Earth's orbit). The effectiveness of this perturbation depends on the orbital period of the particle. If this is much greater than the solar 11 yr cycle (that is, orbital radii >10 AU) it cancels out. If it is much less (orbital radii <1 AU) then inclination changes occur which tend to pull the orbital plane into the solar magnetic equatorial plane. Particles orbiting inside 0.3 AU may even enter regions of magnetic resonance and this can enhance the orbital changes. However random changes in the sector structure weaken these resonances considerably.

Morfill and Grün make an interesting prediction from their calculations. Particle inclinations are either 'focused' towards

David Hughes is a lecturer in the Department of Physics, University of Sheffield.

0028-0836/80/04331-02$01.00

the magnetic equator or 'defocused' during alternate solar cycles. This might be observable as a solar cycle variation in the width or thickness of the zodiacal cloud and should be looked for.

The final problem they consider is that of the inclination of the zodiacal cloud. Recent satellite observations have shown that the cloud is inclined at 3.0±0.3° to the ecliptic, these measurements being taken between 0.3 AU and 1 AU. The two main perturbation forces — gravitation and Lorentz — have symmetry planes inclined at 1.6° and 7.3° to the ecliptic respectively. Jupiter, the main agent responsible for gravitational perturbation, has a very minor effect inside 1 AU. Morfill and Grün conclude that the inclination of the observed plane of symmetry of the zodiacal light is considerably affected by the interaction of the interplanetary magnetic field on the charged dust particles, even if this field distribution doesn't materially alter the thickness of the cloud.

Snags still exist. The particles contributing most effectively to the zodiacal light are thought to have diameters from 10^{-3} to 10^{-2} cm and the magnetic perturbation is strongly size dependent and is small in this range. Also the orbital distribution of the source must have an influence — an influence that decreases as a function of the lifetime of the particle. Certain short-period comets are the main dust source. The 3° tilt of the zodiacal cloud probably results from a combination of the source inclination distribution and the magnetic perturbation but the relative strengths of these influences still need to be calculated. □

The life of a B lymphocyte

by Miranda Robertson

THE ontogeny of the B lymphocyte is unique in that it is marked by a series of changes in gene expression which involve chromosomal rearrangements reflected in a single molecule: the immunoglobulin secreted by a terminally differentiated plasma cell is the end result of a sequence of genetic decisions bearing both on its antigen specificity and its effector action.

The mechanisms underlying this sequence of decisions, and their relationship to other events in the life of a B lymphocyte were among the topics of discussion at a recent meeting* which covered most of the ground between the emergence of the first B lymphocyte in the fetus and the formation of an interacting network of immunoglobulin-secreting cells in the adult.

Commitment to the B cell lineage in avian embryos does not seem to occur until after the blood-borne stem cells have already migrated to the thymus (where T cells differentiate) and the bursa (where B cells differentiate)[1]. The thymus can be shown to release a chemotactic factor which attracts stem cells and is shut off when a certain number have seeded the thymus. Bursal seeding begins only after the thymus is 'full'. But even at that stage, bursal cells are still capable of responding to thymic chemotactic factor: if unseeded thymic tissue is grafted into a chick embryo after bursal seeding has taken place, bursal cells will migrate to the new thymus and differentiate there (N.M. Le Douarin, Nogent-sur-Marne).

The nature of the signals that irrevocably commit a stem cell to a given lineage is not known for either fetus or adult of any species; in mammals, B cell differentiation begins in placenta and fetal liver and continues in adult bone marrow where other haemopoietic cells also differentiate. Commitment to the B cell lineage is first detectable when immunoglobulin heavy chains appear in the 'pre-B' cells of the bone marrow or fetal liver[2]. It is now known that the appearance of heavy chains signifies not only a decision to express immunoglobulin genes, but also a major decision on the antigen-specificity of the cell and its progeny. This follows from the discovery, first made in light chains [3,4] but now extended to heavy chains[5], that the expression of immunoglobulin genes can occur only after a chromosomal rearrangement which determines the primary sequence of the antigen-binding site.

Generation of antibody diversity

J.S. Seidman (National Institutes of Health) reviewed the evidence from mouse κ light chains that there are three modes of encoding antibody diversity. The complete coding region for the antigen binding site is constructed by the recombination of one of between 100 and 1,000 V genes at random with one of 5 J genes, with slight variations in the site of recombination. If similar recombination events take place independently between similar numbers of V and J genes on light and heavy chains, these sources of diversity could in theory account for the entire immunoglobulin repertoire, even without somatic diversification of hypervariable regions 1 and 2; especially in view of the fact that heavy chain expression precedes and is independent of that of light chains, so that a cell committed to a particular heavy chain specificity may give rise to progeny expressing a variety of light chains[2]. Since immunoglobulin is not expressed on the surface of B cells until light chains have been synthesised, this would imply that exposure to antigen plays no part in determining the repertoire, but merely triggers the selective proliferation of cells with an existing repertoire.

Further evidence against later changes in the antigen-binding site can be derived from observations on cultured cells undergoing the ontogenetic changes that follow the initial expression of immunoglobulin. These changes take place in the effector region of the immunoglobulin molecule, coded by seven genes specifying the constant regions of the five classes of immunoglobulin: IgM, IgD, IgG (which has three subclasses), IgA and IgE. All cells initially express IgM, in which the antigen-binding region of the heavy chain is linked to a μ chain. Some may then also express IgD; a smaller number subsequently switch to IgG, and fewer still to IgA and IgE. Antisera against the idiotypes — antigenic determinants on the antigen-binding site — of cultured leukaemic cells, or cells transformed by Epstein-Barr virus, show that they remain unchanged from the pre-B stage through at least one heavy-chain switch, from μ chains to α chains (M.D. Cooper, Alabama University). A possible weakness in this evidence is that it is not clear what determinants anti-idiotypic antisera are recognising. Experiments with monoclonal anti-idiotypes defined with polyclonal sera comprise families of determinants some of which may not be associated with the antigen-binding site (K. Rajewsky, Cologne University; A. Nisonoff, Brandeis University). Thus it is conceivable that examination with batteries of monoclonal antisera would reveal subtle ontogenetic changes not detectable by other means.

Some participants did indeed seriously argue that antigen-binding specificities do change during ontogeny, largely on the basis of experiments by A. Coutinho (Basel Institute for Immunology), who claims that B cell precursors bear idiotypes not associated with immunoglobulin molecules and that antisera against these idiotypes can not only trigger growth and differentiation of the cells but induce the expression of immunoglobulin molecules with different idiotypes. This claim, however aroused considerable controversy.

Signals for antibody production

That there is more than one receptor through which B cells can be induced to grow and differentiate, and that antigen is only one of the signals for these processes is no longer seriously disputed. The receptor through which antigen acts on B cells is immunoglobulin expressed on the cell

---

membrane. Other receptors, such as those through which mitogens act, probably bind growth factors released by other lymphocytes. At what stages in ontogeny the cells respond to which stimuli is, however, still unclear, partly because of the problem of isolating cells at a defined stage. F. Melchers (Basel Institute for Immunology) was unable to shed any new light on early stages of B cell ontogeny but believes he has clarified the nature of the cell–cell signals that induce the T-cell-dependent production of antibody in B cells expressing surface immunoglobulin.

Three cell types and at least three signals are needed to induce antigen-specific, T-cell dependent immunoglobulin production by B cells. The three cells are the B cell itself, an antigen-specific T cell, and an antigen-presenting cell. The three signals are, first, the antigen; second, a surface antigen coded by the Ia region of the MHC complex and expressed on all three cells: this antigen must be recognised by the T cell as 'self' for the interactions to work (that is, they are MHC restricted); and third, a growth factor produced as a result of the interaction of antigen, T cell and antigen-presenting cell. Melchers has been able to show that the effect of the growth factor depends on the state of differentiation of the B cell. A small, 'resting' B cell that has not encountered antigen will respond with terminal differentiation to an antibody-secreting cell. After stimulation with antigen, the B cell becomes a larger, activated blast: blast cells respond to growth factor with both proliferation and antibody secretion.

One important implication of this schema is that the growth factor itself need not be antigen-specific: the antigen-specificity of the response resides in the induction of growth-factor production, and the induction of blast cell differentiation in B cells. In view of the controversy which has for some time surrounded the question of whether growth factors are, are not, or are sometimes antigen-specific, a system in which at least the cell types and their responses, if not the signals themselves, are defined, could provide important clarification.

On the other hand, this schema is only one among many and is unlikely to settle the issue definitively. Participants were quick to point out, for example, that at present this result can be obtained only with sheep red blood cells, and not with soluble antigens. The eventual clarification of such interactions may well depend on more and better definitions of subsets of cells.

Heavy chain switch

In the normal course of events *in vivo*, the activation of B cells by antigen probably also triggers the heavy chain switch. There is now mounting evidence that chromosomal rearrangements like that which brings about the V–J join also bring about the heavy-chain switch. Honjo and Kataoka[7] were the first to produce evidence, from the hybridisation kinetics of heavy chain mRNA probes with myeloma DNA, that the switch is accompanied by the deletion of the genes coding for the C regions expressed earlier in ontogeny. If deletion is the mechanism of the heavy chain switch, it follows, first, that the ordering of the C genes on the chromosomes should correspond to the order in which they are expressed in ontogeny; and second, that the switch should be irreversible. Genetic evidence from recombinant mouse strains however suggests that the δ chain gene is closer to the V genes than that of the μ chain (W.E. Paul, National Institutes of Health), which runs counter to the first prediction; and myeloma cells in culture seem to be able to switch back and forth between the three subclasses of γ chain (K. Rajewsky, Köln University), which runs counter to the second prediction.

However, the genetic evidence, while suggestive, is not conclusive, and the spontaneous reversion of the myeloma cells could be due to abnormal or unstable chromosome complements. In the meantime, evidence consistent with deletion continues to accrue from investigations on chromosomal DNA. Restriction analysis shows that J genes are near the μ gene in germline DNA[8], and that μ genes have disappeared from myelomas secreting γ_1 chains, μ and γ_1 genes from myelomas secreting γ_{2b} chains, μ, γ_1 and γ_{2b} genes from myelomas secreting γ_{2a} chains, and μ and all three γ subclass genes from cells secreting α chains[9].

Differences in membrane and secreted Igs

There is now good evidence that the last step in B cell differentiation, too, is marked by a change in the primary structure of the immunoglobulin molecule: membrane and secreted immunoglobulin are not the same. R.M.E. Parkhouse (National Institute for Medical Research, London) has used a charge-shift electrophoretic assay for detergent binding to show that the constant region fragments of membrane immunoglobulin M and immunoglobulin D have hydrophobic regions not present on the secreted molecule; and P. Vassalli (Geneva University) finds differences in the cyanogen bromide fragment patterns of membrane and secreted immunoglobulin M, though he declined to say in which part of the C region the difference lay. This is a matter of some importance because the membrane and secreted molecules seem to be identical at the C terminal[10] and the difference must therefore be internal.

This question is not likely to be resolved by analysis of the chromosomal DNA, which has so far failed to reveal more than one gene for each immunoglobulin class. At present, it is widely suspected that the switch from membrane to secreted immunoglobulin is due to differential processing of the primary RNA transcript in the nucleus. Since each of the four domains of the C region is coded by regions of DNA separated by noncoding intervening sequences, it is easy to see how differential splicing could produce changes within the C region and not only at its C terminal.

If the existence of one gene for each immunoglobulin class is confirmed, then strong support for the theory of differential splicing is provided by evidence for at least two[11] and perhaps as many as four[12] different immunoglobulin mRNAs in the cytoplasm; and B cells, which were among the first cells in which genes were discovered to contain intervening sequences, may prove to be invaluable in clarifying how the intervening sequences are removed in the course of gene expression. □

AFGHAN ETHNOLOGY

THE events now in progress on the north-western frontier of British India have for the third time in this century directed the serious attention of statemen, historians, and ethnologists to the remarkable people who give their name, or rather one of their names, to the north-eastern division of the Iranian table-land. During the empire of the Sassanides the whole of this region, was known as Khorasan, that is, Khoristan, the Land of the Sun or the East. This term, with the gradual reduction of the Persian sway, has shrunk to the proportions of a province on the north-eastern frontier of the Shah's estates, and has been replaced further east by the ethnical expressions Afghanistan and Balochistan, the lands of the Afghans and Baloches. . . the subjoined rough estimate of the population[of Afghanistan]according to nationalities will show that it is very far from being homogeneous:-

Afghans and Pathâns	Iranian stock	3,520,000
Tajiks	Iranian stock	1,000,000
Hindkis	Hindu stock	500,000
Hazaras and Aimaks	Mongolo-Tatar stock	600,000
Kataghâns	Tûrki stock	200,000
Badakshis	Galcha stock	100,000
Baloches	Iranian stock	100,000
Kizl-Bashes	Tûrki stock	75,000

Exposure to lead in childhood: the persisting effects

from M.R. Moore

THE problem of assessing the long-term effects of environmental lead on the health of both adults and children is bedevilled by the difficulties of measuring exposure over long periods. The only likely contenders for useful measures of long-term lead exposure are concentrations in either bones or teeth and sampling of these presents considerable problems. The more easily measured blood lead concentrations or the various biochemical indicators of lead exposure provide an indication of current or recent levels of exposure only. But in determining the probable damage that will be caused, it is not only the length and severity of exposure that may be important but the age at which exposure occurs. Of all the persons in the community, the newborn child is the most prone to injury from overexposure to lead for several reasons, and the damage that may be caused then will have the greatest long-term social and economic consequences.

There are two distinct problems. First, that of overt lead poisoning, whose sometimes fatal effects are not in dispute. Second, and of greater interest at present, are the insidious effects of long-term lower level lead exposure to which various health effects have been ascribed, such as mental retardation, kidney damage and changes in cardiovascular function, but around which there is certainly some controversy about the levels of exposure at which these changes may begin to take place.

The scientific problem in these circumstances is to try and define some break-point in the continuum of exposure at which one can definitely say that injury has taken place. This is inevitably difficult since lead has always been and always will be present in the biosphere and will be taken into the body in food and drink. As there can be no question of reducing lead exposure levels to zero, scientific and medical policy must be the attainment of minimal risk of exposure.

One of the most important factors determining the eventual body-burden of lead is its rate of absorption from the gastrointestinal tract. Recent studies have clearly shown that this may be considerably influenced by the composition of the diet and is almost certainly greater than the commonly-quoted figure of 10% of the total ingested lead. A similar problem is also found in determining the absorption of inhaled lead. Although initial studies indicated pulmonary absorption leading to a rise in blood lead of 1 μg% for every μg m^{-3} of lead in the air, the most recent studies would suggest that the figure is at least twice this, but is totally dependent on particle size and various other physical constraints, such as the volume of air breathed[1].

The problem of exposure in newborn and young children is particularly important as newly-born children, and indeed other mammals, absorb considerably greater percentages of lead from their diet than they do in adult life[2,3]. And they can be exposed to lead in the environment through several routes. *In utero* the fetus is exposed to lead concentrations which are approximately the same as those found in maternal tissues, as the placenta is a poor barrier to lead[4]. After birth, the situation changes dramatically when two different populations of children can be seen. One is breast fed, the other is fed with prepared milk feeds, usually by reconstitution of dried milk powders with domestic water supplies. The concentration of lead in breast milk is approximately the same as that found in human plasma, that is, about one tenth of the concentration of lead in whole blood, and generally will constitute little hazard to children, even where maternal over-exposure has taken place. The lead concentration of all proprietary dried milk feeds is low. Where however these feeds are made up with water in which there are very variable, but often considerable concentrations of lead, the child may be exposed to very high concentrations of lead at a time of life when his or her developing tissues are most susceptible to any toxic insult. Where concentrations of lead in domestic water supplies are high, which occurs in many areas of the world through soft water supplies being delivered through lead plumbing (see ref. 5 for a recent study) the child is exposed to lead concentrations in the diet which on a weight per kg basis are greater than are likely to be experienced at any other time in his or her life and at a time furthermore, when at least twice as much of this dietary lead will be absorbed compared with later life.

The toxic effects of such exposure are not hard to find. Of all the developing tissues in the body, those most prone to such injury are the brain and the central nervous system which are those least able to repair themselves. A number of studies, both in animals and humans, now provide conclusive evidence that neurophysiological deficit will occur in children over-exposed to lead. The exact degree of over-exposure and change in body lead burden which may result in measurable changes remains to be defined.

The toxic effects of lead on the nervous system in these circumstances are probably biphasic. First, lead affects nervous tissue development and growth[6,7]. These effects are almost certainly irreversible and will result in permanent neurological change, especially where the exposure has taken place early in life. Second, lead acting on various biochemical systems will alter concentrations of neuro-active metabolities. This type of change is probably reversible. Proof already exists that such changes can take place within the haem-biosynthetic pathway with overproduction of δ-aminolaevulinic acid, now shown to be neuro-active[8], and in the adrenergic and cholinergic biosynthetic systems with consequent alterations in neurotransmitter concentrations.[8,9]

In the earliest studies of childhood overexposure to lead it was clear that classroom performance was poorer than in children that had not been exposed. Thereafter, studies showed that mental retardation could be linked with overexposure to lead in drinking water and with high concentrations of blood lead at about the time of birth. Studies in El Paso, Texas linked blood lead concentrations of between 40 and 68 μg per 100 ml with diminished classroom performance (adjusted for age) although there was some controversy over the interpretation of these results.

In the most recent studies a similar degree of diminished learning ability (IQ drop of 4-7 points) and behavioural changes such as diminished attention span, have been associated with increased concentrations of lead in teeth. These studies by Needleman *et al.*[10] and Winnecke[11] are the most convincing evidence to date of low level effects, since the use of tooth lead reflects long-term rather than recent exposure in these children. Children with greater exposure to lead performed significantly less well in the Wechsler Intelligence Scale for Children Test. Although tests for gross motor coordination were not done in Winnecke's study in Germany, changes in classroom behaviour were observed in Boston by Needleman *et al.* The importance of these studies lies in the battery of tests applied and in the matching and allowance for non-lead related variables such as weight, height and socioeconomic class, which were controlled in the analysis of covariance.

The emphasis now being placed on the study of the effective dose–response relationship between lead exposure and possible neuropathological effects in children reflects the fact that the overexposure to lead of young children will have the greatest potential economic

effects through increased requirement for care in later life in those most severely afected and by diminution of intellectual potential. Children are inevitably the unwitting victims of adults' use of lead, especially in industrialised communities and in areas of heavy traffic.

It is impossible to put any value whatsoever on human potential and development but it is safe to say that for any community, the economic burden of looking after persons with mental deficit is high and is increasing. This burden should certainly not be unnecessarily loaded with persons in whom such deficit is avoidable.

In industry, the hazards of over exposure to lead are easily perceived and a solution simple, even if expensive to achieve. But this does not apply to environmental exposure. The simplest cause of environmental exposure to remove would be lead in automobile fuel. This course of action would certainly carry a high potential economic toll and lead in petrol is only one limited source of exposure in Western society. To remove other sources such as lead plumbing would be even more expensive, which must inevitably be balanced against the less easily quantified cost of doing nothing. Perhaps the ultimate aim of any economic as opposed to medical policy in this sphere must be to balance the cost of a healthy community against the costs of achieving a healthy environment. It is particularly poignant as the International Year of the Child comes to an end that children who have so little economic or political muscle, but in whom the toxic effects of over exposure to lead are most manifest should thus have the greatest potential long-term economic effect on the community. □

Body temperature, activity and energy costs

from R.D. Martin

LIVING birds and mammals are distinguished as a group by their maintainance of a high body temperature with the generation of heat in association with a high metabolic turnover. Until recently, however, attempts to provide a convincing hypothesis to account for the evolution of this phenomenon of endothermy have remained inconclusive. Now, information from a number of disparate fields of research seems at last to point the way towards a synthetic theory accounting for the emergence of endothermy despite its high energetic cost.

A major stimulus for re-examination of possible reasons for the evolution of endothermy in birds and mammals comes, strangely enough, from a recent suggestion that this feature had also been developed among the dinosaurs (Bakker *Evolution* **25**, 636; 1971; *Nature* **238**, 81; 1972). Bakker's arguments supporting endothermy in dinosaurs (invoking raised body posture, inferred predator/prey ratios indicating high energy requirements, and bone histology indicative of rapid growth) have encountered criticism from several quarters, but regardless of its specific merits the hypothesis had the advantage that it focused attention more on the topics of locomotor activity, energy requirements and overall metabolic turnover. As Hopson (*Paleobiology* **2**, 271; 1976; *Rev. ecol. Syst.* **8**, 429; 1977) concluded, it seems likely that the dinosaurs were not comparable with birds and mammals in terms of body temperature regulation, but they were undoubtedly peculiar in some aspects of their metabolic house-keeping in comparison with modern reptiles. Thus, any synthetic explanation of the origins of endothermy should ideally account not only for the relevant features of birds and mammals, but also for any identifiable peculiarities of the dinosaurs concerning overall energy relationships.

In diametric opposition to the synthetic trend stimulated by Bakker's work, a special explanation for the evolution of endothermy in mammals alone was subsequently proposed by A.W. Crompton, C.R. Taylor and J.A. Jagger (*Nature* **272**, 333; 1978). Their model involved a two-step acquisition of endothermy: (1) invasion of a nocturnal niche, with development of a moderately elevated, controlled body temperature (25-30 °C), but without any significant increase in resting metabolic rate; (2) re-invasion of a diurnal niche, with further elevation of the controlled body temperature (to close to 40 °C) and an obligatory increase in resting metabolic rate.

One important piece of evidence cited in support of this hypothesis consisted of new experimental evidence that three extant placental insectivores (*Tenrec ecaudatus; Setifer setosus; Erinaceus europaeus*) exhibit a 'reptilian-type' pattern of oxygen consumption during locomotion. This feature was intepreted as a primitive retention in these nocturnal insectivores illustrating the first step in the acquisition of endothermy. However, a nocturnal monotreme (*Tachyglossus aculeatus*) and a nocturnal marsupial (*Didelphis virginiana*) studied under the same conditions exhibited a typical 'mammalian-type' pattern of oxygen consumption during locomotion. Thus the two-step model can only account for the conditions in these two species (and for the vast majority of nocturnal placental mammals which presumably have 'mammalian-type' energetics) by postulating numerous intermediate diurnal ancestors in which the second step would have been accomplished. An alternative explanation is that the tenrecs and the hedgehog exhibit 'reptilian-type' energetics during locomotion for special reasons unrelated to the overall framework of evolution of endothermy in mammals. In any event, the two-step model cannot be applied to the parallel evolution of endothermy in birds (for which no ancestral nocturnal phase can be envisaged) and Crompton *et al.* themselves point out that their hypothesis explicitly rules out any possibility of early trends towards endothermy among therapsids (mammal-like reptiles).

The need for an *an hoc* explanation for the separate evolution of endothermy in mammals has now been questioned in a paper by A.F. Bennett and J.A. Ruben (*Science* **206**, 649; 1979), which concentrates on the high energetic cost of endothermy and the relationship between high metabolic rate and increased capacity for aerobic respiration. The high energetic cost of endothermy in birds and mammals demands that it have a substantial selective advantage. Bennett and Ruben propose that this advantage lies in the far greater stamina in locomotion permitted in vertebrates with high metabolic rates and an associated greater capacity for aerobic respiration.

Taking the same linear relationship between oxygen consumption and speed of locomotion exploited by Crompton *et al.* in their experimental work, Bennett and Ruben have shown that a plateau of oxygen consumption is reached at a critical speed of locomotion. For any given body weight, a reptile will attain this plateau at a much lower speed than a mammal and thus be constrained to carry out anaerobic respiration at an earlier stage. (Interestingly, the relationships between oxygen consumption and running speed determined for the placental insectivores studied by Crompton *et al.* reveal no attainment of an anaerobic plateau, so these mammals are apparently not of the 'reptilian-type' in this respect). Hence acquisition of greater locomotor stamina may well provide a unitary explanation for the evolution of endothermy in the face of greatly increased energy consumption.

Two important corollaries are identified by Bennett and Ruben. First, since locomotor stamina is undoubtedly a prerequisite of bird flight, it would follow that endothermy probably evolved among the ancestors of birds before the emergence of flight. Second, since increased metabolic turnover is directly related to a decrease in the proportion of resources which can be allocated to reproduction by any individual, it is likely that endotherms would be particularly subject to selection pressure favouring the emergence of

R.D. Martin is Reader in Physical Anthropology in the Department of Anthropology, University College, London.

0028-0836/80/04335-02$01.00

secondary mechanisms to enhance infant survival. The characteristic presence of parental behaviour in birds and mammals (associated with vivipary in the latter) may thus be linked to the presence of endothermy.

Going beyond the material presented by Bennett and Ruben, it is also noteworthy that there is probably a close connection between metabolic turnover, activity levels, aerobic capacity and brain size in birds and mammals. The fact that birds and mammals have relatively larger brains than reptiles, amphibians and fish (Jerison *Evolution of the Brain and Intelligence,* 1973) could relate directly to greater locomotor capacity and to the high metabolic levels associated with endothermy. If a single such explanation covering all these aspects is applicable to living birds and mammals, these corollaries (and others as yet unidentified) could considerably increase our understanding of vertebrate evolution. The present controversy over the presence or absence of endothermy in dinosaurs, having stimulated the search for new explanatory principles, may itself find an acceptable solution within this unitary framework, bringing in such topics as relative brain size (Hopson *op.cit.,* 1977; Jerison *op.cit.,* 1973) and evidence for parental behaviour in dinosaurs (Hopson *op.cit.* 1973; Horner & Makela *Nature* **282,** 296; 1979). ☐

Switchboards and folds

from P.D. Calvert

SEMICRYSTALLINE polymers derive their useful properties of strength and toughness from their structure of alternating crystalline and rubbery layers. Hence the way in which the chains are arranged in these layers and bond them together is of importance in guiding our thinking about many aspects of their behaviour.

Small angle neutron scattering (SANS) results on crystalline polyethylene published in 1976 showed that current ideas on the arrangement of the molecular chains in crystalline polymers needed rethinking (see *News and Views* **263,** 371; 1976). Polymer crystals are usually thin, about 10 nm, in the direction traversed by the chains so it is agreed that chains must fold back for several traverses through any crystal. Before 1976 it was widely believed that the chains were folded tightly to give adjacent re-entry with little loose material at the crystal surface. The alternative was the 'telephone switchboard' model where the chains re-entered the crystal at some distance from their exit point. The Faraday Discussion on 'Organisation of Macromolecules in the Condensed Phase' held in Cambridge last autumn gave a clear picture of developments over the past 3 years.

The basic observation by neutron scattering, that there is little change in the radius of gyration of polyethylene on crystallisation, was originally reported by Ballard and coworkers at ICI. They have since shown that polypropylene behaves similarly and workers at Bristol and at Mainz have confirmed the polyethylene result. At Cambridge, J. Guenet, C. Picot and H. Benoit from Strasbourg reported similar results for deuterated polystyrene chains in a high molecular weight ($M_w = 1.7 \times 10^6$) polystyrene matrix. However, in a matrix of lower molecular weight ($M_w = 4 \times 10^5$) the radius of gyration increased by up to 40% on crystallisation. This is of great interest because the fact that no change in radius of gyration is usually observed means that there is little with which really to test theories. One problem with SANS is that segregation of the labelled molecules may occur on crystallisation, but the Strasbourg group claims that this is not so in their samples.

Several different approaches have been successful in fitting the SANS data. D. Yoon and P. Flory (Stanford University) have shown that switchboard models with or without some low probability of adjacent re-entry can fit the data. The Mainz group has used a 'solidification' model in which straightening of chain sections is superimposed on the initial, molten random coil. The Strasbourg group has fitted its data by allowing adjacent re-entry over the central sections of the chain and leaving amorphous 'wings' at either end. The US National Bureau of Standards group here had success with this and with a cluster model, where clusters of three or four adjacent folds are linked by longer loose folds. The lesson seems to be that the many different models can be fitted to the data available so far, which can only be used to eliminate some possibilities. However, matters should improve as measurements are extended up to 'intermediate' angles where the scattering vector is commensurate with the individual folds and clusters rather than the whole chain. Careful measurements of absolute, rather than relative, intensity may also be necessary in these regions.

The ICI/Jülich group has looked carefully at the behaviour of the radius of gyration at low molecular weights in polypropylene (*Polymer* **20,** 399; 1979). In principle, the chain might be expected to resemble a straight rod when it becomes so short that it can only fold once or twice. Then the rod length should be equal to the lamellar spacing seen by small angle X-ray scattering. In fact it is about twice this. This they have explained in terms of chains running through pairs of lamellae. However, we are rather ignorant about the way in which the stacks of lamellar crystals form; it often seems to be a two-step process with later filling-in by small lamellae of the spaces between those which form first. Thus it is difficult to see how really to view this interesting result. This group also reported data on drawn polypropylene where a six-fold draw ratio resulted in a decrease of 3–4 times in the radius of gyration perpendicular to the draw direction, more than the decrease of $\sqrt{6}$ that might be expected. There was also a decrease of 3–6 times in the molecular weight measured by SANS although the chains were unbroken suggesting that the chain was now acting as a series of separate beads.

Given that interpretation of the SANS data on melt-grown crystals is very dependent on the models used, one would hope for signs of theoretical advances. Here the meeting at Cambridge had little to offer. The interpretation of the results of other experimental observations in terms of the switchboard and adjacent re-entry models were debated, as they have been for many years, but little progress has been made. A great deal of information exists but most of it can be interpreted in terms of more than one model. However, it still remains unclear whether the telephone switchboard model can be reconciled with sensible packing densities close to the crystal surface. Recently Flory suggested that there was not time for a full adjacent re-entry conformation to be adopted during crystallisation, given the relaxation time of a whole chain. J. Klein and E. Di Marzio argued against this, the former by calculating the diffusion rate of a chain in a tube and the latter by calculating the time to pull a chain through a hole in a plane, but as all the calculations are on different bases it is difficult to grasp the reasons for the contradictions. A telling point is that polymeric impurities can be pushed aside even during rapid crystallisation. It is worth giving more thought to the relationship between the time required for this process and that for crystallisation.

Studies on solution-grown polyethylene single crystals seemed to have reached a reasonable level of agreement. Yoon, D. Sadler (Bristol) and M. Stamm (Mainz) all talked in terms of chains re-entering close to their point of exit and spread over a few neighbouring crystal planes, in other words not 'adjacent' re-entry but 'nearby' re-entry. However, there are still differences in the form of the models used by the different groups.

The SANS results have changed most people's picture of the crystal surface. They now picture it with many loose loops whereas previously the majority viewpoint was that the surface was virtually smooth. For the future we must await more detail from the neutron scattering at intermediate angles. The most viable theoretical approach seems to me to be to start from the molten random coil and to interpret the action of the kinetics and thermodynamics of crystallisation and annealing but progress has been slow so far. ☐

REVIEW ARTICLE

Thermal X-ray emission from neutron stars

David J. Helfand, Gary A. Chanan & R. Novick

Columbia Astrophysics Laboratory, Departments of Astronomy and Physics, Columbia University, 538 West 120th Street, New York, New York 10027

The Einstein Observatory (HEAO 2) presents the first realistic opportunity to see a neutron star by observing radiation from its surface. In this review we show that the detection of such thermal radiation or the establishment of strong upper limits to neutron star temperatures is of considerable importance to the study of neutron star matter, neutron star structure, and polar magnetospheres.

WHEN the existence of neutron stars was first suggested[1-3], it seemed likely that these objects, with a radius of only 10 km, would forever remain in the realm of theoretical speculation. Observational advances in the past decade have rendered this view obsolete. Neutron stars have been either established or suggested as the underlying object for many astrophysical phenomena: pulsars; X-ray binaries, transients, and bursters; γ-ray bursters; and even active galactic nuclei. Nevertheless, with the possible exception of the decaying tails of X-ray bursts[4], we have yet to 'see' a neutron star in the sense of detecting its surface radiation[5]. Such an observation may well now be possible.

We review here the status of theories concerning the thermal properties of neutron stars with a view towards establishing how observational astronomy may contribute to future studies. Table 1 presents the photon fluxes expected in several regions of the spectrum from a 10 km neutron star at a distance of 100 pc (equal to that of the closest radio pulsar). The legend to Table 1 lists the limiting sensitivities of the best available instruments in each spectral regime. While the Space Telescope will substantially lower sensitivity thresholds in the visible and near UV, much work can already be done in the soft X-ray region with the imaging telescope aboard the Einstein Observatory (HEAO 2).

There are several reasons why neutron star surfaces are thought to be hot enough to emit soft X rays ($T \sim 10^6$ K). At its formation in the imploding core of a supernova, a neutron star will be at a temperature $>10^{11}$ K. It cools rapidly at first through various neutrino processes, but most recent calculations[6] suggest that the surface temperature remains above one million degrees for at least 10^3 yr and above 10^5 K for perhaps 10^5 yr. If this is the case, several neutron stars should be detectable in young and/or nearby supernova remnants. Furthermore, several heating mechanisms have been proposed which may maintain surface temperatures of several hundred thousand degrees or higher in older neutron stars (such as radio pulsars). These include heating of the polar caps via bombardment of the surface with relativistic particles from the magnetosphere, frictional dissipation from the crust–superfluid interface, microquakes and accretion from the interstellar medium.

Heating sources

Initial cooling: Although neutron stars are thought to form at very high temperatures ($T > 10^{11}$ K) in the core of a supernova explosion, much of this initial thermal energy is radiated away in neutrinos during the first hours, leaving a 1-day-old star with an internal temperature of 10^9–10^{10} K. The thermal history of neutron stars has recently been reviewed by Tsuruta[6]. Cooling rates were calculated for various neutron star equations of state, stellar masses and magnetic field strengths. Both photon and neutrino cooling were considered; neutrino processes included were neutrino bremsstrahlung, modified URCA and plasmon processes, as well as minor processes such as photo production of neutrinos, pair annihilation and neutrino synchrotron radiation. The effects of the star's magnetic field and the superfluid nature of its interior were taken into account. In addition to a range of standard equations of state, stars containing pion condensate cores were considered. The thermal properties of more exotic equations of state, including those for pure quark stars, have been studied by Brecher and Burrows[7].

The result of such cooling calculations is a curve giving the neutron star surface temperature as a function of time. Neutrino cooling dominates for at least the first 10^3 yr in all models, so any effect of the magnetic field on photon opacity is of minor consequence. The range of temperatures allowed by standard nuclear models after 350 yr is from 3.5 to 15×10^6 K; after 10^4 yr, the temperatures fall to between 2 and 5×10^6 K. As the result of a less sensitive temperature dependence (T^6 instead of T^8 as for other major processes), neutrino cooling due to pion decays allows the star to reach lower temperatures more rapidly. Although the density ρ_π at which neutron star matter makes a transition to a pion condensate is very uncertain (3×10^{14} g cm$^{-3} \lesssim \rho_\pi \lesssim 3 \times 10^{15}$ g cm^{-3} with $\rho_\pi \sim 6 \times 10^{14}$ g cm^{-3} as the best current estimate[8]), one can compute the maximum cooling effect of pions by choosing the lower limit of 3×10^{14} g cm^{-3}, thus allowing the largest fraction of the stellar mass to be in this state. These maximum pion cooling models yield temperatures of 8×10^5 K and 3×10^5 K after 300 yr and 10^4 yr, respectively[6].

An analytical estimate of the cooling equations by Brown[9] yielded a surface temperature for the Crab pulsar of $\sim 4 \times 10^6$ K, consistent with the results of Tsuruta's[6] full numerical integrations and only slightly above the measured upper limit of 3.0×10^6 K (ref. 10). Malone[11] and Maxwell[12,13] have also studied the cooling problem, and the results are all qualitatively similar. They differ by less than a factor of 2 from the results described above—the discrepancies apparently arise from small differences in the input physics: for example, the choice of an equation of state (Maxwell[12] assumes a uniform density star). However, many of these calculations use core–crust thermal conductivities calculated over seven years ago[14]. Recent work by Ray[15] finds significantly lower conductivity values and thus predicts lower temperatures for recently formed stars. His most extreme model predicts surface temperatures of 1.7×10^6 K and 1.3×10^6 K for stars of age 300 yr and 1,000 yr, respectively. Also, since the core-to-surface thermal conduction time scale is $\sim 10^3$ yr, one cannot distinguish, in these models, between young stars with and without pion condensate cores.

Brecher and Burrows[7] have recently made the first detailed calculations for the cooling of quark stars. These stars tend to have a higher heat capacity, but also tend to cool slightly faster, resulting in predicted temperatures quite similar to those discussed above; a 10^3-yr-old star has a temperature of $\sim 5 \times 10^6$ K. As a result of their higher heat capacity, the stars also tend to remain warm longer. For instance, after 2 Myr (a typical age for radio pulsars), the surface is still at 10^6 K. However, it is uncertain whether a quark star contains a large superfluid component, and, as for normal matter stars, the inclusion of superfluidity effects in these calculations would probably lower these predicted temperatures. The thermal properties of the recently proposed 'abnormal' matter neutron stars[16] have not yet been calculated.

Table 1 Thermal neutron star photon fluxes in the visible, far UV, and X-ray bands*

T (10^6 K)	Flux Visible band†,‡ (3,000–10,000 Å) (mag)	 Far UV band‡ (1,000–2,000 Å) (mag)	 X-ray band§ (0.2–3.0 keV) (photons $\mathrm{cm^{-2}\,s^{-1}}$)
0.1	28.5	25.8	1.3×10^{-11}
0.3	27.3	24.1	1.9×10^{-4}
1.0	26.0	22.7	0.23
3.0	24.8	21.4	12

* A neutron star radius of 10 km and a distance of 100 pc are assumed; interstellar absorption has been neglected.

† Skylight limits the sensitivity of ground-based telescopes to $m_v \sim 23$.

‡ The wide field camera on the Space Telescope is expected to be able to detect 27th mag stars in the far UV and visible regions of the spectrum.

§ The imaging proportional counter on the Einstein Observatory has a sensitivity of 2.5×10^{-5} photons $\mathrm{cm^{-2}\,s^{-1}}$.

Virtually all of the standard calculations of neutron star cooling rates, therefore, suggest surface temperatures of several million degrees for a 300-yr old object, with temperatures remaining within the range $5\text{–}20\times10^5$ K for at least 10^4 yr. The only previous observation applicable to these theories has been the upper limit of $\sim3\times10^6$ K for the Crab pulsar from the lunar occultation measurements[10,17]. With the imaging capabilities and thousandfold increase in sensitivity offered by the Einstein Observatory, we can now expand this data base significantly. A search of nearby supernova remnants will either detect point sources and yield surface temperatures to be used as constraints on cooling theories, or provide upper limits nearly an order of magnitude lower in temperature than previously possible and delimit the viable choices for neutron star equations of state (for example, by distinguishing between the presence or absence of pion condensates).

Figure 1 presents the minimum surface temperatures required for neutron stars to be detected in 10^4-s pointings with the Einstein Observatory imaging proportional counter (IPC) (see ref. 18 for a detailed description). These temperatures were determined by requiring that the number N of photons in a 2 arc min radius detection cell be at least 25 [a 3 σ result for the typical measured IPC background rate of 0.005 counts (s cell)$^{-1}$]. For a thermal isotropically radiating neutron star at a distance d with temperature T_0 and radius R_0, N is given by

$$N(T_0)=\frac{2\pi(1+z)^2R_0^2t}{c^2d^2h^3}\int_{E_\infty^{(1)}}^{E_\infty^{(2)}}\times\frac{E_\infty^2A(E_\infty)\tau(n,E_\infty)}{\exp[(1+z)E_\infty/kT_0]-1}\,\mathrm{d}E_\infty \tag{1}$$

where t is the observing time. The integral is over photon energies E_∞ within the bandwidth, $E_\infty^{(1)}$ to $E_\infty^{(2)}$, of the detector. The subscript ∞ emphasises that the photon energies are as measured by an observer at infinity. On the other hand, T_0 and R_0 (the 'true' temperature and radius) are defined, in the usual convention, at the surface of the neutron star. We have used the relationships

$$\begin{aligned}T_\infty&=(1+z)^{-1}T_0\\R_\infty&=(1+z)R_0\end{aligned} \tag{2}$$

where T_∞ is the temperature measured by the distant observer and R_∞ is the apparent radius that he would deduce from the black body law (see ref. 19). The factor $(1+z)$ is due to the gravitational redshift and, at the surface of the star, is given by

$$1+z=\left(1-\frac{2GM}{c^2R_0}\right)^{-1/2} \tag{3}$$

where M is the mass of the star (see ref. 20). Finally, $A(E_\infty)$ is the effective area of the detector and $\tau(n, E_\infty)$ is the transmission of the interstellar medium as a function of the number density n of neutral hydrogen atoms along the line of sight. We have plotted results for $n=0.3$, $n=1$, and $n=3$ atoms $\mathrm{cm^{-3}}$. The absorption coefficients used were those of Brown and Gould[21].

For all of the present calculations, we have adopted a neutron star mass of $M=1.3M_\odot$ and a radius $R_0=16$ km. This value for M is used in much of the theoretical work described above and is also consistent with the measured masses of neutron stars found in binary systems[22,23]. The adopted radius is that appropriate to this stellar mass, using either the mean field[24] or tensor interaction[25] equations of state[26]. The value of the redshift for this case is $z=0.13$.

Our assumption of isotropic black body emission for the thermal radiation from a hot neutron star is clearly an oversimplification. The strong magnetic field produces a nonuniform thermal conductivity over the surface of the star leading to significant temperature gradients. Brinkmann[27] has also recently described the deviation from a black body spectrum which results from the effect of the field on the optical properties of the surface. He finds that the effects are not large for stars with fields $\gtrsim10^{12}$ G, but the strong dependence of the surface index of refraction on the values of the cyclotron and plasma frequencies causes the expected radiation to be lowered by more than a factor of 5 from the black body value for $B\sim5\times10^{11}$ G. A measurement of the actual emitted spectrum would reveal much about the properties of neutron star surface material and the strength of the magnetic field.

Polar cap heating: The origin of pulsar radio emission has been one of the most difficult theoretical problems in astrophysics of the past decade. However, models have emerged which agree on several fundamental points. Based on the original work by Sturrock[28], these models invoke pair creation by the γ rays produced via the electrostatic acceleration of primary particles from the magnetic polar caps of the star. Although the location of the region of pair production and many other details of the models differ[28–35], all of the models require that a large back-flux of γ rays and relativistic particles be incident on the pulsar's polar cap surface. This flux will heat the polar cap to soft X-ray temperatures (0.1–1 keV) and, assuming that a large fraction of this energy is not lost by heat conduction into the stellar interior, may render the polar cap region visible at distances of up to ~1 kpc. Owing to uncertainties in the distance from the stellar surface at which pulsar radiation in various spectral regimes arises and the values of some parameters in the polar cap theories, we ignore general relativistic corrections in this section; that is, we drop the distinction between R_0 and R_∞, T_0 and T_∞, and so on.

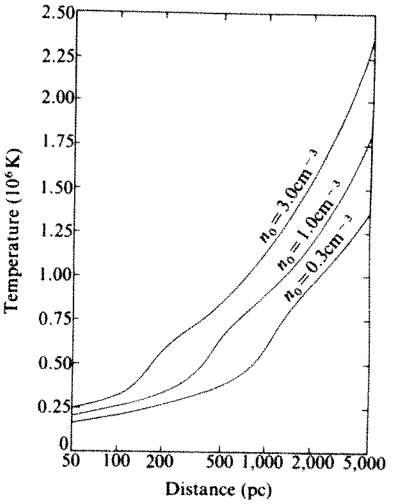

Fig. 1 Temperatures for a 16-km neutron star that produce detectable soft X-ray fluxes (25 counts) in a 10^4-s pointing of the Einstein Observatory IPC. Curves for several representative values of the interstellar neutral hydrogen density, n_0, have been plotted for T as a function of distance. Note that there are 50 known radio pulsars within 500 pc of the Earth.

Table 2 Predicted X-ray temperatures and fluxes for potential γ-ray emitting pulsars

Name PSR	B_{12}/P^2	D (pc)	$\dot{E}$ (10^{33} erg s^{-1})	A (10^{10} cm^2)	T (10^6 K)	IPC counts in 2,000 s (0.1–5 keV)

1933 + 16	12	6,000	5.2	0.75	5.0	3.1

* Values calculated using measured values of L_γ (see text). In other cases, $L_\gamma = \frac{1}{2}\dot{E}$ was assumed.

The models of Ruderman and coworkers[29-32] offer a choice of two regions of the magnetosphere from which polar cap-heating particles emerge. In the so-called 'outer gap' picture[31,32], a large flux of positrons (electrons) originates in a region of magnetospheric charge reversal at a radius of $\sim 0.2\ R_c$ (where R_c is the light cylinder radius) and impinges on the polar cap, heating it to temperatures of $\sim 10^7$ K. This model accounts well for the high energy γ radiation from the Crab and Vela pulsars as well as for the 100 MeV γ-ray pulses recently reported from two older pulsars (PSR0740 − 28 and PSR1822 − 09)[36]. The condition for such outer-gap induced γ-ray emission is

$$B_{12}/P^2 > 10 \tag{4}$$

where B_{12} is the pulsar's dipole magnetic field strength in 10^{12} G, and P is the period in seconds[32]. Of the 110 pulsars in the Galaxy with measured period derivatives (necessary to estimate B_{12}), the 25 sources which satisfy this criterion are listed in Table 2, along with their values of B_{12}/P^2, distance, and spin-down energy loss rates. From the four observed γ-ray pulsars, it seems that the efficiency with which the rotational kinetic energy lost by the star is converted to γ rays, $\eta = L_\gamma/\dot{E}$, is a strong function of B_{12}/P^2: $\eta = 1/3{,}000$ for the Crab ($B_{12}/P^2 = 3{,}500$), $\eta = 1/200$ for Vela ($B_{12}/P^2 = 425$), $\eta = 0.2$ for PSR0740 − 28 ($B_{12}/P^2 = 60$, and $\eta = 1.0$ for PSR1822 − 09 ($B_{12}/P^2 = 11$). For nearly all of the pulsars listed in Table 2 which have not been detected as γ-ray emitters, B_{12}/P^2 is in the range 10–50. By adopting a value of $\eta = 0.5$ for these sources, we can calculate the expected γ-ray flux at the Earth for each object: in every case, the expected flux is below the threshold detection level for COS B of $\sim 5\times10^{-11}$ erg cm^{-2} s^{-1}, so the supposition that all of these sources may display outer-gap discharges is not in conflict with present γ-ray observations.

M. A. Ruderman (personal communication) estimates that the thermal X-ray heating L_x of the polar cap resulting from the bombardment of charged particles will be $\sim 0.1\ L_\gamma$. This assumption, together with L_γ and the polar cap area, defines the temperature of the polar cap. For the area A of a single polar cap shown in column 5 of Table 2, we have used[37]

$$A = \pi R^2(\Omega R/c) \tag{5}$$

where Ω is the pulsar angular spin frequency, c is the velocity of light, and we take $R = 16$ km as before. Column 6 shows the derived temperature of the polar cap [see equation (7)], where we have used the measured value of L_γ for the four γ-ray pulsars and have taken $L_\gamma = \frac{1}{2}\dot{E}$ otherwise.

Note that, with a single possible exception, the X-ray fluxes implied by the temperatures and areas in Table 2 are all well below the sensitivities of previous X-ray sky surveys (The sensitivities of such surveys have typically been of order 1 Uhuru flux unit (UFU) = 1.7×10^{-11} erg cm^{-2} s^{-1} in the 2–10 keV band.) The exception is 1929 + 10, for which the predicted 2–10 keV flux should have been only marginally detectable and for which the value of B_{12}/P^2 is close to the cutoff. There is therefore clearly no serious conflict between the predictions of the model and the existing data.

The final column of Table 2 shows the number of 0.1–5.0 keV X-ray counts in the Einstein Observatory IPC expected in a 2,000-s observation. The calculations were performed as described above assuming an interstellar neutral hydrogen density of 1 cm^{-3} and with A as in column 5. We have taken into account the change in the projected surface area of the polar cap as the star rotates and have averaged radiation from both poles of the star by integrating the contribution from a random distribution of angles between the magnetic pole and the rotation axis. Clearly at least half of the sources would be easily detectable in such short observations. Even if the conversion efficiency is as low as $\eta \sim 0.01$, several objects could still be detected in 10^4-s pointings. Such observations will thus apply a stringent test to this or any similar models for γ-ray production in radio pulsars.

Pulsars with values of B_{12}/P^2 below the cutoff of ~ 10 still produce X-ray emission. In the inner-gap models of Ruderman and Sutherland[29], the predicted X-ray luminosity is given by

$$L_x \approx 1\times10^{30}\frac{\varepsilon\cdot B_{12}}{P^2}\ \text{erg s}^{-1} \tag{6}$$

where ε is related to the binding energies of the atoms in the crust of the polar cap ($10^{-3} < \varepsilon < 1$). Thus, expected X-ray luminosities range from $\sim 10^{32}\ \varepsilon$ erg s^{-1} for a 0.25-s pulsar with $B \sim 5\times10^{12}$ G down to $5\times10^{29}\ \varepsilon$ erg s^{-1} for a 1-s source with a field of 5×10^{11} G.

Assuming a black body spectrum for the radiation, we expect a temperature

$$T = \left(\frac{L_x}{A\sigma}\right)^{1/4} = 0.65\times10^6\left(\frac{L_x}{10^{28}\ \text{erg s}^{-1}}\right)^{1/4}\left(\frac{A}{10^9\ \text{cm}^2}\right)^{-1/4}\ \text{K} \tag{7}$$

where σ is the Stefan–Boltzmann constant [5.67×10^{-5} erg cm^{-2} s^{-1} K^{-4}] and A is the surface area of the polar cap. For even the closest pulsars, previous X-ray results are no help in setting a limit on ε: for PSR0950 + 08 with $P = 0.25$ s, $B = 5\times10^{12}$, and $D = 110$ pc, the flux is <1 UFU for $\varepsilon < 0.5$, and for all other pulsars, $\varepsilon = 1$ is allowed. Theoretical arguments (M. A. Ruderman, personal communication) suggest values for ε of $\sim 1/500$ for the fastest pulsars ($P < 0.1$ s) but allow ε to approach unity as the star ages.

The model of Arons and Scharlemann[33] predicts the lowest X-ray flux of any of the polar cap models suggested thus far. The total X-ray luminosity L_x is given by

$$L_x \approx 2\times10^{30}\left(\frac{0.1}{P}\right)^{27/8}\ \text{erg s}^{-1} \tag{8}$$

Thus, for this model, predicted luminosities range from 3×10^{30} erg s^{-1} for the Vela pulsar to 10^{28} erg s^{-1} and 8×10^{26} erg s^{-1} for stars with 0.5-s and 1.0-s periods, respectively. The implied temperatures fall between 0.4 and 2×10^6 K. As recently noted by Arons[35], equation (8) provides a lower limit to polar cap heating in the context of pair production models. The heating could be greater due to trapping of positrons in a region above the pair creation zone[33] or because of unsteady spark discharges as in the Ruderman and Sutherland models.

Table 3 lists the expected Einstein Observatory IPC counts in a 10^4-s observation for a range of polar cap temperatures. A polar cap area of 10^{10} cm^2 and an interstellar neutral hydrogen density of 1 cm^{-3} have been assumed. Setting our detection threshold at 25 counts, we see that only relatively nearby ($\lesssim$1 kpc) sources can be observed, primarily because these low energy X rays (10^6 K ~ 0.1 keV) are absorbed by the interstellar medium. From a compilation by J. H. Taylor (personal communication) of 325 known pulsars, we can expect only marginal detections under the assumptions of the Arons and Scharlemann model[33]. For the Ruderman and Sutherland theory, on the other hand, we can expect up to 20 strong detections, depending on the value of the parameter ε.

Dynamical friction: The widely quoted 'two-component' model of neutron star structure[38] suggests a neutron superfluid interior surrounded and threaded by a charged component tied to the star's magnetic field. The pulsar's deceleration torque forces the charged component to corotate with the field but does not directly affect the neutral superfluid. On average, then, this latter component is always rotating faster than the exterior, and the frictional coupling between the two components will dissipate some of the star's rotational kinetic energy as heat. Greenstein[39], building on the work of Ruderman and Sutherland[40] who demonstrated that a deceleration of differentially rotating superfluid may not tangle the superfluid vortex lines, has generated a self-consistent model for the temperature of a neutron star as a function of time which includes frictional heating. More recent work[41], including a careful treatment of relevant neutron scattering processes (by phonons, electrons and impurities), predicts that the temperature of a 0.5 $M_\odot$ neutron star will remain above 3.5×10^5 K for 10^7 yr. More massive stars maintain even higher temperatures (for $M = 1.5\,M_\odot$, $T \sim 5 \times 10^5$ K).

Independent lines of reasoning[42–45] lead us to believe that virtually all radio pulsars are $<10^7$ yr old. Figure 1 indicates then that, by using the Einstein Observatory, we may put the frictional heating results to a stringent observational test. The fraction of the stellar material in the superfluid state and thus the predicted temperatures are a strong function of stellar mass. If we accept the theory and yet detect no sources, the results may be interpreted as an upper limit on the masses of the various neutron stars involved. Alternatively, temperature upper limits below those predicted will provide information on neutron star structure. For example, the assumption that the superfluid vortex lines do not pin to nuclei in the crust[46] may have to be relaxed, implying that several other interesting phenomena must be considered[47–49]. Another possibility[41] is that neutron stars have larger radii than those derived from any of the currently employed equations of state. Note that, in this regard, if one measures both the luminosity and the temperature (by fitting a black body spectrum) of a neutron star, the radius—a critically important parameter for distinguishing among stellar models—is uniquely determined.

Starquakes: In addition to the potential thermal energy stored in the differentially rotating neutron star, a large amount of elastic and gravitational energy resides in the solid outer crust. The crust is distorted into an oblate spheroid by its rapid rotation. As the rotation rate decreases, the star tries to readjust, but the immense strength of the crustal material (sheer modulus $\mu \sim 10^{29}$ dyn cm^{-2}) resists, until the stress exceeds a critical value and the crust cracks. The resulting starquake was first proposed by Ruderman[50] to account for the sudden speed-up of the Vela pulsar. Although the magnitude of these 'glitches' ($\Delta P/P \sim 10^{-6}$) coupled with their roughly triennial recurrence casts serious doubt on this application of the starquake theory, it has been shown that erratic behaviour is a hallmark of pulsar rotation rates. The Crab pulsar has undergone at least two such discrete spin-ups (although of a much smaller magnitude: $\Delta P/P \sim 10^{-9}$), an older pulsar, PSR1641 − 45, has experienced a Vela-sized glitch, and a 'restless' wandering of rotation rates (often designated as 'timing noise') has been found in a large number of other objects (refs 51 and 52 summarise recent work). A starquake model may well be applicable to many of these phenomena[53].

Table 3 IPC counts from pulsar polar caps at distance D from Earth

Luminosity (erg s^{-1})	T (10^6 K)	Counts*			
		$D = 0.1$ kpc	0.3 kpc	1 kpc	3 kpc

10^{29}	0.65	56	0.68	0.0024	—
10^{30}	1.24	720	26	0.68	0.011
10^{31}	2.0	6,600	470	22	0.74
10^{32}	3.6	80,000	7,600	480	28

* Counts observable in a 10^4-s IPC pointing assuming an area for the polar cap of 10^{10} cm^2 and an interstellar neutral hydrogen density of 1 cm^{-3}.

The energy released in a typical starquake is of the order of 10^{40}–10^{41} erg (ref. 54). In the simple two-component picture described above, one can calculate the interval between such quakes $t_{\rm sq}$ from the measured values of the star's angular frequency Ω, frequency derivative $\dot{\Omega}$, change in frequency as a result of the glitch $\Delta\Omega$, and several parameters which describe the structural properties of the star[54,55]:

$$t_{\rm sq} = \left(\frac{2A^2}{BI}\right)\left(\frac{\Delta\Omega}{\Omega^2\dot{\Omega}}\right) \tag{9}$$

A is the gravitational energy stored in the star by virtue of its rotation, B measures the elastic energy stored in the solid crust due to its distortion, and I is the star's moment of inertia. While these parameters are quite sensitive to assumptions about the stellar mass and crustal properties, expected time scales range from ~10^4 yr for a 1.5 $M_\odot$ star to a few days for stars one-tenth as massive[55]. The observed interval for both the Vela and Crab pulsars is a few years. For older pulsars, only one large glitch has occurred in ~200 pulsar-years of accumulated data, although events with $\Delta P/P \sim 10^{-10}$–10^{-12} may be occurring frequently (hours to weeks) and manifesting themselves as timing noise[53].

This seismic activity results in an average rate of energy input to the neutron star $L_{\rm sq} \sim E_{\rm sq} t_{\rm sq}^{-1}$. If a large fraction of this energy is ultimately radiated away as thermal photons, the time-averaged luminosity will be ~10^{33} erg s^{-1} for both Crab-type glitches and the more frequent, smaller quakes which result in timing noise. Since the thermal time constant for the star is long relative to $t_{\rm sq}$, this process could maintain the stellar surface at temperatures of ~10^6 K for as long as it operates. Many (~50) nearby pulsars (see Fig. 1) would then be observable with the Einstein Observatory. Greenstein[56] has noted that the deposition of energy in a neutron star following a quake may trigger a thermal instability. By extracting energy from the more rapidly rotating interior, the star's temperature may rise significantly, rendering even more distant objects easily observable for some time after the event.

Accretion: It is beyond the scope of this article to discuss the thermal properties of neutron stars in binary X-ray systems where the dominant source of the observed radiation is material accreted from a normal stellar companion. However, we include a note on temperatures expected from an isolated star accreting interstellar material. If current estimates of the pulsar birthrate (~10^{-1} yr^{-1}) (ref. 42) are even approximately correct and if this rate has persisted throughout most of the life of the Galaxy, there are at present a large number of neutron stars (~10^9 or ~1% of the total galactic mass) which are no longer active pulsars. The implied space density is such that the nearest object is expected to be ~10 pc from the Sun. The accretion rate $\dot{M}$ for such a star with mass M travelling at velocity v through the interstellar medium of density ρ was first given by Bondi and Hoyle[57]:

$$\dot{M} = 3.73 \times 10^8 \left(\frac{\rho}{1\ \text{cm}^{-3}}\right)\left(\frac{M}{M_\odot}\right)^2\left(\frac{v}{100\ \text{km s}^{-1}}\right)^{-3} \tag{10}$$

for spherically symmetric accretion. (The very old, slowly rotating stars under consideration here will most likely have little or

Table 4 Hot neutron stars in supernova remnants

† Ref. 69. ‡ Ref. 70.

no relativistic outflow to resist the accretion, although a significant remnant magnetic field may channel the material onto the polar cap regions.) Measured pulsar velocities range from 20 to 500 km s^{-1} (refs 58–62). Adopting a characteristic conversion efficiency of rest mass energy of the accreted material to X rays of 0.1, we find a luminosity of 4.5×10^{29} erg s^{-1} for a 1.3 $M_\odot$ neutron star travelling at 50 km s^{-1} through a medium with $n_H = 1$ cm^{-3}. Such a star would be detectable to a distance of ~50 pc and might be distinguished from other background X-ray sources without optical counterparts by its large proper motion of ~1 arc s yr^{-1}. Stars passing through regions of much higher density (molecular clouds with $n_H \sim 10^6$) will have proportionally higher luminosities, although the increased absorption in such a region will probably render them undetectable.

Thermal dissipation—general considerations: Greenstein and McClintock[5] pointed out that one might expect heating of neutron stars on general grounds from thermal dissipation of rotational energy. We consider here one circumstance under which such dissipation might take place, and then look at the size of the dissipation effects which could be measured in radio pulsars using the Einstein Observatory.

From the expressions for the rotational energy ($E = \frac{1}{2}I\Omega^2$) and angular momentum ($J = I\Omega$) of a rigid body, we have

$$\Delta E = \Omega\Delta J \tag{11}$$

This specifies a relationship between the energy lost and angular momentum lost by a spinning neutron star as it slows down. Now a photon of energy $E_p = \hbar\omega$ emitted tangentially from the light cylinder (at radius $r = c/\Omega$ from the neutron star) will carry off an amount of angular moment J_p given by

$$J_p = \frac{\hbar\omega}{c}r = \frac{\hbar\omega}{\Omega} \tag{12}$$

so that

$$E_p = \Omega J_p \tag{13}$$

that is, radiation from the light cylinder carries off just the right amount of energy per unit angular momentum to satisfy equation (11); there is none left to heat the star. However, this situation is idealised in that it assumes corotation of the neutron star magnetosphere. In some circumstances (when $\mathbf{E}\cdot\mathbf{B}\neq0$ along the field lines), Ω in fact will decrease outwards, causing the angular velocity Ω_{lc} at the light cylinder to be less than the neutron star angular velocity Ω. In this case, we have

$$E_p = \Omega_{lc}J_p < \Omega J_p \tag{14}$$

and the photons do not carry off sufficient energy per unit angular momentum; there is an excess $E_p - \Omega J_p$ per photon which is available to heat the star.

We can characterise such thermal dissipation from a neutron star in terms of the ratio $\eta = L_x/\dot{E}$ of the (thermal) X-ray luminosity to the rotational energy loss rate. Here η is not an efficiency in the usual sense (it could greatly exceed unity, for example, in the case of a hot young star). However, for old neutron stars which have had sufficient time to cool, η does provide a measure of (or upper limit on) the thermal dissipation of rotational energy.

For pulsars with measured period derivatives, one can calculate $\dot{E}$ using theoretical estimates of the moment of inertia[26]. The results generally lie in the range 10^{31}–10^{33} erg s^{-1}. Figure 1 shows that within ~100 pc, neutron star temperatures as low as 250,000 K, corresponding to luminosities of ~10^{31} erg s^{-1}, can be detected with the IPC. Thus in several cases one could establish limits to η of ≲1%. That is, a fairly small fractional thermal dissipation of the rotational energy is, in principle, detectable. Such observations can therefore be expected to provide important constraints for the construction of pulsar models.

Observations

Past results: The observational situation regarding thermal emission from neutron stars has not been as rich in scope or detail as the theoretical work described above. The first attempt to measure the temperature of a neutron star was carried out in 1963 (before the discovery of pulsars) when a group from the Naval Research Laboratory observed a lunar occultation of the Crab Nebula with a rocket-borne X-ray detector[63]. The result showed that the bulk of the X-radiation from the Crab came from a spatially extended source, implying that the temperature of any associated hot neutron star must be $\lesssim10^7$ K. During the next series of Crab occultations, 11 yr later, two groups flew improved detectors and set limits to the temperature of the now-confirmed neutron star in the Nebula of 4.7×10^6 K and ~3×10^6 K, respectively[10,17]. Poor spatial resolution has meant that observations of other SNR with both rocket and satellite experiments have failed to yield significant ($T < 10^7$ K) upper limits for any other young objects. Limits on the temperatures of older neutron stars (radio pulsars) have been calculated using data from the Uhuru all-sky survey[5]; the results for the nearer pulsars ($D < 500$ pc) lie in the range 2.0 to 3.0×10^6 K, far above most of the predictions summarised above. Similar studies using data from Copernicus[64] and ANS[65] have yielded slightly higher limits. A recent optical spectrographic search of several historical SNR[66] showed no evidence of peculiar objects in the central regions of the nebulae, but the limiting magnitude of the survey was m_{pg} 18.5 (see Table 1). Finally, the best limits on neutron star temperatures recorded before this year were obtained with the extreme UV telescope aboard the Apollo–Soyuz mission[67]. The results for three nearby pulsars ranged from 0.5 to 5×10^6 K but are extremely sensitive to the values assumed for the photoelectric opacity of the interstellar gas.

The Einstein Programme: The observing program of the Einstein Observatory calls for observations of over 50 SNR and 35 radio pulsars. All the historical SNR will be studied extensively with both the IPC and the high resolution imager (HRI—spatial resolution of 5 arc s)[18]; over a dozen older remnants within 3 kpc will also be examined closely for hot neutron star remnants. The pulsar survey includes many objects selected on the basis of short periods, large values of B_{12}/P^2, and large amplitude timing noise to provide the most stringent tests possible for the various theories of pulsar emission mechanisms and neutron star structure discussed above. We have also included an unbiased survey of all objects within 350 pc of the Earth. We present below the first results of these observations.

Supernova remnants: Table 4 lists results for 10 of the SNR observed with the Einstein Observatory. The objects are ordered by age with the six historical remnants heading the list; for the remaining objects we have adopted ages determined by application of the standard blast wave (Sedov) model to the X-ray data[68]. The distances adopted are published values and are consistent with those found from the measured hydrogen

* Polar cap areas have been calculated using equation (5) and assuming a radius of 16 km. A hydrogen density of 1 cm^{-3} has been adopted. Changing either of these assumptions by a factor of 2 changes the derived temperature limits by less than 30%. All temperatures and luminosities listed are 3σ upper limits.

column density derived from the X-ray spectra assuming a reasonable range of average interstellar values of n_{H}. (For example, the radio absorption spectrum[73] and X-ray determined column density of Tycho's remant imply a neutral hydrogen density of $\sim$0.5 cm^{-3} for the adopted distance of 3 kpc.) Table 4 also lists the distance in arc min from the centre of the explosion within which a neutron star would be found if it had a transverse velocity of <1,000 km s^{-1}. (The mean velocity of radio pulsars derived from proper motion measurements is $\sim$150 km s^{-1} and the highest observed velocity from a sample of 25 objects is 500 km s^{-1} (ref. 62).) The temperature upper limits for a point source of X rays in these remnants is also given. For the Columbia IPC observations, we have determined a 3σ upper limit to a point source counting rate by sliding a 2 arc min radius circular detection cell through the allowed region and determining the local background level from a concentric annulus with inner and outer radii of 2 and 3 arc min, respectively. This value is then converted to a temperature limit following the procedure and adopting the assumptions outlined above. For Kepler's remnant, preliminary HRI data have recently become available, and we have used these with a 12 arc s search cell to set an upper limit. Similar procedures were used for the remaining observations (see cited refs for details).

Of the six historical SNR, only the Crab is known to contain a remnant neutron star. The analysis of Einstein data for this source is not yet complete, so its temperature limit remains at the value from the lunar occultation experiments. For all of the remaining historical objects, the measured temperature limits fall below the lower limits predicted by nearly all current work on the cooling of neutron stars.

Among the four older sources, only Vela was known to contain a neutron star, and again the situation remains unchanged. The limits on the remaining three sources are also either below or just consistent with the lower bounds derived from standard cooling theories. However, a point source has tentatively been detected at the position of the Vela pulsar[73], and the derived temperature of 1.5×10^6 K is consistent with that expected for a 10^4 yr old star. The observation is somewhat complicated by the fact that the point source is surrounded by a small (1 arc min) region of diffuse emission and the interpretation of the central cusp of this nebula as thermal radiation from the neutron star should be treated with caution.

Radio pulsars: Seven nearby radio pulsars have been observed in the Columbia survey; the sources are listed in Table 5. No sources have been detected at the nominal pulsar positions. Upper limits to the IPC counting rates and the resultant temperature limits for thermal stellar emission were derived as discussed above. Limits on polar cap temperatures and total luminosities are also given. All of these values are typically an order of magnitude below those previously available and provide interesting constraints on several theoretical problems.

Discussion

An observational determination of the cooling rate for young neutron stars is a fundamental input to models of neutron star structure. Such a determination is within the capabilities of the Einstein Observatory. The results on the historical SNR imply either that many contain no neutron star remnant, or, in the context of our current understanding of cooling theory, pion condensation may need to be invoked in order to enhance the cooling rates. In view of the importance of the latter possibility, we wish to encourage thorough theoretical studies of neutron star cooling to verify this conclusion.

The option that some supernovae leave no neutron star remnant also holds important implications. While supernova models which produce neutron stars have recently been constructed, the alternatives of a black hole remnant or an explosion which dissipates the entire star will have to be explored. A more immediate problem, however, concerns the pulsar birthrate. The current best estimates for the galactic supernova rate is one per 30–50 yr. The pulsar birthrate has been estimated to be one per 5 yr (ref. 42). This latter value is sensitive to several assumptions, such as the electron density of the interstellar medium which sets the pulsar distance scale and the 'beaming factor' which specifies what fraction of the total population is observable. Taylor and Manchester[42] assume a pencil beam radiation pattern for pulsars and adopt a beaming factor of 20%. If, in fact, the pattern were closer to a fan beam such that essentially all pulsars were observable, much of the above-noted discrepancy would disappear. The fact that only one of the five supernovae of the past 1,000 yr has left behind an observable radio pulsar has been used as an argument in favour of the pencil beam model. However, the lack of an X-ray point source in the remaining objects may suggest that only a small fraction of SN events leave neutron star remnants and, thus, even if a fan beam model is adopted, the discrepancy between supernova and pulsar production rates will remain large. Some alternative production mechanism for neutron stars, such as accretion pushing a white dwarf over the Chandrasekhar limit, may have to be considered.

While the observation of newly formed neutron stars in supernova remnants promises to yield valuable information for our understanding of neutron star matter, X-ray data on the thermal properties of radio pulsars will provide constraints on models for many aspects of pulsar behaviour, including crust–core coupling, starquakes, pulsar emission mechanisms, and so on. Our preliminary results illustrate the model testing that such observations may provide, even without the actual detection of thermal radiation. In testing polar cap emission models we have calculated the expected luminosities based on equations (5)–(8); for sources without measured values of $\dot{P}$ (and, thus, no computed value for the field strength), we have assumed $B_{12} = 1$. While none of these objects is expected to exhibit the intense radiation characteristic of the γ-ray emitting pulsars, three of the sources, PSR1642−03, PSR1706−16 and PSR1952+29 constrain the value of ε in the inner gap theory[29] to be $\varepsilon \lesssim 0.1$ (the limits are still above the predictions from the minimum flux polar cap model of Arons and Scharlemann[33]). Using the frictional heating model[40], we can set mass limits on the three sources with temperatures of <300,000 K of $<0.5\,M_{\odot}$, significantly below the measured masses of neutron stars in binary systems. Alternatively, in a model-independent way, we can say that for PSR1642 − 03 and PSR1706 − 16, the efficiency for conversion of rotational to thermal energy is <1%. More results will make all these constraints much more definitive as we open a new window for observational studies of neutron stars through the search for their thermal X-ray emission.

We thank M. A. Ruderman for a critical reading of the manuscript and for helpful discussions. This work was supported by NASA under contract NAS8-30753.

ARTICLES

Reactivation of basement faults and crustal shortening in orogenic belts

J. A. Jackson

Department of Geodesy and Geophysics, Madingley Rise, Madingley Road, Cambridge, UK

During the early evolution of some fold mountain belts old listric normal faults in a stretched and thinned basement beneath the sedimentary column may become reactivated as thrust faults. The reversal of motion on these faults allows considerable shortening to occur without subduction or excessive thickening of continental crust. This reactivation hypothesis is supported by the present-day seismicity of the Zagros collision zone and the structure of sedimentary basins.

PLATE tectonics has been very successful in describing the overall deformation and kinematics of the large ocean basins but there is no comparably simple description to account for the general behaviour of the continents.

Recent studies of continental deformation have indicated some of the notable differences between oceanic and continental behaviour. The major strike-slip faults in the Alpine–Himalayan Belt[1-3] seem to slide large wedges of continental material away from zones of collision, thereby avoiding the excessive thickening of continental crust. Such large strike-slip features are easily visible on satellite photographs, and their spectacular nature, together with various models proposed to explain their large-scale significance[2-5], have to some extent diverted attention from the large areas of the Alpine–Himalayan belt which are undergoing active compression or extension.

These studies show that present day continental deformation is not a simple phenomenon. The deformation was unlikely to be less complicated in the past, and models for the evolution of old fold mountain belts based on oceanic compressive margins probably have limited value. In particular, little progress seems to have been made towards solving the classical space problem in orogenic belts: if the upper crust is shortened several tens of kilometres by folding and thrusting, what happens to the basement? Very often the sediments involved in foreland folding and thrusting are separated from their basement by a decoupling horizon, often of evaporites or shale, which provides a surface of décollment separating structures above from those below. Subduction has been discussed as a mechanism for removing continental crust[6,7], and it has been concluded that the buoyancy of continental material should hinder its subduction and lead to crustal thickening instead[7,8].

Sedimentary basins

Helwig[9] pointed out how this space problem in shortened orogenic belts is greatly diminished if the basement underneath the folded belt is thin to start with. Subsequent shortening then

0028-0836/80/040343—04$01.00

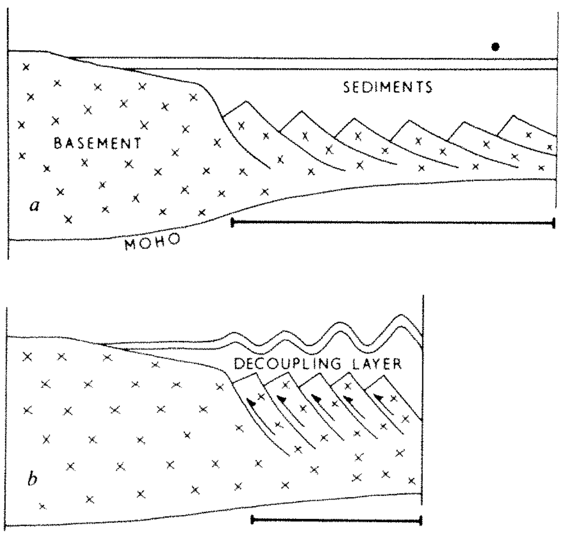

Fig. 1 Reactivation of basement faults. *a*, Sedimentary basin formed by deposition on a basement which has been stretched and thinned by listric normal faulting. *b*, When the basin contracts motion is reversed on the normal faults which are now used as thrusts. The sedimentary column takes up the shortening by folding.

thickens it, but not to an abnormal degree. McKenzie[10] has since shown that the subsidence of continental sedimentary basins can be quantitatively described by a simple model in which the lithosphere is rapidly stretched and thinned, sinks quickly to maintain isostatic equilibrium, and then sinks more slowly as it cools in a manner similar to that described by the successful oceanic models[11]. The initial stretching of the basement at shallow depths is thought to occur by listric normal faulting and thereafter stretching ceases and subsidence continues without further faulting. This model is supported by the crustal thickness and heat flow of the Aegean, which is still being stretched by normal faulting, and seems to account well for the subsidence history of the North Sea[12] and many of the intra-Carpathian basins[13], all of which show an initial normal faulting episode followed by subsidence with no further faulting. Royden *et al.*[14] have shown that the gross features of the same model will account for the stretching and subsidence preceding the break-up of a continent to form an Atlantic-type margin. It thus seems probable that thick sedimentary sequences generally form on thin extended basement which was stretched by normal faulting. Evidence for attenuated basement is best seen in seismic refraction profiles and has been demonstrated in the North Sea[15,16] and Pannonian Basin[13]. The Aegean is in an earlier stage of development, with high heat flow[17], thin crust[18,19] and active normal faulting[20]. Helwig's[9] suggestion may, therefore, have some validity and the basement under the thick piles of sediments that make up fold mountain belts was probably thin before the onset of compression. The early stages in the development of a fold mountain belt following continental collision are now considered.

It is proposed that thick sediments were initially deposited on a subsiding basement which had been stretched by normal faulting (Fig. 1). The faulting was very probably of a low angle listric nature, spread over a region several tens of kilometres wide as observed in the Great Basin[21]. As stretching proceeded, an Atlantic-type margin was ultimately formed with thick sediments on the continental shelf overlying a thin basement. In the early stages of continental collision the basement takes up the shortening by reversing the sense of motion on the pre-existing normal faults (Fig. 1), which are now used as thrusts (reverse faults). The basement tends to return to its original thickness while the overlying sedimentary column, having been deposited on an extended basement, is forced to take up the shortening by folding. Thus in the early stages of collision the space problem is avoided without thrusting continental basement into the mantle or thickening it beyond its original (unstretched) state.

Seismicity of the Zagros mountains, Iran

The Zagros mountains of Iran provide an example of a young fold mountain belt currently shortening as a result of the collision between Arabia and Iran. The structure of the Zagros is very simple superficially, with a thick conformable sequence of Palaeozoic–Mesozoic–Tertiary shelf deposits warped into gentle folds in a single process in the latest Tertiary[22–24]. Long linear fold axes and seismic activity that is predominantly thrusting of the same orientation (refs 1, 25 and Fig. 2) both indicate a general NE–SW shortening. Although strike-slip faulting is present on the north-east front of the Zagros, especially in the north[26,27], it is not seen in the fault plane solutions of the folded belt (Fig. 2) and the relative motion between Arabia and Iran is normal to the strike of the belt.

The Folded Belt[22] of the Zagros is seismically very active with earthquakes spread over an area ∼300 km wide and with a distinct northeastern boundary roughly coincidental with the Zagros Thrust Line (or Main Zagros Reverse Fault, Fig. 2 and ref. 27), which in turn marks the edge of the Zagros sedimentary trough. These earthquakes are probably all shallower than 40 km (see ref. 28 for discussion) and there is no reliable evidence that they increase in depth towards the north-east margin of the Zagros. Consequently there is no evidence for seismic shortening on a single shallow-dipping plane, as is commonly assumed for areas of oceanic underthrusting. Fault plane solutions in the Zagros consistently show thrusting with comparatively high angle (40–50°) fault planes (ref. 29 and Figs 2 and 3). This is in marked contrast to the shallow angle (0–10°) thrusting which occurs in areas where oceanic underthrusting of continents is or was taking place, such as the Hellenic Arc, Makran and Eastern Himalaya[29]. The seismic activity of the Zagros Fold Belt reflects high angle reverse faulting on a large number of faults distributed across the whole width of the belt.

Although microearthquake surveys in the Zagros have shown that small earthquakes do occur within the sedimentary column[30–32] it has been suggested that the largest shocks, which reach m_b 6.0–6.3, have focal depths of about 15 km, that is, beneath the sedimentary cover and in the crystalline basement. Berberian and others[27,33] reached this conclusion from a study of damage distributions and because of the lack of surface faulting

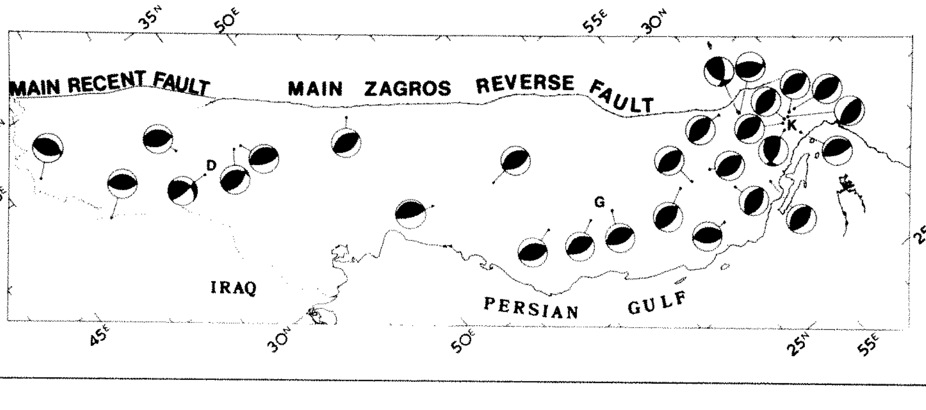

Fig. 2 Fault plane solutions from the Zagros from ref. 25, to illustrate the high angle thrusting in the Folded Belt south-west of the Main Zagros Reverse Fault (called the Zagros Thrust Line by Stocklin[24] and others). D, G and K mark the positions of the Dezful Embayment, Ghir and Khurgu earthquakes. Black quadrants are compressional.

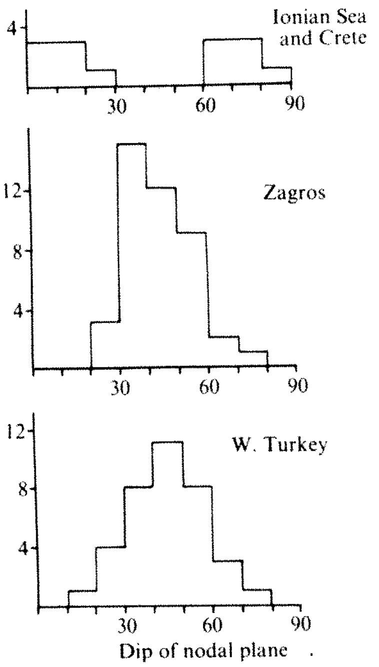

Fig. 3 Histogram to illustrate the high angle (40–50°) nature of the fault planes in the Zagros compared with those in the Ionian Sea and Crete, which are both part of the Hellenic arc where active subduction (intermediate depth earthquakes and andesitic volcanism) is taking place and thrusting is on shallow dipping (0–10°) fault planes. The Zagros histogram is similar to that of western Turkey where active extension by normal faulting is occurring. Dips are taken from the fault plane solutions in refs 1, 20, 25 and are mostly well controlled in the Zagros, even though the strikes may not be.

in the Zagros after major earthquakes. At the base of the sedimentary column is the thick infracambrian Hormuz Salt Formation, and additional salt is present in the Jurassic and especially in the Tertiary Gach Saran Formation[23]. Any basement faulting is unlikely to propagate to the surface through these ductile horizons. It is also unlikely that shocks the size of the 1972 Ghir earthquake ($m_b = 6.0$), with a source dimension of about 30 km (refs 34, 35), could be contained within 6 km of sediment thickness without showing surface faulting. The most convincing evidence of basement faulting comes from detailed examination of the long period teleseismic waveforms from Zagros earthquakes. Shocks in the magnitude range m_b 5.5–6.0 are common in the Zagros, and their far-field long period radiation is usually very simple. In particular, the first cycle of the waveform can easily be modelled and is very dependent on focal depth. At long periods crustal structure has little effect on the first cycle of the waveform if the source is above the Moho, and earthquakes of this size can be modelled effectively by a single source as they rarely exhibit multiple rupture characteristics. Studies of the waveforms[36] demonstrate that in three areas of the Zagros—the Dezful Embayment, Ghir and Khurgu (Fig. 2)—earthquakes occurred at depths of 12–15 km. In each case this is below the probable thickness of the sediments[37–39]. An example of this waveform modelling is shown in Figs 4 and 5. There is, therefore, the strong probability that the basement beneath the Zagros Fold Belt is deforming by high angle (40–50°) reverse faulting.

Evolution of the Zagros

There is much evidence that, during the Mesozoic and Tertiary, what is now the folded belt of the Zagros was a subsiding continental margin[23,24,40,41]. As the basement was almost certainly cut by normal faults which caused its extension before the onset of subsidence and sediment deposition in the Permo-Triassic, the present day reverse faulting is probably happening on the old normal fault surfaces which have been reactivated. This would explain the high (40–50°) rather than low (0–10°) angle nature of the fault dips, and the similarity of the dips of fault planes in western Turkey (currently extending by normal faulting) with those in the Zagros (Fig. 3). Reactivation of old faults is a common and important phenomenon[42] and the reactivation of old normal basement faults as thrusts has been reported from Chile[43]. The possibility of reactivation in the Zagros was alluded to by Falcon[22], and Stocklin[24] proposed that the Zagros Thrust Line itself was a reactivation of an old Precambrian rift boundary which controlled the distribution of the Hormuz salt. The north-west trend of the Zagros is found in the Precambrian of the north-east Arabian shield[24]. The same trend is evident in the sediment isopachs of the northern Zagros (Lurestan and Kuhzistan) throughout the Mesozoic[44,45].

An objection to this suggested basement involvement is the evidence from seismic reflection lines in old fold mountain belts, such as the eastern Rockies[46,47], which shows apparently undeformed Precambrian shield dipping gently beneath the foreland folds. However, it is likely that in these older orogenic belts the amount of shortening involved is considerably greater (~160 km, or 50%, in the Canadian Rockies[46,47] than that which has taken place so far in the Zagros Fold Belt (about 20–50 km, or 20%, ref. 22) which is in a much younger state of development. The contraction mechanism proposed here will presumably work until the reverse motion on old normal faults restores the basement at least to its original thickness. Thereafter the basement will either become thicker than its pre-stretched state or be thrust into the mantle. It is probable that the sediments of the folded belt of the Zagros are still almost above the original basement on which they were deposited. As shortening continues, the folded cover will start to migrate south-west over the undeformed Arabian shield, separated from its basement by the décollment at the level of the Hormuz salt. The foreland folds of the Rockies, Appalachians and Jura are no longer above their original basement which was left behind in the internal zones. Those orogenic belts which are known to have thick crust

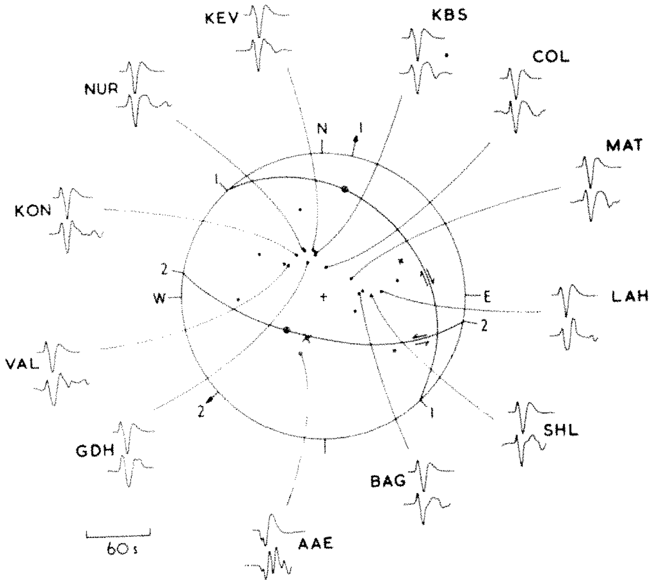

Fig. 4 Waveforms from a shock in the Dezful Embayment (Fig. 2) on 5 June 1977. The fault plane solution shows predominantly thrusting. Filled symbols are compressional first motions, open are dilatational and crossed are nodal. Synthetic waveforms matched the observed well at a focal depth of 12 ± 3 km (Fig. 5). For each station the observed seismogram is shown beneath the synthetic. Note particularly the kink in the downward pulse at AAE which is the pP arrival. Numbered arrows mark the slip vectors corresponding to planes 1 and 2.

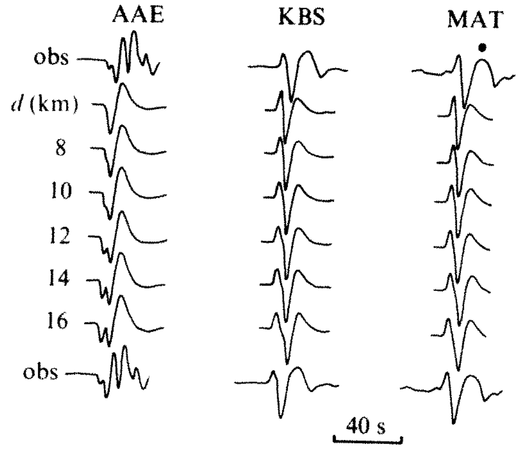

Fig. 5 Variation of waveform with depth (*d*) at selected stations in Fig. 4.

are all older and in more advanced states of development than the Zagros and have involved more shortening. An interesting prediction of the scheme proposed here is that, in the initial stages of continental collision, the basement under the orogenic belt should be thinner, not thicker than that of its neighbouring craton. At present no adequate refraction data from the Zagros is available to test this.

Conclusions

The origin of a young folded belt proposed here accounts well for the present-day seismicity and deformation of the Zagros. Such an origin involves the reactivation as thrusts of listric normal faults in a stretched and attenuated basement on which thick sediments of the Atlantic-margin type were deposited, and does not necessitate either abnormal thickening or subduction of continental crust in the early stages of continental collision. How long this process can continue is not clear. It is unlikely to account for all the features of older orogenic belts which have involved considerably greater shortening. However, even if operative in only the early stages of collision, it greatly reduces the space problem encountered in palinspastic reconstructions of orogenic belts[49].

I thank D. H. Matthews, J. G. Sclater, D. P. McKenzie, G. C. P. King and T. J. Fitch for helpful discussions, D. P. McKenzie for unpublished fault plane solutions used in Figs 2 and 3, and T. J. Fitch for help in producing Figs 4 and 5.

Lateral mobility in reconstituted membranes—comparisons with diffusion in polymers

Melvin Schindler* & M. J. Osborn
Department of Microbiology,

Dennis E. Koppel
Department of Biochemistry, UCONN Health Center, Farmington, Connecticut 06032

The diffusion coefficients (D) *of lipopolysaccharide, phospholipid, and* Escherichia coli *matrix protein were determined in reconstituted multibilayer membranes. Over a range of protein concentration of 0–60% by weight,* D *for lipopolysaccharide decreased 10-fold, whereas* D *for phospholipid remained essentially constant. The diffusion coefficient of matrix protein at a concentration of 50% was* $\leq 10^{-12}$ cm^2 s^{-1}*. These results are discussed in terms of a model for diffusion in polymeric networks.*

THE fluid dynamics of biological membranes has been clearly established with the emergence of physical techniques to determine quantitatively the diffusion characteristics of membrane components[1–4]. Measurements of diffusion constants by fluorescence photobleaching methods have provided evidence for the lateral mobility, over micrometre distances, of lipids, glycolipids and integral membrane proteins in eukaryotic cells (see, for example, refs 5–10). In addition, measurements of lipid and glycolipid diffusion have been obtained in phospholipid model membrane systems devoid of proteins[11,12]. To extend these results and provide a systematic approach to an understanding of membrane diffusion, we have developed a reconstituted membrane system containing an integral membrane protein. We believe that the techniques used can be

extended to reconstitute other membrane systems for mobility investigations.

The reconstituted system to be described is composed of matrix protein, phospholipids and lipopolysaccharide isolated from the outer membrane of Gram-negative bacteria, *Escherichia coli* and *Salmonella typhimurium*. The outer membrane contains approximately 20–25% phospholipid, 30% lipopolysaccharide and 45–50% protein[13]. The matrix protein of *E. coli* (molecular weight of monomer, 36,000) is a transmembrane protein which forms hydrophilic pores, allowing low molecular weight carbohydrates, amino acids and ions through the permeability barrier of the outer membrane[13]. In association with lipopolysaccharide, it forms a phage receptor[14]. Electron microscopy of *E. coli* membrane preparations has demonstrated that matrix protein forms a highly periodic monolayer consisting of homopolymer trimers interacting to cover the peptidoglycan surface[15,16]. Reconstituted in vesicles, it retains its pore function[17], can inactivate phage and forms voltage-dependent aqueous channels in planar lipid bilayers[18]. Lipopolysaccharide is an amphipathic glycolipid that is only found in the outer membrane of Gram-negative bacteria and seems to be a major contributor to the permeability barrier in these organisms[19].

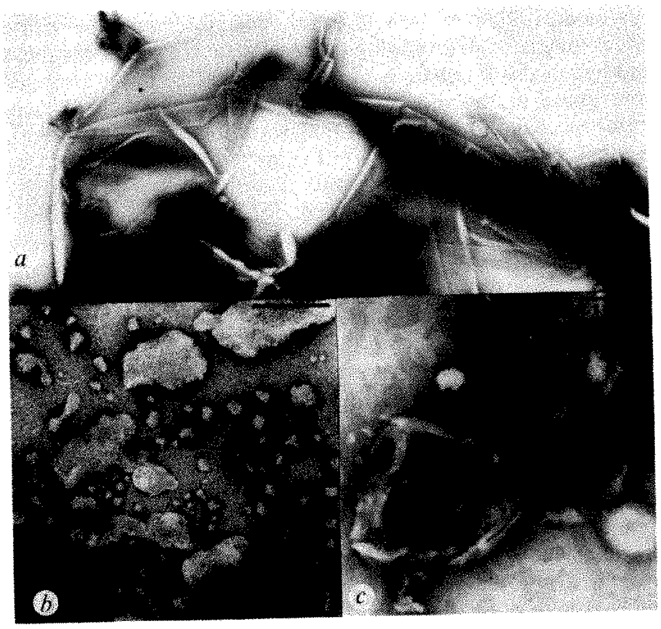

Fig. 2 Electron microscopy of vesicle preparations. Vesicles composed of phospholipid/matrix protein/lipopolysaccharide at ratios of 1:1.3:1 (*a*), 1:4:1 (*b*), and 1:0:1 (*c*), were negatively stained with 2% uranyl acetate on Formvar-coated specimen screens. Samples were examined with a Hitachi 11 E electron microscope at 75 kV. Scale bar, 250 nm.

The experiments to be described suggest that diffusion of membrane components in the plane of the membrane is analogous to the diffusion of non-electrolyte molecules in a polymer network. Lieb and Stein have presented such a comparison for diffusion *through* biological membranes[20,21]. Our results should enable us to extend their observations and make some general statements concerning two-dimensional diffusion in membranes.

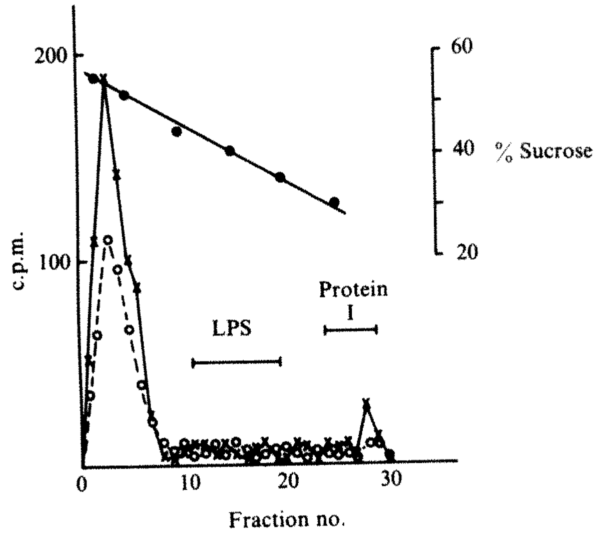

Fig. 1 Sucrose density gradient of reconstituted vesicle preparation (1:1.3:1, phospholipid/protein/lipopolysaccharide). Vesicles were prepared by the method of Nakae[17] with minor modifications. Phospholipids were isolated from *E. coli* K12 grown at 37 °C by the method of Raetz and Kennedy[34]. Lipopolysaccharide was derived from strain G30 of *Salmonella typhimurium* by the method of Galanos *et al.*[35]. Further purification was achieved by electrodialysis[36]. Matrix protein was isolated by the procedure of Hindennach and Henning[37]. The protein was then applied to a P-150 column (2.5 × 40 cm) water jacketed and eluted at 37 °C with 10 mM Tris, 2% SDS, 0.5 M NaCl and 5 mM EDTA to remove bound lipopolysaccharide. The protein was solubilised by slow dialysis of an 8 M urea–protein solution against 10 mM HEPES, *p*H 7.5. Protein concentrations were monitored by modified Lowry procedure and spectrophotometrically using an extinction coefficient, $A_{280}^{1\%} = 1.3$. Following an overnight incubation procedure[17], 20 mM disodium EDTA was added to the vesicle preparations, which were then placed on ice for 10 min and dialysed overnight at room temperature against 10 l of distilled water. Vesicles (50 µl) containing ^{3}H-labelled phospholipid (×) and ^{14}C-labelled lipopolysaccharide (○) were resuspended in 1 m of 25% sucrose (w/w) in 10 mM HEPES, *p*H 7.5, and layered onto a sucrose gradient containing 2.1 ml each of 50, 45, 40; 35 and 30% sucrose (w/w) over a cushion (0.5 ml) of 55% sucrose. All sucrose solutions contained 10 mM HEPES, *p*H 7.5. Centrifugation was carried out in a Beckman SW 41 rotor at 36,000 r.p.m. for 18 h at 4 °C. Gradients were fractionated by puncturing the bottom of the centrifuge tube and collecting drops. Protein was assayed by fluorescamine labelling and fluorimetric analysis of each gradient fraction.

Characterisation of vesicles and multibilayers

Isopycnic sucrose gradient centrifugation of vesicles (Fig. 1) showed a single homogeneous peak containing phospholipid lipopolysaccharide and protein. Figure 2*a* is a negative-stained preparation of the vesicles (phospholipid/protein/lipopolysaccharide, 1:1.3:1) before multibilayer formation. At protein concentrations of >20% by weight, long sausage-shaped sacks (~1 µm long) were the predominant vesicle species with a subpopulation of smaller vesicular structures which were probably intermediates between small unilamellar vesicles and the larger cylindrical vesicles. Figure 2*b* is a negative-stained preparation of vesicles (1:4:1) at higher resolution demonstrating ordered membranous lattice structures. These structures do not appear in protein-free vesicles (Fig. 2*c*). Comparison of Fig. 2*b* and *c* provides evidence that (1) the matrix protein is physically integrated into the membrane, as also indicated by the sucrose density gradients, and (2) the protein is uniformly distributed over the surface of the membrane. Figure 3*a*, *b* shows thin sections of multibilayer preparations from such vesicles. These sections indicate that stacked bilayers are formed from the vesicles and that these bilayers extend over long distances (approximately 1–2 µm in the figure).

Determination of diffusion coefficients

Lateral diffusion coefficients of fluorescently labelled phospholipid, lipopolysaccharide and protein were determined in 'fluorescence redistribution after photobleaching' experiments. In this technique (also referred to as 'fluorescence photobleaching recovery'), translational transport in the plane of the membrane is characterised by the kinetics of fluorescence 'recovery', due to the spatial redistribution of fluorescently labelled molecules after an initial, localised photobleaching pulse. A new multi-point analysis was used in which the fluorescence redistribution is monitored by a focused laser beam sequentially positioned at each of several locations immediately adjacent to the bleached area. The spatial information thus obtained provides sensitivity to possible systematic flow and a direct means of determining characteristic transport distances and hence absolute values of transport coefficients. A detailed description of the theory and experimental optics and electronics used in the multi-point analysis is presented elsewhere[22]. Briefly, a standard fluorescence microscope, equipped for incident light excitation, is used to focus the laser beam onto the sample and collect the fluorescence for detection by a thermoelectrically cooled photomultiplier tube. The precise orientation of the incident laser beam, and hence the location on the sample of the focused spot along a scan axis, is modulated by a servo-activated galvanometric optical scanning mirror. The laser intensity is switched between monitoring and bleaching levels, differing by a factor of 2×10^4, by a combination of diaphragms, beam-splitters and an electronic shutter.

N-4-nitrobenzo-2-oxa-1, 3-diazole (NBD) fluorescence was monitored with an incident wavelength of 4,765 Å and a combination of Leitz dichroic mirror TK510 and barrier filter K510. Rhodamine fluorescence was monitored with an incident wavelength of 5,309 Å and a combination of Leitz dichroic mirror TK580 and barrier filter K570. The membranes were examined before the photobleaching experiments with dark-field or phase-contrast transmitted light illumination. All photobleaching measurements were carried out with a 10×/0.25 NA dry achromat.

In most experiments, the fluorescence was monitored at three positions on a scan axis, with Δx, the position of the monitoring beam relative to the bleach position, equal to 0 and $\pm3.0\ \mu\text{m}$. Experimental values of $F(\Delta x, t)$, the fluorescence intensity at a time t after the bleaching pulse, were fitted to the following form

$$F(\Delta x, t) = F(-)\{1-\beta\alpha(t)\exp[-(\Delta x)^2/w^2(t)] - (1-\beta)\alpha_0\exp[-(\Delta x)^2/w_0^2]\} \qquad (1)$$

with

$$\alpha(t) = \alpha_0/(1+t/\tau_\text{D}) \qquad (2)$$

$$w^2(t) = w_0^2(1+t/\tau_\text{D}) \qquad (3)$$

where

$$\tau_\text{D} = w_0^2/4D \qquad (4)$$

is the characteristic time for diffusion; $F(-)$ is the prebleach fluoresence intensity; α_0 is a constant ($0<\alpha_0<1$) which characterises the extent of bleaching; β is the fractional recovery at infinite time; and w_0 is the $1/e$ radius of the assumed gaussian profile of the fluoresence scan at time zero. From each set of data, we computed values of β, τ_D, w_0, and hence D.

Separate control experiments were carried out to check for the possible occurrence of dye-sensitised protein aggregation induced by intense laser irradiation. After the same irradiation doses that produced extensive protein cross-linking in red cell ghosts labelled with fluorescein–concanavalin A (ref. 23), we observed no evidence of protein aggregates on SDS-polyacrylamide gels of labelled vesicles containing 50% protein.

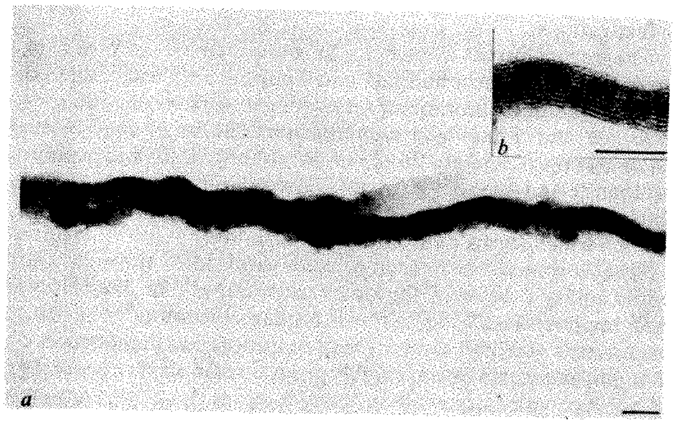

Fig. 3 *a*, *b*, Thin section of multibilayers prepared from vesicles (ratio 1:1.3:1). Multibilayers were prepared by using several techniques cited in Wu *et al.*[12]. A 15-μl portion of the vesicle preparation was applied to a slide resting on a slide warmer set at 45 °C. After drying, another 15 μl was applied. This procedure was followed until 90 μl of vesicle preparation had been deposited on the slide. The slide warmer was then switched off and the slide allowed to reach room temperature. To rehydrate the membrane, a coverslip was sprayed with an aerosol containing 50 mM HEPES, *p*H 7.5, providing a uniform distribution of small droplets. The wetted side of the coverslip was then placed face down on the dried vesicle preparation. A Teflon cover was put over the coverslip and the slide placed between two aluminium blocks. A 25 lb lead brick was then placed on the top block for 20 s. Following pressing, the slide was removed and the coverslip edges sealed with melted paraffin. Samples to be prepared for thin section were sealed with paraffin on only two sides of the coverslip. The multibilayers were fixed in 2% glutaraldehyde and 0.1 M sodium cacodylate, *p*H 7.35, by placing pieces of filter paper over the sample and soaking the paper in fixative. The preparations were left overnight at 4 °C after changing the filter paper and then applying buffer. Post-fixation (1 h, 24 °C, 2×) was carried out with 2% OsO_4 using the filter paper technique of application. After a buffer rinse with filter paper the samples were dehydrated in series ethanols to 100%. During dehydration the coverslip floated off with the multibilayers remaining attached to it. The preparations were then infiltrated with three changes of Epon 812 (multibilayer side), embedded in Epon 812 and hardened at 60 °C for 2 days. Various areas were selected and then re-embedded to allow sectioning normal to the membrane surface. Thin sections (silver) were stained on the grid with 2% uranyl acetate followed by Reynold's lead citrate, 5 min each. Scale bar, 100 nm.

Diffusion of lipopolysaccharide, phospholipid and matrix protein

All diffusion measurements were carried out using a double label: *N*-4-nitrobenzo-2-oxa-1, 3-diazole phosphatidylethanolamine (NBD-PE) and rhodamine-labelled lipopolysaccharide or matrix protein. In each instance, recovery of NBD fluorescence was measured in tandem with measurement of rhodamine recovery on the same patch of reconstituted membrane. All measurements can therefore be related to a phospholipid mobility allowing accurate comparisons. Figure 4*a* shows a set of fluorescence recovery curves for rhodamine-labelled lipopolysaccharide in a multilayer membrane 1:1.3:1 by weight phospholipid/protein/lipopolysaccharide. The fluorescence was monitored at three equally spaced positions with a 3.0 μm separation. Note that the two curves measured at 3.0 μm on either side of centre are identical, consistent with an isotropic diffusive transport mechanism. The solid lines are theoretical curves calculated according to equations (1)–(4), corresponding to $\beta = 0.80$, $\tau_D = 153$ s, $w_0^2 = 10.8\ \mu\text{m}^2$ and $D = 1.76\times10^{-10}\ \text{cm}^2\ \text{s}^{-1}$. Figure 4*b* shows fluorescence recovery curves for NBD-PE and rhodamine-labelled lipopolysaccharide measured on a single patch of membrane, of the same composition as described above. For simplicity, only the fluorescence measured coincident with the bleaching positions is shown. For comparison, the fractional recoveries

$$f(t) = \frac{F(0, t) - F(0, 0)}{F(0, \infty) - F(0, 0)} \qquad (5)$$

are plotted on a normalised time axis, t/w_0^2. These data correspond to a value of $D_\text{LPS}/D_\text{PL} = 0.14$ (D_LPS and D_PL refer to the diffusion coefficients of lipopolysaccharide and phospholipid, respectively).

Figure 5 is a compilation of our results for NBD-PE and rhodaminated lipopolysaccharide. With the exception of the open points (see below), the data were derived from membrane preparations with a ratio of phospholipid to lipopolysaccharide of 1:1. At 24 °C, the mobilities of lipopolysaccharide and phospholipid are essentially the same in the absence of protein ($D_\text{LPS} \simeq 1\times10^{-9}\ \text{cm}^2\ \text{s}^{-1}$; $D_\text{PL} \simeq 1.5\times10^{-9}\ \text{cm}^2\ \text{s}^{-1}$) (Fig. 5*a*). The mobility of phospholipid in this system is about an order of magnitude slower than reported for model systems containing a single phospholipid species[11,12]. Decreased phospholipid mobilities have already been noted in mixed lipid systems[1,24]. The rate of phospholipid diffusion is practically independent of protein concentration. However, D_LPS decreases by a factor of 10 between 0 and 60% protein content.

The open points in Fig. 5 represent data from membranes with a phospholipid to lipopolysaccharide ratio of 12:1. These values are in line with the others, suggesting that diffusion rates are primarily determined by the total protein concentration and not the individual ratios of phospholipid or lipopolysaccharide to protein. Note also that the diffusion coefficient for lipopolysaccharide is significantly greater at 37 °C than at 25 °C, whereas that for the phospholipid remains practically the same; $D_{\mathrm{LPS}\ 37^{\circ}\mathrm{C}}/D_{\mathrm{PL}\ 25^{\circ}\mathrm{C}} \sim 2$, whereas $D_{\mathrm{PL}\ 37^{\circ}\mathrm{C}}/D_{\mathrm{PL}\ 25^{\circ}\mathrm{C}} \sim 1$ for 40% protein. Matrix protein at concentrations of 40% or 60% demonstrated extremely low diffusion coefficients at room temperature ($\leq 10^{-12}$ cm^2 s^{-1}).

In all our measurements, the phospholipid recovery was ~100% whereas that for lipopolysaccharide was ≥75%. In each case, recovery was monophasic. Thus, there is no evidence of an immoblised 'boundary' lipid; on a time scale of seconds—the time required for diffusion over micrometre distances—all the lipid is exchangeable.

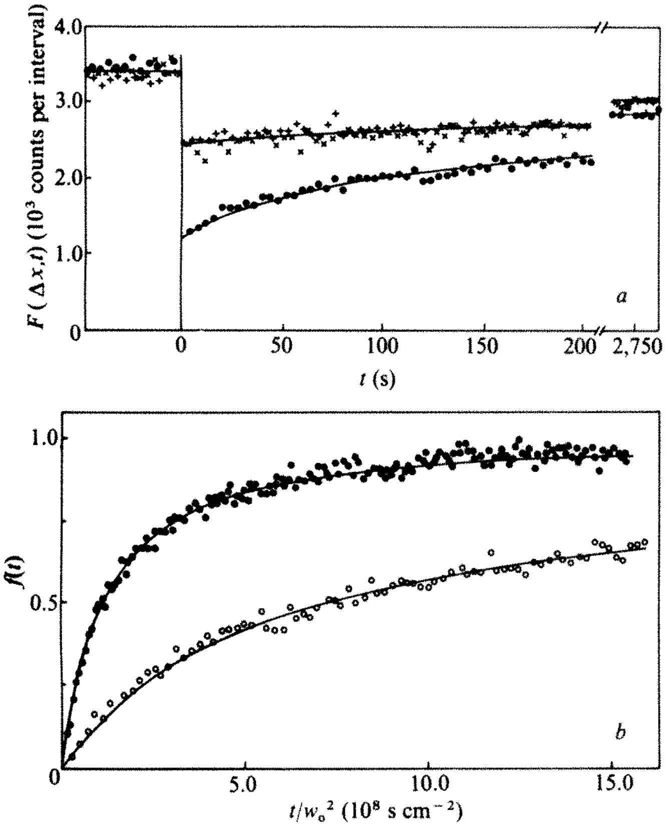

Fig. 4 *a*, Fluorescence recovery curves for rhodamine-labelled lipopolysaccharide in a multibilayer membrane 1:1.3:1 by weight phospholipid/protein/lipopolysaccharide. The fluorescence was monitored coincident with the bleaching pulse, that is, $\Delta x = 0$ (●), and at equal distances on either side of centre, $\Delta x = \pm 3.0$ μm (+, ×). The solid curves are theoretical values corresponding to $\beta = 0.80$, $\tau_D = 153$ s, $w_0^2 = 10.8$ μm^2, and thus, $D = 1.76 \times 10^{-10}$ cm^2 s^{-1}. Fluorescent components were derivatised in the following way. Electrodialysed G30 lipopolysaccharide (5 mg) was dispersed in 1 ml of 2% $NaHCO_3$, *p*H 8.5. Rhodamine isothiocyanate (5 mg; Kodak) was added and the reaction allowed to proceed for 1 h at 4 °C. The reaction mixture was then chromatographed on a G-25 Sephadex column (1.5 × 25 cm) eluted with water. The rhodaminated lipopolysaccharide was eluted in the void volume, lyophilised, and then resuspended in 1 ml water. The suspension was washed three times with acetone. The lipopolysaccharide precipitated was judged pure by paper chromatography. NBD-PE (Avanti) demonstrated one spot on chromatography. Rhodamine modification of matrix protein involved the addition of 1 mg rhodamine isothiocyanate to a solution of matrix protein (2 mg ml^{-1}) in 2% SDS and 10 mM HEPES, *p*H 7.5. The reaction was allowed to proceed overnight at 4 °C. The protein was then precipitated five times in cold 90% acetone. The residue was lyophilised and then solubilised in 10 mM HEPES, *p*H 7.5. Amino acid analysis indicated that one amino group was modified per protein molecule. In addition, circular dichroism showed that the solubilised protein and rhodaminated protein maintained their predominantly β-sheet conformation (data not shown). Fluorescently labelled analogues of each component were incorporated at molar ratios between 1:100 and 1:1,000 to the unlabelled species. *b*, Fractional recoveries for NBD-PE and rhodamine-labelled lipopolysaccharide measured on the same area of a membrane 1:1.3:1 by weight phospholipid/protein/lipopolysaccharide. The theoretical curves correspond to a ratio of $D_{\mathrm{LPS}}/D_{\mathrm{PL}} = 0.14$.

Biomembranes as polymer networks for diffusion

The lateral mobility of cell membrane components is usually interpreted in terms of a fluid mosaic model[25]. The membrane is pictured as a two-dimensional viscous solution with diffusion coefficients controlled by the membrane viscosity. The theory for diffusion in a two-dimensional fluid was put on a rigorous basis by Saffman and Delbrück[26]. They showed that to a first approximation diffusion coefficients would be inversely proportional to the viscosity of the membrane and the vertical length of the diffusing molecule within the membrane. The theory demonstrated only a weak dependence on the cross-sectional area of the diffusing entity. In the context of the fluid mosaic model one would thus predict the following: (1) molecules as similar in lateral dimension as phospholipid (0.54 nm^2 cross-sectional area) and lipopolysaccharide (2.50 nm^2 cross-sectional area per monomer, molecular weight 3,600)[27] should diffuse at very nearly the same rate, and (2) differences in membrane composition or temperature should change diffusion coefficients by altering membrane viscosity, and hence should affect all coefficients proportionately. These predictions are obviously at odds with our experimental results for multibilayers containing protein.

The data presented in Fig. 5 show that as the concentration of matrix protein increases in the membrane, the mobility of lipopolysaccharide is greatly reduced whereas that for phospholipid remains essentially constant. Moreover, as the temperature increases from 24 °C to 37 °C the diffusion constant of lipopolysaccharide increases significantly whereas that for phospholipid is unchanged.

Our results can be explained in a general way by reintroducing the idea that for some purposes, a biomembrane behaves like a polymeric network. The concept of biomembranes as polymers was first introduced by Lieb and Stein[20,21] to explain transverse diffusion (non-mediated transport) of non-electrolytes across erythrocyte membranes. These studies were later extended to other membranes and demonstrated that, as with polymeric networks, (1) diffusion is a sensitive function of size, (2) diffusion is correlated with the short dimension of the diffusing particle, (3) as the temperature increases, the diffusion rates increase correspondingly more for larger particles than for smaller ones, (4) adding low molecular weight 'plasticisers' (for example, anaesthetics) increases the overall diffusion rates. The results strongly supported the hypothesis that transmembrane diffusion is more accurately described by comparison with non-porous networks of hydrophobic polymers than simple viscous liquids. We propose that the same analogy can be made for translational diffusion of membrane components within the plane of the membrane.

A simple physical model can help provide an understanding of the proposed polymer characteristics. The random thermal motion of polymer chains can be thought of as forming free volumes or 'holes' into which the diffusing molecules can move. The rate of diffusion would then be controlled by the rate of appearance of holes and the probability distribution of hole sizes. Net motion will occur only when a hole is created that exceeds a certain critical size approximately equal to the size of the diffusing molecule. This model thus predicts a sharp size-dependent rate of diffusion. Anything that decreases the average hole size will preferentially slow down the diffusion rate of larger diffusing molecules.

Specific interactions between matrix protein and lipopolysaccharide[14,16,18] could also lead to differential diffusion changes. Such an association mechanism by itself, however, cannot account for the magnitude of the effect observed at low and intermediate protein concentrations. Theoretical values of D_{LPS} were calculated for a model in which specific binding occurs. It was assumed that bound lipopolysaccharide, which would be essentially immobile, is in rapid exchange with free lipopolysaccharide, consistent with our observations of a monophasic recovery. D for free lipopolysaccharide was

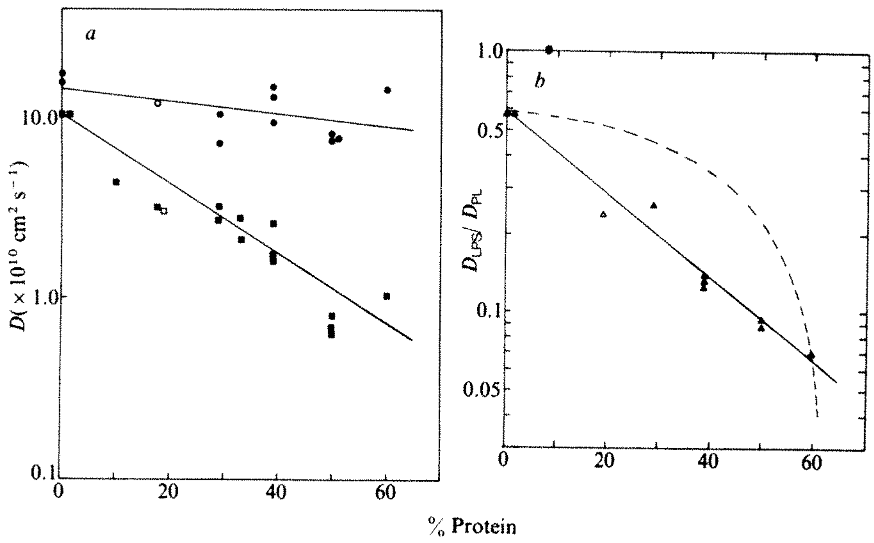

Fig. 5 *a*, Diffusion coefficients of NBD-PE (●, ○), and rhodamine-labelled lipopolysaccharide (■, □) as functions of the percent protein in multibilayer membranes. *b*, Ratios of D_{LPS}/D_{PL}. All ratios were determined from pairs of consecutive measurements carried out on the same patch of double-labelled membrane. The dashed line is a theoretical plot the significance of which is described in the text. The open symbols indicate a preparation with a 12 : 1 (w/w) ratio of phospholipid/lipopolysaccharide. All others correspond to a 1 : 1 ratio.

assumed to vary with protein concentration in a form identical to that found for phospholipids. The dashed curve in Fig. 5*b* corresponds to a stoichiometric binding, with an infinite association constant, of three lipopolysaccharide molecules to a matrix protein monomer[18] in membranes with a phospholipid/lipopolysaccharide ratio of 1 : 1 by weight. Values calculated for lower association constants would deviate from the experimental curve even more significantly. In addition, these calculations predict that for a given protein concentration, D_{LPS} should decrease as the ratio of lipopolysaccharide to protein is decreased. In fact, however, at a protein concentration of 20%, D_{LPS} for a sample with a lipopolysaccharide to protein molar ratio of 3 (open symbols) was essentially indistinguishable from that of samples with a lipopolysaccharide to protein molar ratio of 20.

In the context of the fluid mosaic model, various attempts have been made to relate lateral diffusion to rotational mobility interpreted as membrane microviscosity[1,28]. In our view of membranes as polymeric networks, there need be no simple relationship between lateral and rotational diffusion. Molecules free to rotate rapidly in limited regions might not be able to move laterally over large distances; and changes in membrane composition that moderatly affect rotation rates could have profound effects on the lateral diffusion[28].

The concepts as outlined are particularly useful in relating our findings to the outer membrane of *E. coli*. Our multilayer results indicate that lipopolysaccharide and phospholipids are relatively mobile. However, other evidence suggests that the outer membrane is rigid, with largely immobile components[29,30]. This difference can again be explained in terms of polymer domains. Underlying the outer membrane is a highly cross-linked peptidoglycan structure that is covalently anchored to the outer membrane[31]. The peptidoglycan could thus control the diffusion of outer membrane components. Depending on the degree of cross-linking or attachment of proteins, it is conceivable that some areas exist in the outer membrane that allow greater degrees of mobility than other areas. This might have particular relevence to growth zones in the membrane and phage infectivity.

Schlessinger *et al.*[32] reported diffusion characteristics in cells in which the state of aggregation of one receptor affects the diffusion of another (anchorage modulation hypothesis). These results can be explained by changes in the polymeric nature of the membrane mediated by cytoskeleton components (microfilaments, microtubules).

Investigations of lateral mobilities of proteins in neonatal erythrocytes by Tokuyasu *et al.*[33] have shown membrane domains free of an underlying spectrin network. Lateral mobility in these domains was demonstrated to be significantly greater than in the spectrin-containing areas.

Because our data and most other mobility-related observations can successfully be interpreted using a polymer network approach, we believe that such an analysis might provide a general guide to membrane events. In addition, it would be able to reconcile the dual aspect of membranes—their viscoelastic properties, such as hyperelasticity and shear, and their fluid dynamics. The fluid mosaic model in our interpretation would be a special case of the polymer membrane in which the degree of polymerisation approaches zero.

We thank Ms Kathy Book and Dr T. J. MacCallister for their help in devising methods for thin section analysis of our multibilayer preparations. These investigations were funded by NIH grant AI08650 to M.J.O., GM23585 to D.E.K. and a grant from the UCONN Research Foundation. M.S. is an NIH postdoctoral fellow.

The role of gene deletion in the immunoglobulin heavy chain switch

T. H. Rabbitts, A. Forster, W. Dunnick & D. L. Bentley
MRC Laboratory of Molecular Biology, Hills Road, Cambridge, UK

We have examined the arrangement of the genes for the mouse heavy chain subclasses γ_{2b}, γ_{2a} and γ_1 by the Southern hybridisation procedure. Evidence has been found for rearrangement involving the γ_{2b} and γ_{2a} C_H genes in the DNA of cells making IgG2b and IgG2a respectively. The DNA of an IgG2b-secreting line lacks detectable $C\gamma_1$ gene, whilst the DNA of an IgG2a-secreting line lacks detectable $C\gamma_1$ and $C\gamma_{2b}$ genes. The DNA of a cell line secreting IgA lacks detectable $C\gamma$ genes. These observations implicate deletion in the mechanism of the H-chain switch and allow a preliminary ordering of some of the C_H genes in the mouse genome.

IMMUNOGLOBULIN polypeptides comprise two heavy (H) and two light (L) chains, each in turn consisting of an amino-terminal variable (V) region and a carboxy-terminal constant (C) region. The H-chain constant regions are sub-divided into five subclasses (μ, δ, γ, ε, α) each of which associates with a V-gene at a certain stage of B-cell differentiation. In 1965, the two genes–one polypeptide hypothesis[1] suggested that the V and C regions were separately encoded and that an integration event brought these two segments together. Extensive data now exist on the events involved in the differentiation of the L-chain genes in mouse. For example, it is now known that kappa (κ) chain genes have separately encoded V and C segments[2-4] which are rearranged in the formation of the active κ gene[2,3,5]. The $C\kappa$ gene, in germ-line DNA, is separated by intervening sequences from a set of segments called J-segments[2-5]. Integration involves fusion of a $V\kappa$ segment with one of the J segments and the intervening sequence, being retained between J and C (refs 2–7), is removed post-transcriptionally by RNA splicing enzymes[8,9]. In the H-chain gene system the $C\mu$ seems to be the initial expressed H-chain class[10,11]. However, H-chain gene expression involves the H-chain switch that is manifested by the predominance of IgM (μ-chain class) in the primary response and by the predominance of IgG (γ-chain class) in the secondary response[11]. Also the terminal stage of this pathway can be, in some cases, a switch to IgA (α-chain class) production[11]. At the DNA level this switch would seem to involve a V_H gene first being expressed with one C_H gene (such as $C\mu$), then being 'switched' from this C_H gene to a different one (such as $C\gamma$) and possibly later being switched to a further different C_H gene (such as $C\alpha$). A critical feature of the switch is the expression of a V-region idiotype with the different C_H classes[12,13]. Several hypotheses have been proposed to account for the switch: principal among these are:

(1) *Sequential insertion model.* An initial event integrates a V_H gene with the C_μ gene and subsequently this V_H gene is re-integrated with a $C\gamma$ gene and finally with $C\alpha$ (ref. 14).
(2) *Multiple insertion model.* The integration event involves integration of copies of a V_H gene with each C_H gene[14].
(3) *Post-transcriptional model.* A single integration event is invoked at the most distal part of the C_H gene's array. The V_H gene plus C_H gene array is transcribed as a unit into a precursor RNA which can yield V_H–C_H combinations by RNA splicing[8,15].
(4) *Deletion model.* Integration occurs between a V_H gene and the $C\mu$ gene with subsequent switching facilitated by deletion of material between the integrated V_H gene and the next C_H gene[16].

Each of these theories is testable since the various C_H genes can be regarded as markers for H-chain gene arrangements and rearrangements. Honjo and Kataoka[16] have used cDNA probes (made by reverse-transcribing mRNA) to test these hypotheses by solution hybridisation and they concluded that the H-chain gene switch operates by a deletion mechanism. We have examined the hybridisation of cloned cDNA plasmids, containing γ_{2b} and γ_1 sequences, with genomic DNA made from cells producing different Ig H-chain classes. The results indicate rearrangement involving γ_{2b} and γ_{2a} genes in the DNA of cells producing the respective immunoglobulins and are consistent with the idea that the H-chain switch at least partly involves deletion events.

Cross-hybridisation of mouse γ subclasses

The cloned cDNA probe used in the experiments described here was $p\gamma_{2b}/7$, a cDNA complementary to part of the C_H region of γ_{2b} cloned in the plasmid vector pMB9 (this clone was prepared by Schibler, Marcu and Perry[17,18]). This probe has been used in Southern hybridisation experiments[19] after labelling with ^{32}P by nick-translation[20,21]. Briefly, the hybridisation procedure involves agarose gel electrophoresis of restriction enzyme digested DNA followed by immobilisation of the DNA on cellulose nitrate filters. These filters were hybridised to the ^{32}P-labelled cloned DNA (or cDNA transcribed from purified mRNA with reverse transcriptase), washed and hybridisation bands visualised by autoradiography.

Cross-hybridisation has been reported between the γ subclasses in liquid hybridisation[22]. We have examined the cross-hybridisation between γ_{2a}, γ_{2b} and γ_1 gene sequences using the filter hybridisation method. The $p\gamma_{2b}/7$ clone is cleaved by the restriction enzyme *Hha*I to yield a fragment of about 2.2 kilobases which contains the γ_{2b} cDNA insert[17]. We found by screening a number of different restriction enzymes that the γ_{2b} cDNA insert was internally cleaved by the enzymes *Sac*I, *Pvu*II, *Pst*I, *Kpn*I, *Bst*I (unpublished data). Accordingly $p\gamma_{2b}/7$ DNA was digested with *Hha*I alone or *Hha*I plus one of these enzymes, fractionated on agarose gels and the DNA transferred to cellulose nitrate filters. These filters were hybridised with either nick-translated ^{32}P-labelled $p\gamma_{2b}/7$ DNA (Fig. 1*a*) with cDNA made from purified γ_{2a} H-chain mRNA (Fig. 1*b*) or with cDNA made from purified γ_{2b} H-chain mRNA (Fig. 1*c*). Clearly there is no distinction between the hybridisation of cDNA made from either γ_{2a} or γ_{2b} mRNA and the digests of the $p\gamma_{2b}/7$ clone. Both of these cDNA probes (Fig. 1*b*, *c*) hybridise specifically to the restriction fragments containing γ_{2b} sequence whilst the ^{32}P-$p\gamma_{2b}/7$ clone DNA hybridises in addition to plasmid-derived restriction fragments (Fig. 1*a*). The presence of cleavage sites for the various enzymes within the γ_{2b} insert is

0028–0836/80/040351—06$01.00

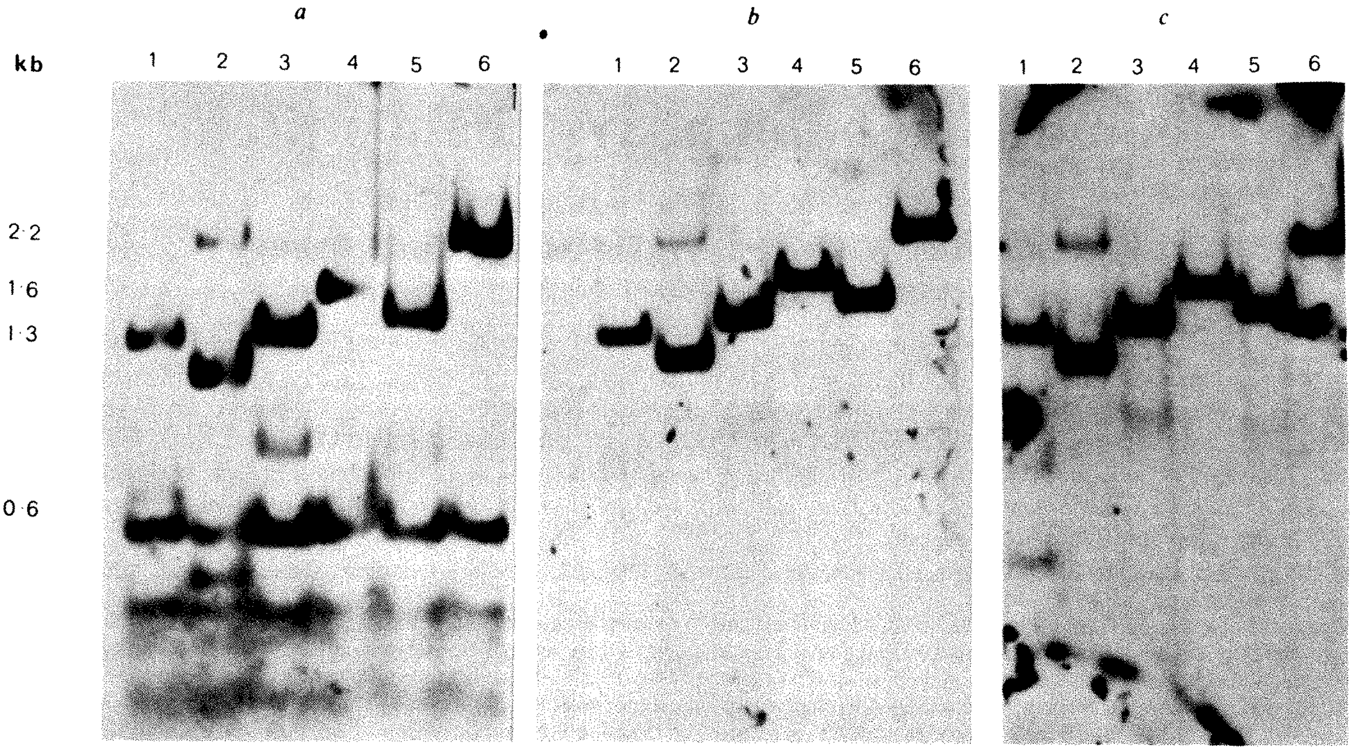

Fig. 1 Cross-hybridisation of pγ_{2b}/7 and cDNA made from cells producing γ_{2a} or γ_{2b} H-chain mRNA. 100 ng pγ_{2b}/7 were digested to completion with *Hha*I and further digested with *Sac*I, *Pvu* II, *Pst*I, *Kpn*I or *Bst*I. The digests were fractionated by electrophoresis on 2% agarose gels, the DNA was denatured and transferred to cellulose nitrate filters[19]. The filters were subsequently hybridised to *a*, nick-translated ^{32}P-labelled pγ_{2b}/7 DNA; *b*, T_{10}-primed ^{32}P-labelled cDNA synthesised on γ_{2a} H-chain mRNA using reverse transcriptase[2]; or *c*, T_{10}-primed ^{32}P-labelled cDNA made on γ_{2b} H-chain mRNA. The hybridisations were carried out for 36 h at 65 °C in 6 × SSC, 0.1% SDS, 50 μg ml^{-1} denatured sheared salmon DNA, 10 μg ml^{-1} poly(A) plus Ficoll, bovine serum albumin and polyvinyl pyrrolidine as prescribed by Denhardt[40] and Jeffreys and Flavell[41]. Post hybridisation washes were carried out at 65 °C, first with 6 × SSC containing the above components and then five washes (30 min in each) with 1 × SSC plus the above additions. A final wash was with 1 × SSC, 0.1% SDS was carried out before overnight autoradiography with prefogged X-ray film at −70 °C (ref. 42). Slot 1, *Hha*I + *Sac*I; slot 2, *Hha*I + *Pvu*II; slot 3, *Hha*I + *Pst*I; slot 4, *Hha*I + *Kpn*I; slot 5, *Hha*I + *Bst*I; slot 6, *Hha*I alone. Molecular weights are given in kilobases (kb).

manifested by reduction in the size of *Hha*I fragments after redigestion with the appropriate enzyme. Evidently, therefore, γ_{2a} and γ_{2b} sequences cross-hybridise with more or less equal efficiency in the hybridisation conditions used. A similar approach has been used to demonstrate the cross-hybridisation of γ_1 and γ_{2b} sequences (data not shown).

Hybridisation analysis of the genes for the γ subclasses in various myeloma cell lines

The various cell lines or tumours used in this study are listed in Table 1 and each cell line was monitored for the production of the respective type of immunoglobulin (by *in vitro* incorporation of ^{14}C-labelled amino acids). The strategy of our experiments has been to use the genomic DNA of these cell lines to hybridise (using the Southern filter hybridisation procedure) with probes for γ_2 and γ_1 genes using hybridisation conditions established in the previous section, where γ_2 and γ_1 genes cross-react to varying degrees. Figure 2 shows the result of a Southern hybridisation between the cloned γ_{2b} DNA and *Eco*RI-digested DNA of various types. The kidney DNA (slot 4) shows two major hybridisation components of about 20 and 7 kilobases respectively. Kataoka *et al.*[23] have recently isolated a genomic DNA clone (from *Eco*RI-digested mouse DNA) which was shown to contain the γ_{2b} C_H-gene by partial nucleotide sequencing. This cloned DNA has a size of around 7 kilobases and allows an unequivocal assignment of the 7-kilobase component as containing the γ_{2b} gene. Interestingly, we find that DNA from cells synthesising γ_{2a} showed only the large hybridising component (slot 2). Since the 20-kilobase fragment is the only hybridisation component observed in this DNA, it can be assigned to the fragment containing the γ_{2a} C_H-gene and the similar component of the kidney DNA will therefore represent the γ_{2a} gene. The hybridisation of γ_{2b} DNA to *Eco*RI-digested DNA of IgG2b-producing cells (Fig. 2, slot 3) and IgG1-producing cells (slot 1) show essentially the same pattern as kidney DNA, except that the IgG1 DNA exhibits a new hybridisation band (about 4.3 kilobases): the origin of this component is not yet known. The data in Fig. 2 show that we cannot detect the γ_{2b} C_H-gene in cells producing IgG2a although we were able to detect this gene and the γ_{2a} C_H-gene in the other DNAs examined.

Two main possibilities may explain our inability to detect the γ_{2b} gene in the IgG2a-producer DNA. Either the gene is absent from this DNA or the H-chain switch involves rearrangements of the γ_{2b} C_H-gene in this DNA in such a way that γ_{2a} and γ_{2b} genes appear in a single fragment. The latter possibility is ruled out by the data in Fig. 3 where we have compared the hybridisation of γ_{2b} cloned DNA to either liver DNA or IgG2a-producer DNA digested with various enzymes. *Bst*I or *Bst*I plus *Eco*RI digests of liver DNA yielded hybridisation bands of 6.7, 5.5 and 5.0 kilobases (Fig. 3), whereas the IgG2a-producer DNA only yielded a 5.5-kilobase fragment. This latter fragment must, therefore, represent the γ_{2a} C_H-gene whilst the 5.0-kilobase hybridisation fragment seen in the liver DNA contains the γ_{2b} C_H-gene[23]. The IgG2a-producer DNA appears not to contain this 5.0-kilobase γ_{2b} fragment. In addition, if the γ_{2b} gene were present in IgG2a-producer cells, *Bst* digestion (which cleaves within the γ_{2b} coding region, see Fig. 1) should yield an additional hybridising fragment due to cleavage within the γ_{2b} sequence. As no such band appears we conclude that the 5.5-kilobase band does not include the γ_{2b} C_H-gene. This conclusion is corroborated by the results of *Kpn* digestion (Fig. 3). *Kpn* or *Kpn* plus *Eco*RI digestion of liver DNA yielded major hybridisation components at 18.5 and 5.1 kilobases whilst the IgG2a-producer DNA yielded only the 18.5-kilobase fragment. By arguments analogous to those used previously, the 18.5-kilobase fragment must represent the γ_{2a} C_H-gene and again, since *Kpn* cleaves within the γ_{2b} insert (Fig. 1), this 18.5-kilobase fragment cannot contain the γ_{2b} gene as an additional hybridising fragment would appear in such a circumstance. The 5.1-kilobase *Kpn* fragment of liver DNA can be assigned to the γ_1 C_H-gene[24] so we conclude that we cannot detect a γ_1 C_H-gene in IgG2a-producer DNA. (This conclusion has been confirmed by the inability of a γ_1 cDNA probe to hybridise this C_H-gene in the IgG2a-producer DNA [unpublished data].) Furthermore, liver DNA yielded a strongly hybridising *Kpn* fragment of 4.2 kilobases which is cleaved by *Eco*RI: the intensity of this hybridisation suggests that the fragment contains the γ_{2b} C_H-gene, and this conclusion has been confirmed by restriction mapping of a genomic γ_{2b} C_H-gene clone[23]. We do not observe any such component in the IgG2a-producer DNA which extends our conclusion that this DNA lacks the γ_{2b} C_H-gene.

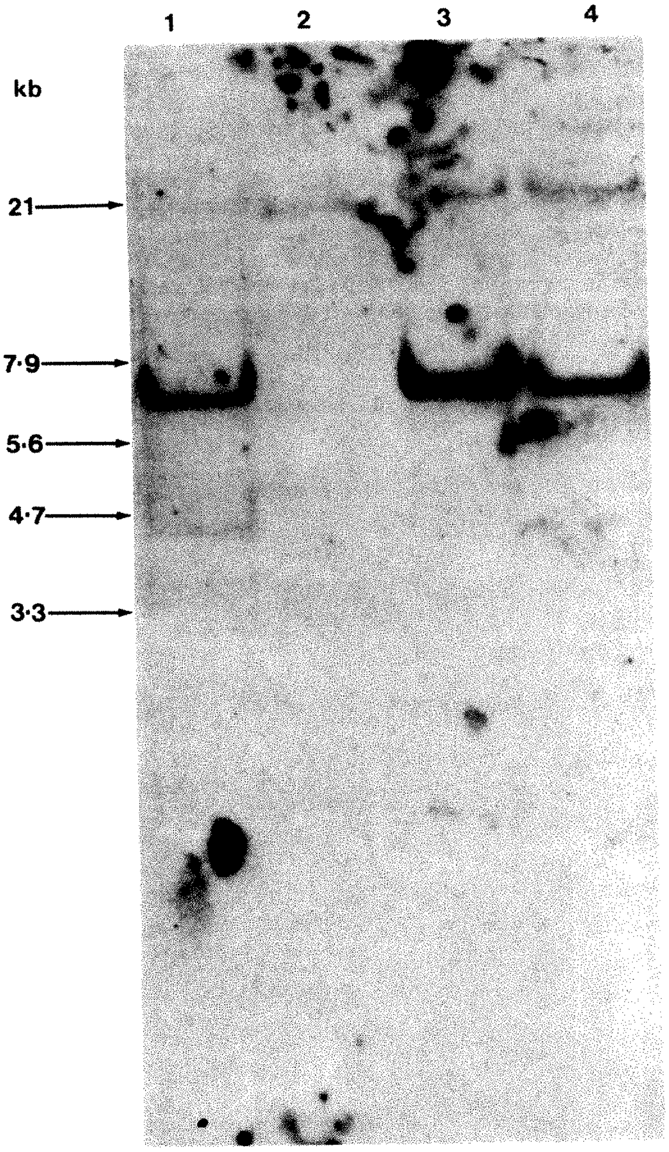

Fig. 2 Pattern of hybridisation of γ_{2b} cDNA to *Eco*RI-digested nuclear DNA from cells synthesising various Cγ subclasses. High molecular weight nuclear DNA[2] from cells producing Ig of the classes γ_1, γ_{2a}, γ_{2b} or DNA of kidney cells were digested to completion with *Eco*RI, fractionated by 0.8% agarose gel electrophoresis and the DNA transferred to cellulose nitrate filters[19]. Hybridisation of the filters was carried out for 48 h with 25 ng ml^{-1} nick-translated pγ_{2b}/7 (specific activity 5×10^7 c.p.m. μg^{-1}) in 6×SSC (hybridisation, post-hybridisation washing and autoradiography was carried out as legend to Fig. 1). This autoradiograph shows hybridisation to DNA of cells making γ_1 (slot 1), γ_{2a} (slot 2), γ_{2b} (slot 3) and DNA of kidney cells (slot 4). Size calibration was carried out by co-electrophoresis of an *Eco*RI digest of λ phage DNA followed by ethidium bromide staining before transfer of DNA to the filters.

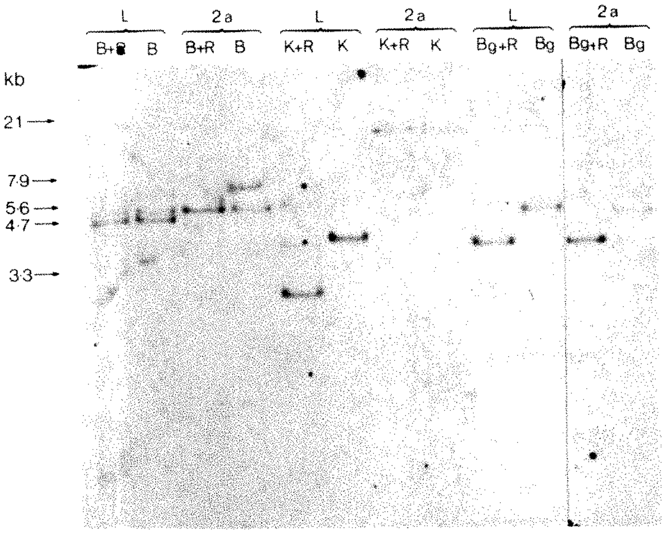

Fig. 3 Hybridisation of γ_{2b} cDNA to liver DNA and DNA of an IgG2a-secretor digested with various restriction enzymes. Liver DNA or DNA prepared from an IgG2a secretor were digested with the restriction enzymes *Bst*I, *Kpn*I or *Bgl*II or mixtures of these enzymes with *Eco*RI. The digests were fractionated and hybridised to ^{32}P-labelled pγ_{2b}/7 as in Fig. 2 legend. B = *Bst*I; B + R = double digest of *Bst*I + *Eco*RI; K = *Kpn*I; K + R = double digest of *Kpn*I + *Eco*RI; Bg = *Bgl*II; Bg + R = double digest of *Bgl*II + *Eco*RI; L = liver DNA; 2a = DNA of IgG2a-secretor.

The comparison of liver DNA and IgG2a DNA in Fig. 3 also includes the results of digestion with *Bgl*II which provides evidence for rearrangement events involving the γ_{2a} C_H-genes. The liver DNA cleaved by *Bgl*II produced two main bands of hybridisation of about 5.2 and 4.9 kilobases. Both of these bands are susceptible to *Eco*RI since double digests produce a new major band at about 3.9 kilobases. The IgG2a cell DNA shows only a single major hybridisation band of about 3.8 kilobases when digested with *Bgl*II plus *Eco*RI: *Bgl*II digestion alone, however, produced a distinctly different pattern of hybridisation compared to liver DNA. Now only the 4.9-kilobase fragment is common between liver DNA and the IgG2a cell DNA whilst new bands of about 8 and 6.3 kilobases occur in the IgG2a cell DNA. One or both of these bands presumably reflects rearrangements resulting from V_H-gene integration with the γ_{2a} C_H-gene within the DNA of cells destined to synthesise IgG2a. In summary, the data in Figs 2 and 3 support the argument that the DNA of the cell line producing IgG2a lacks C_H genes for γ_{2b} and γ_1 and shows that evidence of rearrangement events specifically involving the γ_{2a} C_H-gene can be found in cells making IgG2a.

Further analyses regarding the presence of the γ_1 and γ_2 genes in cells making IgM, IgG1 and IgA are shown in Figs 4 and 5.

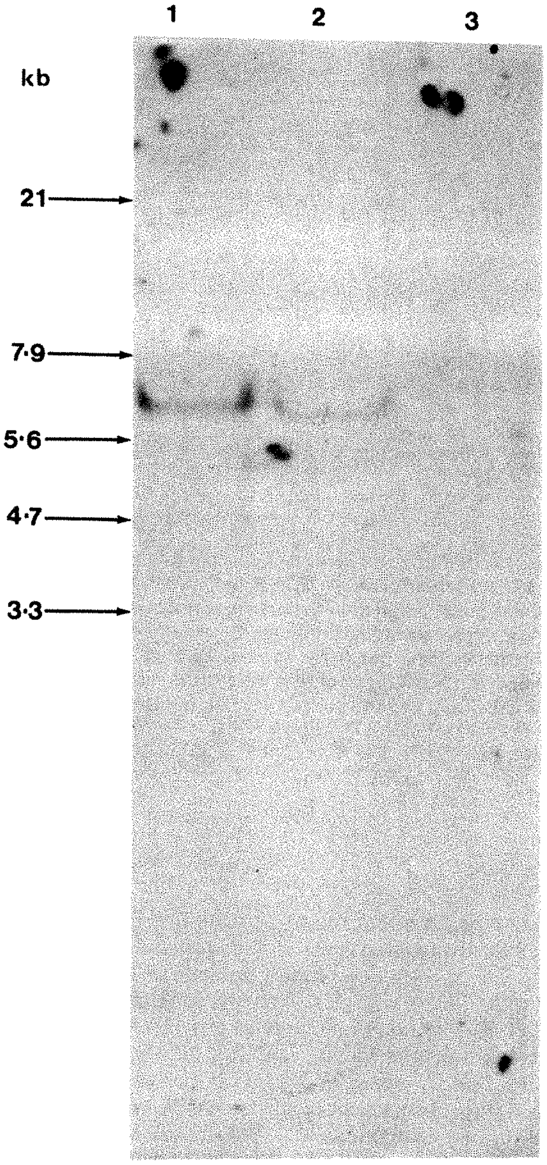

Fig. 4 Hybridisation pattern of γ_{2b} cDNA to DNA from cells making γ_{2b} or α heavy chains. As for Fig. 2, *Eco*RI-digested DNA of liver cells, of cells making IgG2b or IgA was electrophoresed, transferred to filters and these filters hybridised to ^{32}P-labelled pγ_{2b}/7 in 6×SSC followed by washing and autoradiography. Samples loaded were DNA from γ_{2b}-producing cells (slot 1), from liver cells (slot 2) and from α-producing cells (slot 3).

Figure 4 shows the hybridisation patterns of pγ_{2b}/7 with *Eco*RI digests of DNA from the IgG2b secretor (slot 1), liver (slot 2) and an IgA secretor (slot 3). The DNAs of the IgG2b secretor and liver display the characteristic *Eco*RI hybridisation fragments of the γ_{2b} (about 7 kilobases) and the γ_{2a} C_H-genes (about 20 kilobases). The IgA cell DNA (Fig. 4, slot 3), however, failed to hybridise the pγ_{2b}/7 probe, indicating the absence of γ_{2b} and γ_{2a} genes from these cells. Although we do not have a cDNA probe for α-chains, these cells were shown to secrete IgA by *in vitro* incorporation of ^{14}C-labelled amino acids (data not shown). In addition, the same *Eco*RI-digested IgA cell DNA was found to hybridise normally to a κ-L-chain probe. We conclude, therefore, that this IgA-producing cell line does not possess γ_{2a} or γ_{2b} genes.

The presence of both γ_{2a} and γ_{2b} hybridisation components in the DNA of cell lines producing IgM or IgG1 plus clear evidence of rearrangement involving γ_{2b} C_H-genes specifically in the DNA of cells making IgG2b is shown in Fig. 5. In Fig. 5, tracks 6–8 show hybridisation patterns of the pγ_{2b}/7 to various *Eco*RI digests. Track 6 contained *Eco*RI-digested DNA of the IgG2a secretor showing the 20-kilobase Cγ_{2a} hybridisation band. DNA of both the IgM secretor (track 7) and the IgG1 secretor (track 8) shows this hybridisation band. These DNA types also show the γ_{2b} C_H-gene hybridisation band of around 7 kilobases, showing that these cells possess the genes for γ_{2b} and γ_{2a}. Tracks 1–5 show hybridisation of the γ_{2b} probe to *Kpn*-digested DNA. The hybridisation of liver DNA and the IgG2a-producer DNA parallels that shown in Fig. 3 with the γ_{2b} C_H-gene fragment (4.2 kilobases) and γ_{2a} C_H-gene fragment (18.5 kilobases) occurring in liver DNA but only the latter in IgG2a cell DNA. The patterns of hybridisation to *Kpn* digests of IgG1 cell DNA (slot 1) and IgM cell DNA (slot 4) are identical to liver DNA, confirming that the γ_{2a} and γ_{2b} C_H-genes are present in these cells. The hybridisation of pγ_{2b}/7 to *Kpn*-digested DNA of the IgG2b secretor, however, shows a more complex pattern (slot 2). In addition to hybridisation of the γ_{2a} C_H-gene (18.5-kilobase component) and to the γ_{2b} C_H-gene (4.2 kilobases) we observed two new hybridisation bands of about 13 and 6.5 kilobases. These latter bands do not appear in any of the other DNA types studied and must, therefore, originate from rearrangement events which involved integration of the γ_{2b} C_H-gene in precursor cells of these IgG2b producers. These data also suggest that at least two chromosomes carrying γ_{2b} C_H-genes are present in these cells since we observe a mixed pattern

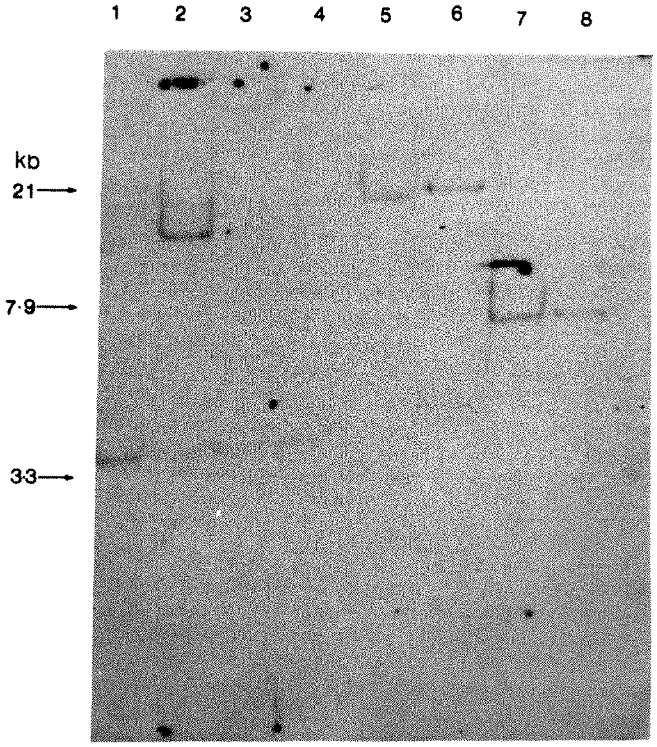

Fig. 5 Hybridisation pattern of γ_{2b} cDNA to *Kpn*I and *Eco*RI digests of various mouse DNA. The DNA of liver cells or cells making heavy chains of the class γ_1, γ_{2b}, γ_{2a} and μ were completely digested with *Kpn*I and DNA of cells making γ_1, μ and γ_{2a} were completely digested with *Eco*RI. The resulting DNA fragments were separated by 0.8% agarose gel electrophoresis, transferred to cellulose nitrate filters and hybridised and washed to ^{32}P-labelled pγ_{2b}/7 DNA in 1×SSC conditions (in which γ_1 and γ_{2b} cross-hybridisation is minimised, unpublished observation). The autoradiograph shows the hybridisation patterns of DNA digested with *Kpn*I (slots 1–5) and *Eco*RI (slots 6–8) and the DNA loadings in the slots are from cells of the type γ_1 (1), γ_{2b} (2), liver (3), μ (4), γ_{2a} (5), γ_{2a} (6), μ (7) and γ_1 (8).

Table 1 Cells used for hybridisation studies

Cell type	Mouse strain	Immunoglobulin produced
McPc 1748	BALB/c	IgM
MOPC 21	BALB/c	IgG1
P1	BALB/c	IgG2a
MPC 11	BALB/c	IgG2b
MOPC 315	BALB/c	IgA
Liver	BALB/c	—
Kidney	BALB/c	—

of the 'rearranged' γ_{2b} components plus a pattern similar to that seen in liver DNA.

The hybridisation conditions used in the type of experiment shown in Fig. 5 minimised the cross-hybridisation of γ_1 and γ_{2b} (unpublished observation). We have also tested for the presence of the γ_1 C_H-gene Kpn fragment in various DNAs in low stringency conditions where γ_1 and γ_2 do cross-hybridise (Fig. 6). Liver DNA and an IgM-producer DNA show (amongst other cross-hybridising genes) the 5.1-kilobase *Kpn* fragment characteristic of the γ_1 C_H-gene[24]. The *Kpn*-digested DNA from the γ_{2b}-producer, however, fails to display this γ_1 C_H-gene component, indicating the absence of this gene from this DNA.

Restriction mapping data implicate gene deletion in the H-chain switch

The data presented in this article show that the DNAs of myeloma cells producing various immunoglobulins can be mapped with respect to their subclass genes using cloned cDNA sequences. This analysis revealed two major features. Evidence of rearrangement events involving C_H-genes for γ_{2a} and γ_{2b} was found in the DNA of cells expressing γ_{2a} or γ_{2b} genes respectively. These rearrangements, analogous to those observed by restriction mapping κ-chain genes[2,3,5] presumably represent alterations of the DNA located around these genes during integration with the V_H gene in the creation of the active transcription unit. The alterations in this respect seem to be independent since we only find evidence of rearrangements specifically involving a C_H gene in the DNA of cells producing the respective class of H-chain, for example, evidence of γ_{2b} rearrangement could only be found in the DNA of cells making IgG2b and not, say, in cells making IgM. However, the alterations seem to interrelate to the extent that when γ_{2a} cell DNA is examined we find evidence of rearrangements affecting γ_{2a} C_H-genes in these cells, but no evidence of the continued existence of γ_{2b} genes in the DNA. Furthermore, the γ_{2a} and γ_{2b} cells lack detectable γ_1 C_H-genes, whilst μ and γ_1-producing cells possess all three subclass genes. IgA-secreting cells fail to show evidence of any of these γ-subclass genes in their DNA. The presence or absence of the detectable genes in the tumours examined are summarised in Table 2 which includes gene assignments based on appropriate synthesis of Ig chains by cell cultures. Honjo and Kataoka have previously reported similar findings concerning the absence of various C_H genes in myeloma cell lines[16]. Previous evidence[10,11] suggests that the switch goes from $C\mu$ to $C\gamma$ to $C\alpha$. Therefore cells making IgM must necessarily contain the $C\mu$ gene, the $C\gamma$ subclasses, plus $C\alpha$, whilst cells making IgA do not necessarily require the previously utilised C_H genes (such as C_γ). In view of the pattern of absence of the C_H genes from the various tumours, therefore, the most compelling conclusion is that the absence of detectable C_H genes is the consequence of deletion operating during the switch of the V_H gene as previously proposed[16]. The switch operates intrachromosomally[25,26] and the putative deletion event must therefore operate in the same way. It is known that there is close linkage between the C_H genes in mouse[27]. In a deletion process, the pattern of absence of C_H genes from cells would allow a preliminary spatial ordering of some C_H genes in the germ-line DNA. This ordering of C_H genes would appear to be $C\mu$, $C\gamma_1$, $C\gamma_{2b}$, $C\gamma_{2a}$, $C\alpha$ (Table 2) and an identical order of C_H genes was obtained by Honjo and Kataoka[16] using solution hybridisation kinetics.

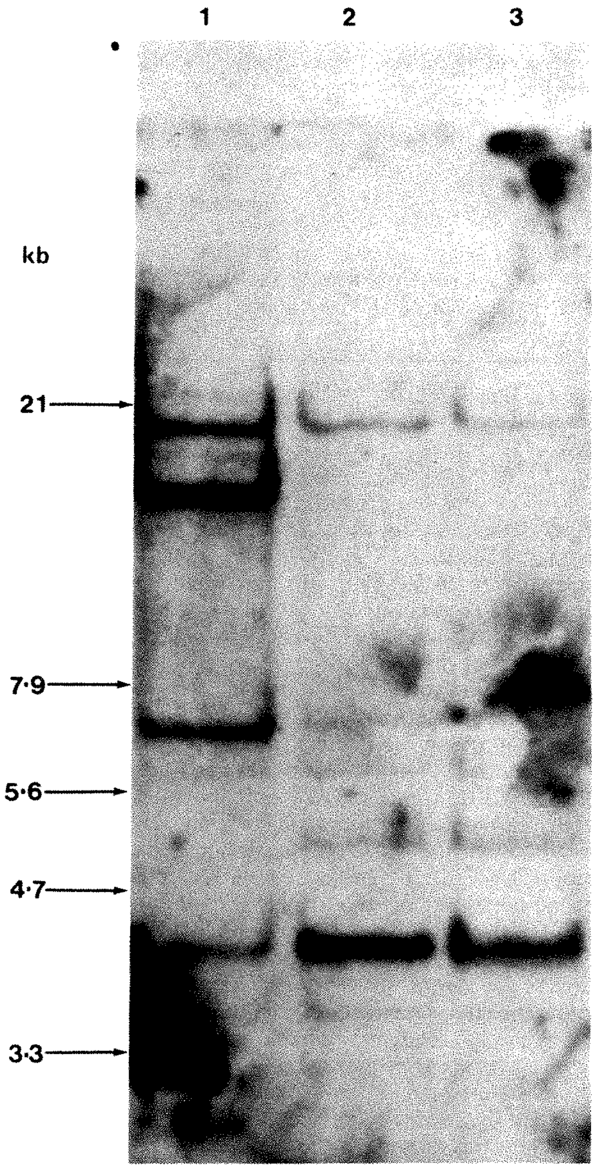

Fig. 6 Hybridisation pattern of *Kpn*I-digested nuclear DNA with γ_{2b} cDNA under low stringency hybridisation conditions. *Kpn*I-digested DNA from γ_{2b}-producing cells, liver cells or μ-producing cells was fractionated and hybridised as in Fig. 4 except that the lower stringency 6 × SSC conditions were used. The slots shown are (1) DNA of γ_{2b} cells, (2) liver DNA, (3) DNA of μ cells.

It is of interest to discuss the possible molecular basis of a deletion process particularly with reference to possible J_H segments. Integration of the V_L with C_L genes involves J segments which are fused with the V segment[6,7,28-30]. It seems likely that similar J segments will occur in the H-chain system[31] and that V_H–J_H fusion will be the initial step of integration of the V_H gene. Therefore we can expect that the selected V_H segment will fuse with one of an array of J_H segments, located close to the $C\mu$ gene. An intervening sequence probably separates the J_H and $C\mu$ of the newly created transcription unit (indeed it has been shown that an intervening sequence does occur between V and

Table 2 Summary of detection of H-chain genes showing probable arrangement of C_H genes in germ-line DNA

		Genes present and arrangement of C_H genes				
		μ	γ_1	γ_{2b}	γ_{2a}	α
C_H gene expressed	μ	√	√	√	√	ND
	γ_1	ND	√	√	√	ND
	γ_{2b}	ND	×	√	√	ND
	γ_{2a}	ND	×	×	√	ND
	α	ND	×	×	×	

√, Relevant gene present in the DNA. ×, Relevant gene was undetected in the DNA. ND, not determined, as no probe was available.

$C\alpha$ in a clone isolated from cells making IgA[32]), and the transcription unit now utilised by the cell will be V J_H ... intervening sequence ... $C\mu$. Assuming that V_H–J_H fusion occurs similarly to the V_L–C_L events, the resulting gene segment will consist of a continuous base sequence of V_H and J_H. This sequence will not contain any non-coding bases between V and J which might act as signals for re-integration of the V_H to a new J_H segment in the switch. The switch must therefore operate differently from V_H integration. Two main possibilities exist. First, it might occur by unequal cross-over between sister chromatids before cell division. The site of recombination might be between similar or identical J_H segments associated with the C_H genes, or sequences occurring within the intervening sequence between the VJ-$C\mu$ transcription unit and between the various C_H genes could be used for the recombination event. The second possibility draws an analogy from the mechanisms proposed for κ-chain integration which invoke the pairing of repeat sequences before $V\kappa$–$J\kappa$ fusion[5,6]. Thus it is possible that the switch of the V gene involves such repeat sequences present both within the intervening sequence of the VJ-$C\mu$ transcription unit and within the sequences separating the various C_H genes. Pairing of such repeat sequences followed by excision of the looped-out material could then facilitate the switching of a V_H gene between C_H genes.

A deletion mechanism for the switch has previously been proposed on the basis of solution hybridisation data by Honjo and Katoaka[16]. These workers deduced that the switch operated on only one of the allelic chromosomes with the non-expressed chromosomes remaining unchanged. Our data suggest the different possibility that the switch occurs on both allelic chromosomes since the experiments show, apparently, the absence of C_H genes from both chromosomes. However, the aneuploid nature of myeloma karyotypes may indicate that the cells used have lost the non-expressed allelic chromosome. We must also consider the possibilities that the deletions which we have observed are merely the manifestation of the aberrant myeloma karyotypes and as such would have no particular bearing on the H-chain switch. However, the observation that rearrangements involving the C_H genes of γ_{2a} and γ_{2b} can be specifically detected in the respective secretor DNA together with the apparent absence of certain C_H genes in the same DNA argues for the authenticity of the conclusion. In addition, experiments testing the rearrangement of some κ-producing myeloma cells[1,2] also indicated possible rearrangement of the non-expressed allelic chromosome, so chromosome loss may not be the full explanation. We are left with the possibility that the V/C integration (both L and H chain) and even the H-chain switch occurs on both allelic chromosomes, and it is possible that such alterations on both chromosomes may explain the presence of extra hybridisation bands in certain digests of γ_{2a} and γ_{2b} DNA.

The involvement of deletion in the H-chain switch may not be the whole answer to the problem, since cells clearly cannot go back to express a gene which has been deleted. Therefore we can ask the question about the situation regarding cells which co-produce μ and δ-H-chains[33,34]. A possible explanation is that these cells contain stable mRNA from one or other of these genes so that continued production of the protein can occur after switch/deletion to the second gene. However, it is still possible that μ–δ co-production occurs by V–C joining in the nuclear RNA precursors. Such a general mechanism was proposed for the H-chain switch[8,15,35] but it has been shown that at least μ and γ C-gene sequences do not co-exist in the nuclear RNA precursors[18]. However, the nuclear RNA precursors of μ/δ-producing cells may contain a precursor of the type $V_HC\mu C_\delta$ from which can be made either mRNA $V_HC\mu$ or $V_HC\delta$ by RNA splicing. This would be a simplification of previous schemes[8,15]. In the context of possible RNA splicing or recombination it is interesting that variant myeloma cells have been detected which show evidence of switching within the γ subclasses[36–39]. These cells may or may not be representations of the normal switch events and DNA cloning of the variant genes should settle this problem.

We thank Drs R. Perry, K. Marcu and U. Schibler for providing clone pγ_{2b}/7. We also thank Professor A. Williamson, Drs Askonas, N. Richardson and A. Munro for cell lines and B. Wright and M. Clark for carrying out cell incorporations. W.D. was supported by a fellowship from the Jane Coffinn Childs Memorial Fund for Medical Research.

Radio emission from radio-quiet quasars

In a search for radio emission from bright, optically selected quasars, we detected ~50% of the quasars at 5 GHz. This radio detection rate is so much higher than that for faint quasars (<10%)[1–4], that it requires that the distribution of radio(R)-to-optical(O) luminosity ratios (L_R/L_O) be correlated with optical properties and/or with distance (or cosmic epoch). The values of L_R/L_O in our sample range from ~10^{-2} to <10^{-5} (where radio detection is no longer possible). So broad and smooth a distribution argues against a distinct dichotomy between 'radio-quiet' and 'radio-loud' quasars. The quasars in our sample which remain undetected at radio frequencies must exhibit a spectral-flux distribution rising from the radio to optical, previously considered an 'abnormal' spectrum for a quasar.

Although quasars were originally discovered on the basis of strong radio emission, it now seems that most optically selected quasars are undetectable as radio sources[1–4]. In fact, most optically selected quasars show no clear evidence, at any frequency, for synchrotron radiation. For most quasars, whether radio-quiet or radio-loud, the IR–optical emission is not highly polarised (≲1%) (refs 5, 6), not a simple power law[7], and not highly variable[8]. In contrast, the radio emission from virtually every extragalactic radio source, and the IR–optical continuum radiation in a small subset of quasars, namely, the BL-Lac objects[9,10] and the 'optically-violent-variable' (OVV) quasars[11], seems explicable in terms of the synchrotron process.

There is still no obvious way to predict, on the basis of IR–optical properties, that a given quasar is radio-quiet[7]. Indeed, how quiet is 'quiet'? If there were a distinct dichotomy between 'radio-quiet' and 'radio-loud' quasars[12], the distribution of radio-to-optical luminosity ratios (L_R/L_O) would probably be bimodal. On the other hand, if radio-quiet and radio-loud quasars are merely extrema of the same phenomenon (as is the case for models involving geometric orientation, such as the relativistic-jet model[13–15]), the distribution of (L_R/L_O) for optically selected quasars should be very broad and smooth.

To answer the question, 'How quiet is quiet?', and to examine the distribution of radio-to-optical luminosity ratios (L_R/L_O), we initiated a search for radio emission from bright, optically selected quasars, with the very large array (VLA) of the US National Radio Astronomy Observatory (NRAO). Using the 1.5-m Mt Lemmon (Arizona) telescope of the University of Minnesota (UMinn) and University of California at San Diego (UCSD), we also obtained optical and IR photometry to seek correlations between IR–optical properties and radio emission.

The investigation reported here differs in two respects from most previous searches for radio emission from optically selected quasars[1–4]. First, we considered only the optically brighter, optically selected quasars—typically, at least 10 times brighter than the optical limits used in previous searches. Second, we used the VLA at 4.885 GHz: At this frequency, the VLA is roughly 10 times more sensitive than any other radio telescope. Combining these two factors then, the present investigation probes the radio-to-optical luminosity-ratio (L_R/L_O) distribution down to values ~100 times smaller than those examined in previous searches. In fact, the limiting spectral flux of the 5-GHz search is even slightly smaller than the intended optical limit of the sample selected—namely, 0.6 mJy at 703 THz ($B = 17$ mag). Consequently, to escape radio detection, a quasar from this optically selected sample must have an inverted spectrum—that is, its spectral-flux distribution (perhaps due to the superposition of multiple components) must rise from radio to optical frequencies.

We now briefly describe the samples and the results. A more detailed presentation, including the IR and optical photometry and possible interpretations in terms of physical mechanisms, appears elsewhere[16].

The sample consists of 22 bright, optically selected quasars (Table 1), studied previously[17–21] and contained in the quasar catalogue of Burbidge, Crowne and Smith[22]. During our radio and IR–optical observations (spring 1978 to spring 1979), only 16 of the selected quasars had a B magnitude brighter than 17. While the sample is not complete, it is, we believe, unbiased with respect to radio emission: quasars are neither included nor excluded because of their radio properties.

We detected 9 of the 22 quasars, including 8 of the 16 with $B \leqslant 17$, at a level >0.6 mJy at 4.885 GHz. Most of the radio sources are unresolved on the VLA, and thus are more compact than a few arc seconds. The detection rate is much higher than that of any previous search for radio emission from optically selected quasars; nevertheless, about half the quasars in our bright-quasar sample remain undetected at radio wavelengths, with a standard deviation of 0.15 mJy about a mean of 0.06 mJy. Therefore, as Fig. 1 shows, more than half the quasars have spectral-flux distributions increasing from radio to optical frequencies, that is, negative radio-to-optical spectral indices, $\alpha_R^O < 0$, for $\alpha_R^O \equiv -[\Delta(\ln F_\nu)/\Delta(\ln \nu)]$.

The distribution of α_R^O exhibits no clear separation between 'radio-loud' and 'radio-quiet': it appears smooth from $\alpha_R^O \approx 0.7$ down to $\alpha_R^O \approx 0.0$, at which point the radio emission is no longer detectable for every quasar in the sample. Thus we find no evidence to support the conjecture that 'radio-loud' and 'radio-quiet' quasars belong to two distinctly different populations[12].

Elsewhere[16], we consider in detail plausible explanations for the observed large range in radio-to-optical luminosity ratios. If

0028–0836/80/040357—02$01.00

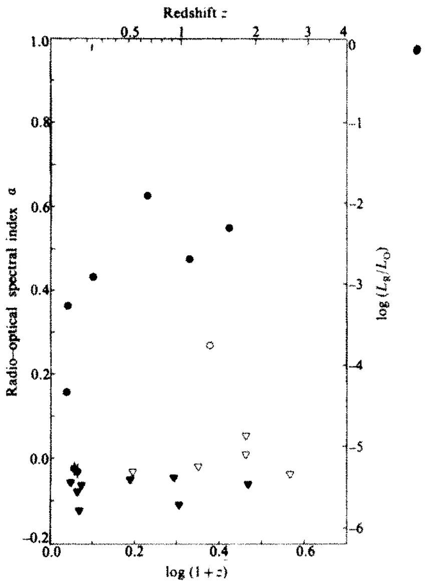

Fig. 1 Distribution of radio-to-optical luminosity ratios (L_R/L_O) for a sample of bright optically selected quasars, plotted against $(1+z)$, with z the redshift. ○, Radio detections; ▽, 2σ upper limits. The filled symbols represent the brighter quasars ($B<$ 17 mag).

the IR–optical emission from quasars is synchrotron (or processed, for example, Compton scattered, synchrotron) radiation, the frequent weakness of synchrotron emission at radio frequencies might result from synchrotron self-absorption or from free–free absorption by intervening material, such as broad-line emitting regions. (This latter explanation is quite reasonable; however, it would be inadequate if truly radio-quiet BL-Lac objects were to be discovered.) If the IR–optical continuum is not synchrotron radiation, there need not be any correlation between radio and optical luminosities. Relativistic-jet models[13,14] owing to differences in orientation, require a rather broad distribution of radio-to-optical spectral indices[15,23]. In this respect, our results are in qualitative agreement with relativistic-jet models; however, agreement in detail requires an hypothesis somewhat more complicated than that considered so far[15] (see below).

Finally, we question why the radio-detection rate for our sample (~50%) is so much higher than that for other searches (~10%)[1–4]. That we consider only optically bright quasars and have utilised the remarkable sensitivity of the VLA partly explains the higher detection rate for our sample. However, even with a 100-fold less sensitive radio search ($F_\nu<60$ mJy, or 100 mJy, say), we would still have detected about 30% (5 out of 16) of the quasars with $B\leq17$ mag.

It seems, therefore, that quasars of bright apparent magnitude exhibit a significantly higher incidence of radio emission than would be expected on the basis of a scaling of detection thresholds. In as much as the optical-selection techniques are unbiased with respect to radio emission, the fraction of quasars with (L_R/L_O) or ($-\alpha_R^O$) above some threshold should be independent of the limiting optical flux or any other optical-selection criterion provided that the ratio (L_R/L_O) is uncorrelated both with optical properties and with distance (and, hence, cosmic epoch). That this fraction does depend on the limiting optical flux, shows that the distribution of (L_R/L_O) must depend on optical properties and/or epoch (or distance). Owing to the small size of the present sample, one cannot readily determine which of these dependences is more important (see Fig. 1); however, the more rapid evolution observed for optically selected quasars, in comparison to that observed for flat-spectrum radio sources[24], suggests that evolution in the distribution of (L_R/L_O) plays some part.

J.J.C. thanks the A. P. Sloan Foundation for a grant. The National Radio Astronomy Observatory (NRAO) is operated by Associated Universities Incorporated under contract with the NSF. IR and optical astronomy at the University of Minnesota is supported through NSF grant AST78-14464; radio astronomy at the Virginia Polytechnic Institute and State University was supported in part through NSF grant AST77-08013.

We report here on the unusual behaviour of MXB1730−335, the rapid burster[1] as observed by the X-ray astronomy satellite Hakucho between 8 and 22 August 1979[2]. MXB1730−335 is a unique burst source which generates rapidly repetitive bursts lasting between a few and tens of seconds. In the present observations, however, its behaviour was very different to that previously observed, in that the bursts of a trapezoidal profile were dominant. The profile is characterised by a flat top lasting between 30 s and 10 min. A long train of such trapezoidal bursts was seen for the first time and clearly revealed a new mode of the rapid burster.

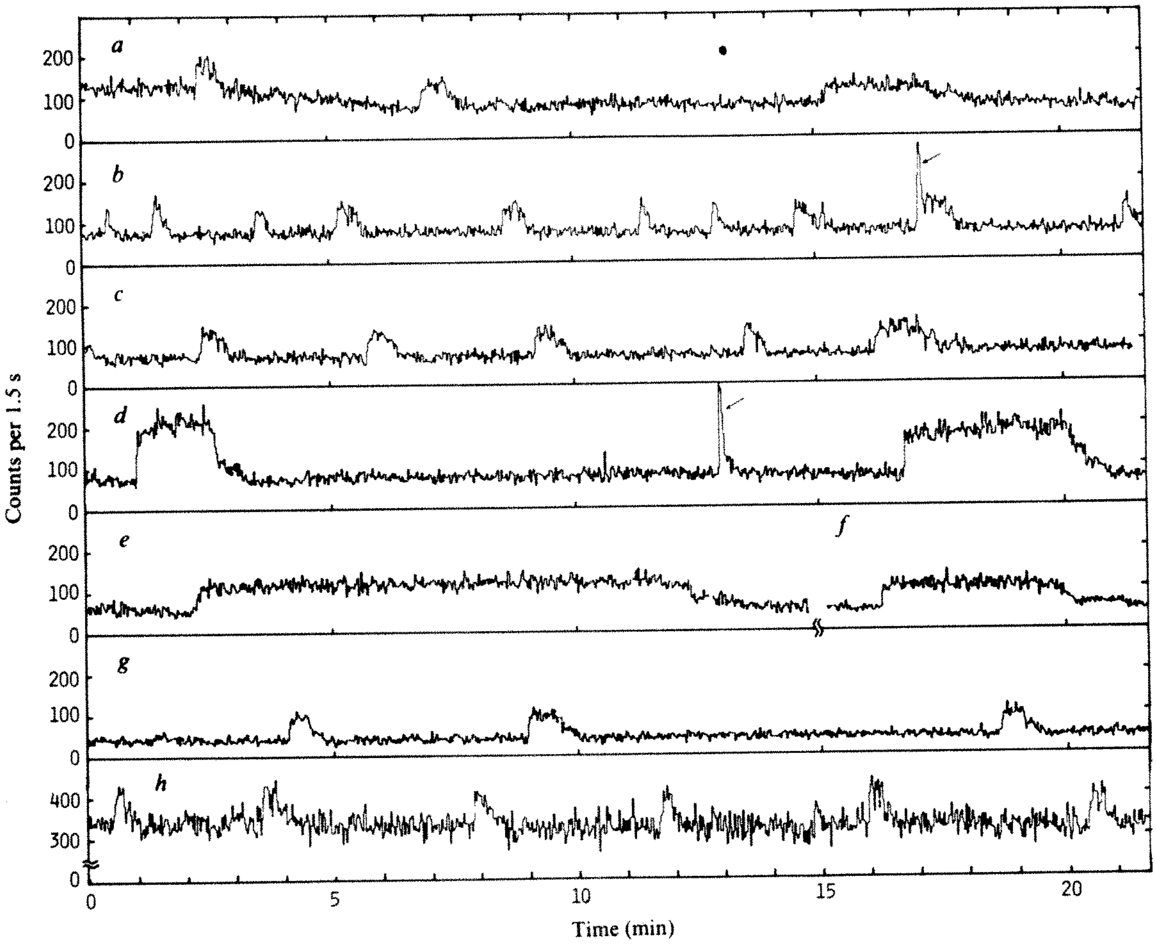

Fig. 1 Segments of the X-ray count-rate record. The graphs *a–g* are from counter FMC 2, and *h* is the sum of the rate from CMC 1 and 2. Since the exposure of the target and the covered energy range (*a*, *b*, 1.5–10 keV; *d–h*, 3–10 keV) are not corrected for, displayed count-rates should not be directly discussed. Two bursts indicated by arrows are from MXB1728 – 337, a nearby burster. Each segment starts at the following times (UT): *a*, 8/8, 1 h 55 min 19.2 s; *b*, 8/8, 3 h 37 min 39.8 s; *c*, 8/8, 5 h 19 min 45.3 s; *d*, 8/8, 19 h 48 min 00 s; *e*, 8/11, 19 h 19 min 54.3 s; *f*, 8/12, 16 h 08 min 24.1 s; *g*, 8/14, 17 h 22 m 58.3 s and *h*, 8/17, 13 h 43 min 39.1 s.

The observation was carried out with an X-ray burst monitor which consists of two sets of rotating modulation collimators: two coarse modulation collimators (CMC 1,2) and a fine modulation collimator (FMC 1) with a field of view of 17.4° and 5.8° (FWHM), respectively. Positions of steady sources and the burst, when it occurs, can be determined with the burst monitor to an accuracy of 0.5° or better. An additional counter (FMC 2) with 5.8° field of view (FWHM) provides non-modulated source signal for comparison. Further details of the instrumentation and the performance of Hakucho are described elsewhere[3].

Since 31 July the burst monitor has been observing a sky region which includes the galactic centre. At 0 h 10 min UT, 8 August, a source in the field of view, whose position was determined with the CMC in a 0.5° error circle including MXB1730 – 335, began to generate a train of bursts (the source was soon confirmed by the FMC 1). The activity of the source was watched through 22 August. The turn-on of the rapid burster was roughly on schedule as expected from the suggested periodicity[4,5] of ~6 months: the previous active period was early March 1979[6].

Figure 1 shows several segments of the X-ray count-rate record. In the early period of the activity starting at 0 h 10 min UT of 8 August, unusual bursts of a trapezoidal profile appeared among bursts of a normal exponential shape (Fig. 1*a*). The data from 3 h 37 min to 4 h 00 min UT of 8 August (Fig. 1*b*) show characteristic features of bursts from the rapid burster such as those observed by SAS 3 (refs 1, 7). After a pause of data acquisition for ~6 h, a long burst train entirely trapezoidal in

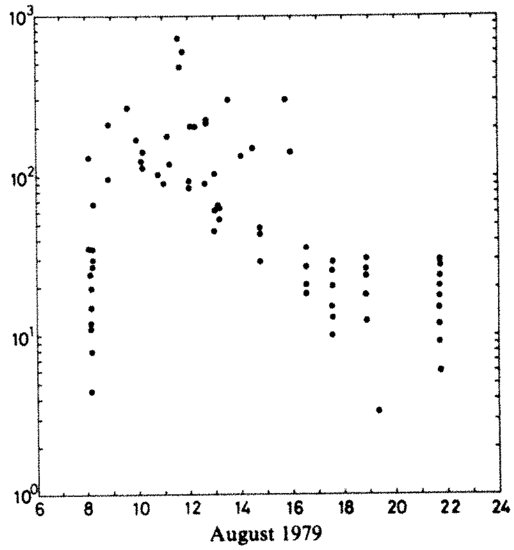

Fig. 2 Plot of the burst duration measured at half maximum of the burst height. Not all the bursts, particularly those of short duration, are plotted. Most bursts of the duration longer than 30 s are of trapezoidal shape. The error of the duration is ~3 s and ~5 s for the period before and after 17 August respectively.

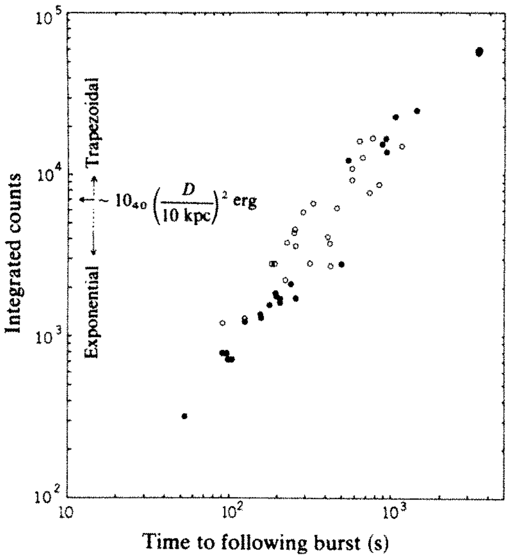

Fig. 3 Integrated counts for a burst over 1.5–10 keV versus the time to the following burst. Correspondence between the total count within an error of ±15% and the total energy is indicated on the ordinate. Note, however, that the energy estimate is tentative. ●, 8.0–11.8 August; ○, 12.5–18.9 August 1979.

form appeared (Fig. 1*d*, *e*). About 90 trapezoidal bursts were observed between 8 and 16 August during a total exposure time of ~35 h.

The predominance of such trapezoidal bursts is new property of the rapid burster[7], although a few such unusual bursts from the rapid burster were noted during the previous turn-on period (ref. 6 and personal communication from W. Lewin).

The burst durations (FWHM) observed for selected satellite orbits are plotted in Fig. 2. The burst duration increased soon after the turn-on of the rapid burster, exceeding 10 min at its maximum. After 12 August trapezoidal bursts of shorter duration predominated (Fig. 1*g*), while the duration scatters. Then, on 16 August bursts of an exponential shape again appeared among trapezoidal bursts and after 17 August, the feature became similar to that of the normal rapid burster (Fig. 1*h*). The activity continued until 22 August when we lost MXB1730–335 from our sight because of the solar direction constraint.

The time profile of the trapezoidal burst is characterised by the following features: a fast rise within ~1 s, a nearly constant plateau and a slow fall to half the maximum in 10–30 s with the association of a shoulder or an after pulse in the decaying phase. These features seem to be independent of the pulse width. The peak luminosity of the trapezoidal bursts is of the order of 10^{38} $(D/10\mathrm{kpc})^2$ erg s^{-1}, D being the distance to the source, but is found to vary by as much as a factor of four. From a simple analysis, the spectral hardness ratio is found to remain constant within statistical uncertainty throughout the flat portion of the trapezoidal burst.

For cases when two or more bursts occurred in an uninterrupted observation window, the integrated counts in each burst (burst size) are plotted against the time interval to the succeeding burst in Fig. 3. While the estimate is tentative, the total energy for most of the trapezoidal bursts $>10^{40}$ $(D/10\mathrm{kpc})^2$ erg. The correlation between the burst size and the interval is similar to that shown by the SAS 3 result (ref. 7 and refs therein); that is, the larger the burst size, the longer is the time until the next burst.

The average slope of the points in Fig. 3 is somewhat steeper than a linear relationship. Whereas, we note episodes in which the burst size versus interval relation is closely linear and hence the time-averaged luminosity is about constant. For example, the filled circles in Fig. 3 indicate two such episodes. The slope is greater than unity because an increased average luminosity tends to favour a larger burst, although the burst size fluctuates. The average luminosity was found to vary by a factor of three over the period of the present observation, during which the burst size spanned two orders of magnitude.

The train of trapezoidal burst is probably a new mode of the Type II burst (ref. 7 and refs therein) which is presumably caused by an instability of the accretion flow onto the neutron star surface. The present data indicate that the trapezoidal bursts predominate when the average luminosity is above a certain value. This implies that a relatively small change in the mean accretion rate corresponds to a drastic change in the burst profile. Instead of increasing the frequency of usual bursts of exponential shape, trapezoidal bursts of various widths are produced with the peak luminosity near the Eddington limit for a 1 $M_\odot$ star. Note, however, that this peak luminosity is also variable. This newly discovered mode of burst undoubtedly imposes a strong constraint on the model of the rapid burster.

We thank Professor T. Hayashi and Mr K. Inoue of ISAS who managed the project CORSA-b (Hakucho), and also the staffs of the Department of Space Engineering, ISAS, who launched the satellite. The assistance of messrs Y. Sakurai, Y. Shinkai and A. Tanogashira in the data reduction is appreciated.

Neutral ^{14}N in the interstellar medium

A. A. Konovalenko & L. G. Sodin

Institute of Radiophysics and Electronics, Kharkov, USSR

The transition frequencies between the hyperfine structure sublevels of atomic nitrogen lie in the decametre waveband. As Shklovsky[1] predicted, these transitions can be observed in the form of narrow spectral lines. The ^{14}N ground state ($^4S_{3/2}$, nucleus spin $I = 1$) is split into three sublevels $F = 5/2$, $3/2$ and $1/2$ with frequencies and transition probabilities

$$\nu = 26.127\ \mathrm{MHz},\quad A = 4.32\times10^{-20}\ \mathrm{s}^{-1}\ \text{for}\ F = 5/2 \rightarrow 3/2$$

and

$$\nu = 15.676\ \mathrm{MHz},\quad A = 1.29\times10^{-20}\ \mathrm{s}^{-1}\ \text{for}\ F = 3/2 \rightarrow 1/2$$

The Einstein coefficients given here have been calculated from the improved values of line intensities[2]. We describe here an attempt made between 1978 and 1979 at the Institute of Radiophysics and Electronics, Academy of Science of the Ukrainian SSR, to detect the ^{14}N absorption line for some point and extended cosmic objects. This effort has been successful for Cassiopeia A.

The observations were carried out using the UTR-2 radio telescope[3] at a frequency of 26.13 ± 20 kHz (collective area of the antenna about 5×10^4 m^2). The emission spectrum was measured with a spectrometer[4] consisting of a receiver with a frequency synthesiser, a digital correlator and a computer controlling the antenna beam and converting the autocorrelation function into the spectrum. Measurements of autocorrelation functions were taken with the beam directed to the source of interest alternatively by the maximum and the first zero (for between 0.5 and 1s). The two values were further subtracted instrumentally. The difference autocorrelation functions were stored and converted into the spectrum. The total storage time of the difference autocorrelation functions was from 1 to 5 h in one observation night. The resolution varied in different observation sessions from 1 to 4 kHz.

The 26.13 MHz absorption line was first detected in the signal of Cas A on 17 June, 1978 after which measurements carried

0028–0836/80/040360—02$01.00

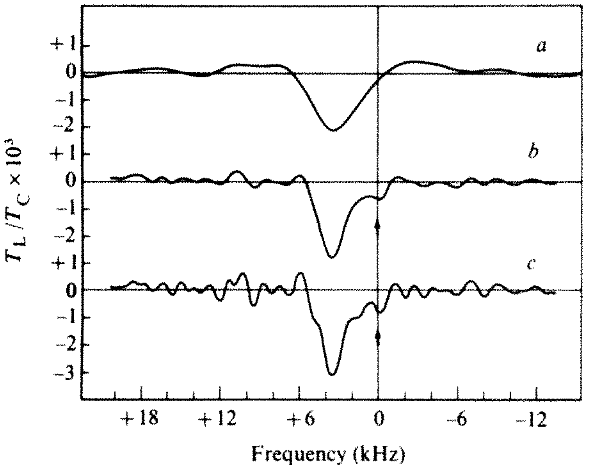

Fig. 1 Absorption spectra in the ^{14}N line $F = 5/2–3/2$ for Cassiopeia A. *a*, Resolution 4 kHz, storage time $T = 26$ h; *b*, resolution 2 kHz, $T = 25$ h; *c*, resolution 1 kHz, $T = 24$ h. The arrow shows the frequency corresponding to the Orion arm.

out over the next year established a coincidence of the observed changes in the mean frequency of the line with the orbital Doppler shift (0.67 kHz with respect to the standard of rest).

Figure 1 shows three spectra from Cas A plotted with different resolutions in the frequency-T_L/T_C scale (where T_L and T_C are temperatures in the line and the continuum). Figure 2 shows the predicted Doppler frequency shift due to the orbital motion of the Earth and measured mean frequencies of the line for different observations. Figure 3 shows the H I absorption line in terms of velocities instead of frequencies[5] and the ^{14}N line reduced to a zero orbital velocity. Strong absorption can be seen in the Perseus arm ($V = -38$ to -48 km s^{-1}) and weak absorption in the Orion arm ($V = -0.8$ km s^{-1}). The measured optical depths at the line minimum are 3×10^{-3} for the Perseus arm and 5×10^{-4} for the Orion arm. The expected absorption line width in the Orion arm[5] is ~0.4 kHz. Hence, the intensity of this part has been underestimated in our measurements.

Thus, the periodic change of frequency coinciding with the orbital Doppler effect and comparing the H I in Cas A spectrum suggests that we have discovered the $F = 5/2 \rightarrow 3/2$ line of ^{14}N.

Measurements for Cygnus A have shown that in its direction $\tau < 2 \times 10^{-4}$; measurements for the Galaxy centre were greatly hampered by interference from broadcasting stations and only allowed us to estimate $\tau < 6 \times 10^{-4}$.

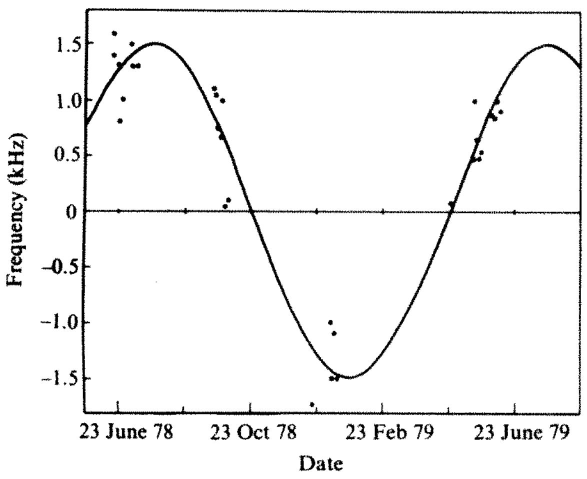

Fig. 2 Change of frequency due to the orbital motion of the Earth. Solid line, calculations; ●, measurements.

To estimate the abundance of nitrogen in the absorbing arms we use the relationship

$$S = \int \tau(\nu)\,d\nu = \tau_{\max}\Delta\nu_{\text{eff}} = \frac{\hbar c^2}{4kT_S}\frac{A}{\nu}\frac{g_F}{\Sigma g_F}n$$

where $\tau(\nu)$ is the line profile; $\hbar$, k, c are Planck's constant, Boltzmann's constant and the velocity of light, respectively; A, and ν are the probability and frequency of the transition; g_F the statistical weight of the sublevel; T_S the spin temperature; and n the density of atoms.

For ^{14}N we have $n_N = 0.7 \times 10^{18} S_N T_{SN}$ (subscript N denotes the values for nitrogen). Our measurements give $S_N \simeq 6$ s^{-1} for the Perseus arm, hence assuming $T_{SN} = 50$ K, we find $n_N = 2.8 \times 10^{20}$ cm^{-2}.

Comparing the abundance of ^{14}N using the H I line, in accordance with Schutter and Verschuur[5], S_H can be estimated as $S_H \simeq 10^6$ s^{-1}, and with $A_H = 2.85 \times 10^{-15}$ s^{-1} and $\nu_H = 1.42 \times 10^9$ Hz we obtain

$$\frac{n_H}{n_N} \simeq 130 \frac{T_{SH}}{T_{SN}}$$

If we assume $T_{SH} = T_{SN}$, the abundance of nitrogen with respect to hydrogen would be more than one order of magnitude higher than the average value in the Galaxy (that is 5×10^{-4}). Other explanations of the unexpectedly strong absorption in the ^{14}N line are also possible.

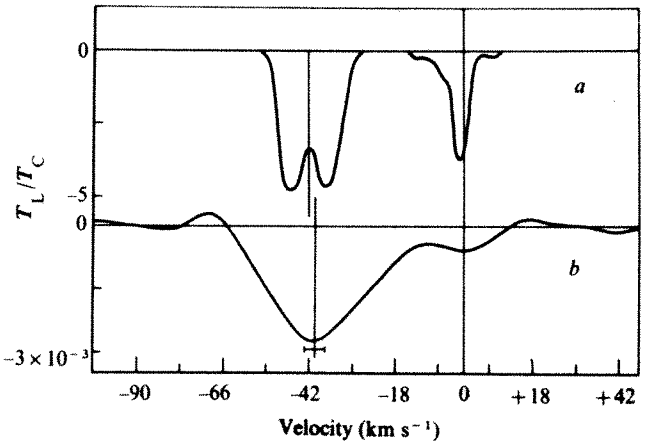

Fig. 3 Velocity spectra in the absorption clouds of the Orion and Perseus arms. *a*, H I line, 1,420 MHz; *b*, ^{14}N line, 26.13 MHz.

(1) The true value of S_H in the gas cloud of the Perseus arm is $S_H \gg 10^6$ s^{-1}. Other measurements[5] allow any value of $\tau_H > 4.7$. In this case the estimate for hydrogen density would need to be increased by more than an order of magnitude and the OH/H I relationship (see ref. 6) revised assuming a higher value for τ_H.

(2) The spin temperature $T_{SN} \ll T_{SH}$: this could be the result of either some specific features in the population of the ^{14}N levels (which can be checked by a theoretical calculation) or nitrogen distribution in the colder parts of the gas cloud.

Further investigations are planned with the aim of discovering the line $F = 3/2 \rightarrow 1/2$ ($\nu = 15.7$ MHz).

We thank S. Ya. Braude for stimulating the investigations, as well as for discussions.

Catalytic combustion in a tube with electrical discharge: preliminary measurements of augmented reaction rates

F. A. Kulacki & S. Boriah

Department of Mechanical Engineering, The Ohio State University, Columbus, Ohio 43210

Since Senftleben[1] first indicated that in the presence of electric fields, heat transfer rates may be increased substantially beyond natural convection values, correlations have been proposed relating electric field and fluid flow parameters to film coefficients of transfer. The 'corona wind', which exists in a non-uniform electric field before spark breakdown, can be used to alter the hydrodynamics of convective diffusion processes such that an augmentation of transport rates in wall boundary layers can be achieved[2–6]. Corona wind augmentation of wall reactions, particularly catalytic combustion processes, has not previously been considered[7,8], but as catalytic combustion is a convective diffusion process, the superposition of the corona wind on the flow field near the catalytic surface may augment overall reaction rates by increased mixing. For very rapid surface reactions, where molecular diffusion inhibits the overall rate and lowers overall rate constants, corona wind augmentation may limit the effects of diffusion and, thereby, increase catalyst effectiveness. Improvements in the overall rate constant, or mass transfer coefficient, would be useful in many areas, including air pollution control, energy conservation, and the design of compact, controlled heat flux catalytic combustors. We report here our test of the catalytic combustion of hydrogen at one atmosphere on platinised alumina in a flow reactor with a uniformly accessible catalyst surface. By this experimental design we may be able to obtain reaction rate data from the kinetically controlled to the diffusion limited regimes of combustion owing to the high activity of hydrogen on metallic platinum. A uniformly accessible catalyst surface also permits analysis of the reaction rate data using either one- or two-dimensional approaches.

The experimental reactor is an annulus of large radius ratio, and the corona discharge is applied from a small diameter (0.053 cm) stainless steel wire suspended under tension along the centreline. The outer cylinder is a 95.5% Al_2O_3 tube of dimensions 4.50 cm o.d. × 3.91 cm i.d. × 58.4 cm long. This tube is coated internally with platinum at an average of 13.3 g m^{-2}. The reactor wall is maintained at a constant temperature to within ±5 °C with electrical heaters, and bulk flow temperatures are held at about one-half the wall value to minimise the possibility of gas phase reaction. The catalyst surface is grounded and a positive d.c. potential (300 V maximum a.c. ripple over the range 6–11 kV) is applied to the central wire. Premixed hydrogen and air enter the reactor in nearly fully developed flow. The combustion of hydrogen is determined by measurements of both inlet and outlet bulk concentrations with a gas chromatograph.

Reaction rate data as a function of average mole per cent of hydrogen, $\bar{y}$, at a constant corona current, I, at a wall temperature, T_w, of 427 °C are presented in Fig. 1. At this wall temperature, the reaction is diffusionally limited in laminar flow[9–10], and the rate data exhibit the expected first-order dependence on $\bar{y}$. Rate data at lower wall temperatures[11] are also first order with respect to $\bar{y}$. From the data of Fig. 1, increases in the reaction rate of the order of 20–25% are observed for moderate levels of corona current. These increases may be interpreted as an augmentation of the mass transfer coefficient owing to the uniformly accessible catalyst surface[12].

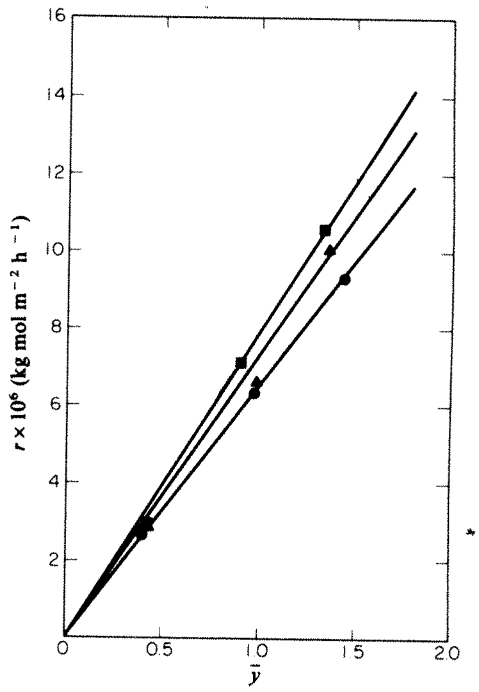

Fig. 1 Reaction rate for combustion of hydrogen on platinised alumina at constant corona current where $T_w = 427$ °C; $T_B = 260$ °C; Re = 1,437. ■, $I = 500$ μA; ▲, $I = 300$ μA; ● = 0.

The combined roles of the Reynolds number and corona current are shown in Fig. 2. Reaction rate data versus corona current for given values of Reynolds number and inlet concentrations of hydrogen, y_i, are presented in Fig. 2*a* in terms of the fractional increase of reaction rate due to the corona discharge. The range of corona current is somewhat larger than shown in Fig. 1 and includes all of the values possible before spark breakdown. For a given value of I, the increase in reaction rate depends on the Reynolds number and y_i in a complex fashion (Fig. 2*b*). At low Reynolds number, the reaction is nearly complete, and $\Delta y/y_i$ is close to unity. Thus, the presence of the corona discharge results in a small increase in reaction rate even though corona wind velocities are of the order of the bulk convective velocity. At larger Reynolds numbers, $\Delta y/y_i$ is smaller, but because the bulk convective velocity is large enough to eliminate essentially the influence of the corona wind, a reasonable augmentation of the rate is obtained. At still larger Reynolds numbers, for example, $Re = 2{,}617$ in Fig. 2*a*, greater fractional increases in reaction rate are obtained. At this Reynolds number, the flow is probably turbulent, but apparently not of large enough velocity to wipe out the influence of corona discharge on the hydrodynamics at the catalytic wall. Limitations of the experimental reactor prohibited us from obtaining reaction rate data at larger Reynolds numbers at this wall temperature. However, one can expect that at larger Reynolds numbers, the axial convective transport would completely dominate the mass transfer problem and that the corona discharge would result in no augmentation of the reaction rate. A similar transition to turbulent flow behaviour has been observed in the heat transfer problem for both tube flows and external boundary layers[13–14]. Note that a cross-plot of data similar to that of Fig. 1 would yield different fractional augmentation values, but the same conclusions would be reached on the role of the Reynolds number.

When the reaction rate data are plotted as a function of Reynolds number at a constant corona current, the fractional augmentation of reaction rate exhibits the highly non-linear behaviour shown in Fig. 2*b*. Here, increases in Reynolds number past a certain value (depending roughly on wall temperature and corona current) result in a rapid decrease in $(r_e - r_c)/r_0$. This is

0028-0836/80/040362—03$01.00

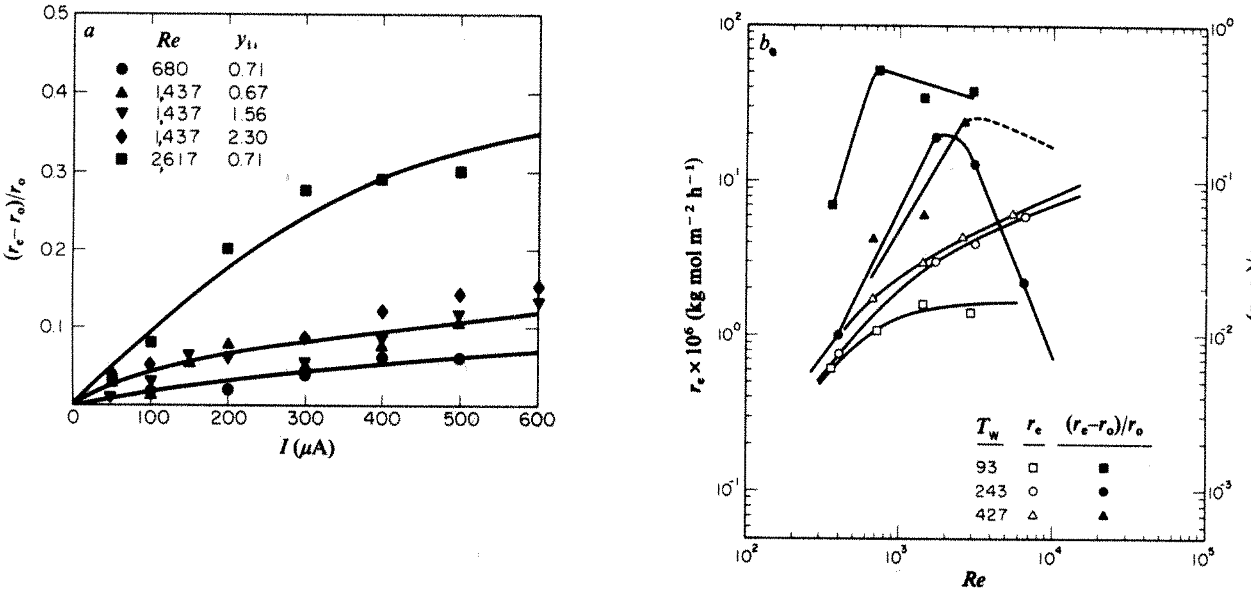

Fig. 2 *a*, Fractional increase in reaction rate as a function of corona discharge current: $T_w = 427$ °C; $T_B = 263$ °C. *b*, Reaction rate and augmented reaction rate as functions of Reynolds number at constant corona current ($I = 300$ μA).

particularly evident at $T_w = 243$ °C, where the augmented reaction rate rapidly approaches the value for no corona current as the Reynolds number attain values normally associated with turbulent tube flows. Note also that fractional augmentation of reaction rate at a given Reynolds number exhibits a complex dependence on wall temperature. This is shown in Fig. 2*b* where $(r_e - r_0)/r_0$ for $T_w = 93$ °C is much larger than at $T_w = 243$ °C and 427 °C even though the overall reaction rate is lower. Additional experiments are needed, however, to determine completely the dependence of augmented reaction rates on *I*, *Re* and T_w.

The degree to which molecular diffusion limits the overall reaction rate is expressed in terms of the effective first-order rate constant derived from a one-dimensional analysis of the overall reaction rate data[9,10]. Rate constants without corona discharge present exhibit a transition from mixed kinetics at $T_w = 93$ °C to nearly diffusion controlled at $T_w = 427$ °C (Fig. 3*a*). The presence of corona discharge produces the increase in rate constants as shown in Fig. 3*b* for a narrow range of Reynolds numbers. Here it is seen that, at $T_w = 427$ °C where rate constants can be interpreted as mass transfer coefficients[9,10,12], the corona discharge can produce up to a 50% augmentation in the rate constant. The error bars on each of the data points in Fig. 3*b* represent the maximum variation in the measured values.

Analysis of these experimental data has revealed no general mass transfer correlation for the data at $T_w = 243$ °C and 427 °C. Tentatively, we conclude that the augmentation of the reaction rate, or the rate constant, at these temperatures varies as $I^{1/2}$ at a constant Reynolds number. This result is reassuring in view of the work of Velkoff and Godfrey[13] and Mizushina *et al.*[14]. However, additional experiments and analysis are needed to permit a mass transfer correlation of general engineering utility. For the data in the regime of mixed kinetics, that is, $T_w = 93$ °C, it is doubtful that diffusional and kinetic effects can be separated for a wide range of corona current.

This research was sponsored by the NSF under grant ENG 7605032 and the Gas Research Institute under grant GRI-5009-362-008.

Seasonal change in the flux of organic carbon to the deep Sargasso Sea

W. G. Deuser & E. H. Ross

Woods Hole Oceanographic Institution, Woods Hole,
Massachusetts 02543

Recent evidence[1–5] has suggested that diurnal and annual periodicities affect the deep sea which traditionally had been thought to be the least variable environment at the surface of the Earth[6,7]. We report here what we believe to be the first direct measurements of seasonal change in the total flux of particles <13 cm and in the flux of organic carbon associated with those particles. The change seems to be related to seasonal change in the primary productivity of the surface water.

Between April 1978 and July 1979 a series of samples of particulate matter were collected in a sediment trap similar to the type described by Honjo[8]. The trap has a collecting cross-section of 1.54 m^2 and could accept particles <13 cm. The largest particles collected, in fact, were about 10 mm in length. Collection periods ranged from 60 to 68 days. The trap was moored 1,000 m above the sea floor and intercepted the particle flux at a depth of 3,200 ± 100 m. It did not collect during its descent or its ascent. The collection site was 25 nautical miles south-east of Bermuda. The experiment was not designed primarily to measure the organic carbon flux. No preservative or poison was contained in the collection cup of the sediment trap, but their absence is not expected to cause significant loss of organic carbon at that depth within 2-month collection periods[8].

Data on the total particle catch, on the mass distribution of particles smaller and greater than 125 μm, and on organic carbon content are shown in Fig. 1. The data are averaged over the collection periods. The last two sampling periods cover approximately the same time of year as the first two. For comparison, Fig. 1 also shows the monthly averages of the daily net primary productivity measured by Menzel and Ryther[9] between December 1957 and April 1960. Those measurements were made at a location 10 miles from the mooring site of our sediment trap.

Figure 1 shows: (1) fluctuation of a factor 2.75 in the amount of particulate matter collected per unit time; (2) relatively smooth variations of the amounts through the 16 months, with highs in April/May and lows in the summer months; (3) similar variations in the size fractions and the organic carbon as in the total amounts; (4) an indication of some year-to-year variation, with the 1979 high about 1.7 times as high as the 1978 one; and (5) similar locations of the highs and lows in the particulate flux and in the primary productivity.

Most of the material collected in the trap was of biogenic origin, with clay and other non-biogenic mineral particles representing only a minor part of the <37-μm size fraction. Most of the material consisted of whole individuals or fragments of Pteropoda, Foraminifera, Radiolaria, Gastropoda, diatoms and coccoliths, with occasional otoliths, squid beaks, fragments of bryozoan colonies and plant debris. Faecal pellets in various states of preservation were common and may have been more so in the undisturbed suspension in the collection cup of the trap. The organic carbon content was determined only on subsamples of the <125-μm fraction because of the greater heterogeneity of the coarser material and the destructive nature of the measurement. However, the <125-μm fraction comprised 82 ± 4% of the total samples and we do not believe that extrapolation of the organic carbon content as measured on that fraction over the entire samples introduces a significant error. The organic carbon in all samples had a rather uniform δ^{13}C of -21.4 ± 0.3‰ relative to the PDB standard, a typical value of open-ocean particulate organic carbon[10].

The data suggest that the flux to the deep sea of particles and of organic carbon in all but very large particles not captured by the trap is not uniform with time. There is indication of a seasonal cycle in that supply which, in the positions of its maximum and minimum, is similar to the seasonal cycle in primary production measured by Menzel and Ryther[9]. Unless the food supply to the deep-sea benthos consists predominantly of the very large particles not collected by a sediment trap of this type, these data represent the first indication of fluctuations in the supply of organic matter to the deep sea remote from major land areas. Seasonal variations in the standing crop of organic aggregates had been noted earlier by Riley *et al.*[11]. The highs and lows in the supply are apparently linked to the highs and lows of primary production in the surface waters and thereby point towards a possible link between seasonality of surface productivity and seasonal breeding and growth cycles in the deep sea[2–5]. Because productivity was not measured simultaneously with our trap collections, and our collections extended over two-month periods, we cannot see what delay there is between the peak in surface productivity and the peak in arrival of particulate matter in deep water. The biweekly measurements of Menzel and Ryther showed peaks in primary production from February to April; our measurements of the particulate flux peak in April/May but the peaks in the deep water may also extend back into March which was not sampled in either year. The data suggest that seasonality in the organic carbon flux is not wiped out at a depth of 3,200 m, indicating rapid settling of the greater part of the organic matter, much of it probably in the form of faecal pellets[8,12,13].

The year-to-year variation is of the same order as that observed by Menzel and Ryther[9], but we may have missed the 1978 peak just before our sampling programme began.

It is possible that the observed fluctuations are due to the trap collecting particles carried in by currents from different directions at different times of the year. If this mechanism operates it does not seem to do so on a very large geographical scale. The material must have come from an area with very similar seasonal pulsation as is shown by the correspondence with the primary production cycle. We have also observed a similar correspondence in the succession of population peaks of planktonic foraminiferal species in the surface water[14] and the arrival of those peaks in the sediment trap. Any lateral influx of particles into the water surrounding the sediment trap does not apparently eliminate the seasonal signal.

The variations in the particle flux shown in Fig. 1 might also have been caused by varying particle trapping efficiency of a uniform flux if there were a seasonally changing current regime at the depth of the trap. Gardner[15] has shown that funnel-shaped traps with baffles at the top, similar to the design used in this study, have an overall trapping efficiency of 70–90% for

0028-0836/80/040364—02$01.00

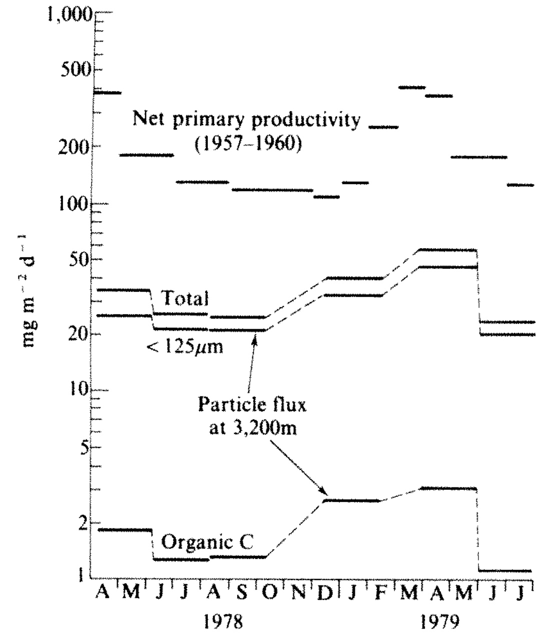

Fig. 1 Comparison of monthly averages of daily net primary productivity (in terms of carbon) for the years 1957–60 (ref. 9) with the average daily yields of total sediment (dry weight) and particulate organic carbon during six recent 2-month sampling periods by a sediment trap. The measurements refer to locations 15 and 25 miles, respectively, south-east of Bermuda. The trap was placed 3,200 m below the surface and 1,000 m above the sea floor.

particles <25 μm in horizontal flows up to 9 cm s^{-1}. For larger particles the efficiency should be greater. Gardner also showed that the efficiency of particle retention in the trap varies with flow speed and angle of attack of the flow. While we have no current data from the mooring site and depth, continuous measurements at a depth of 4,018 m, 27 miles north-northwest of Bermuda (N. Hogg, personal communication) show no indication of a seasonal signal in either speed or direction. The period covered by that measurement series was April 1975 to January 1976. Current speeds were generally <15 cm s^{-1} and 70% of the time <7.5 cm s^{-1}. There is no evidence that the current regime at the trap site should be significantly different. Neither is there any theoretical reason nor experimental evidence for seasonal current changes at that depth anywhere in the North Atlantic. Therefore, we consider it unlikely that the flux variations we have observed are a sampling artefact. We cannot, however, completely dismiss the possibility that the observed fluctuations are random rather than seasonal. Observations over a much longer time span are needed for a proper assessment of that possibility.

It is interesting to compare the range and means of the net primary production[9] and of the arrival of organic carbon at a depth of 3,200 m at very nearly the same location. Menzel and Ryther measured net primary production in the range 100–800 mg C m^{-2} d^{-1} with a mean around 200 mg. Our measurements at 3,200 m show fluxes ranging from 1 to 3 mg with a mean close to 2 mg. It thus seems that 1% of the net production at the surface penetrates beyond 3,000 m with the small-particle flux, a figure which agrees with many earlier deductions[16] as well as with *in situ* respiration measurements of benthic communities at comparable depths[17].

Direct measurement of the attenuation of ocean waves by pack ice

Vernon A. Squire & Stuart C. Moore

Scott Polar Research Institute, University of Cambridge, UK

Early experimental work in the Antarctic[1] using a ship-borne wave recorder has shown that pack ice can significantly attenuate incoming ocean waves, particularly those of shorter period. Wadhams[2,3] has subsequently reported similar wave decay through Arctic ice in data obtained remotely by means of airborne laser profiling and inverted echo sounding from a submarine. The two predominant mechanisms by which the decay can occur—scattering by individual ice floes and energy loss by creep within each flexing floe—have been studied theoretically by Wadhams[4,5], Squire[6,7], and Squire and Allan[8]. We present here the results of further experiments to measure wave decay which took place in the Bering Sea during spring 1979 from the research ship Surveyor of the National Oceanic and Atmospheric Administration[9]. During the cruise, oceanographic, meteorological and remote sensing data were also collected[10,11]. The results show the energy decay of waves in pack ice to be exponential with an attenuation coefficient which increases with decreasing wave period.

The attenuation experiment comprised eight floe stations of similar size and thickness, which lay along a line parallel to the direction of the observed principal swell (the attenuation line). They were chosen so that their separation increased away from the ice edge (Fig. 1). The seven floes within the ice pack were visited using the ship's Bell 206 helicopter equipped with a GNS-500A global navigation system which had been preprogrammed from Loran-C on Surveyor. Distances calculated from position fixes should therefore be good to within 0.2 km (Table 1). The first floe, situated on the ice edge itself ~1 km from Surveyor, was reached using the ship's whaleboat. The heaving motion of each floe was measured using a Schaevitz-EM vertical accelerometer. For logistic reasons we were not able to instrument floes simultaneously so that the complete experiment lasted about eight hours. Ideally such an experiment should take place over a very short time so that waves incident on the ice cover may be assumed to be statistically stationary. To

Table 1 Position of ice floes along attenuation line

Floe station	1	2	3	4	5	6	7	8
Distance from ice edge (km)	0	0.7	2.2	5.3	10.3	18.9	38.6	65.1

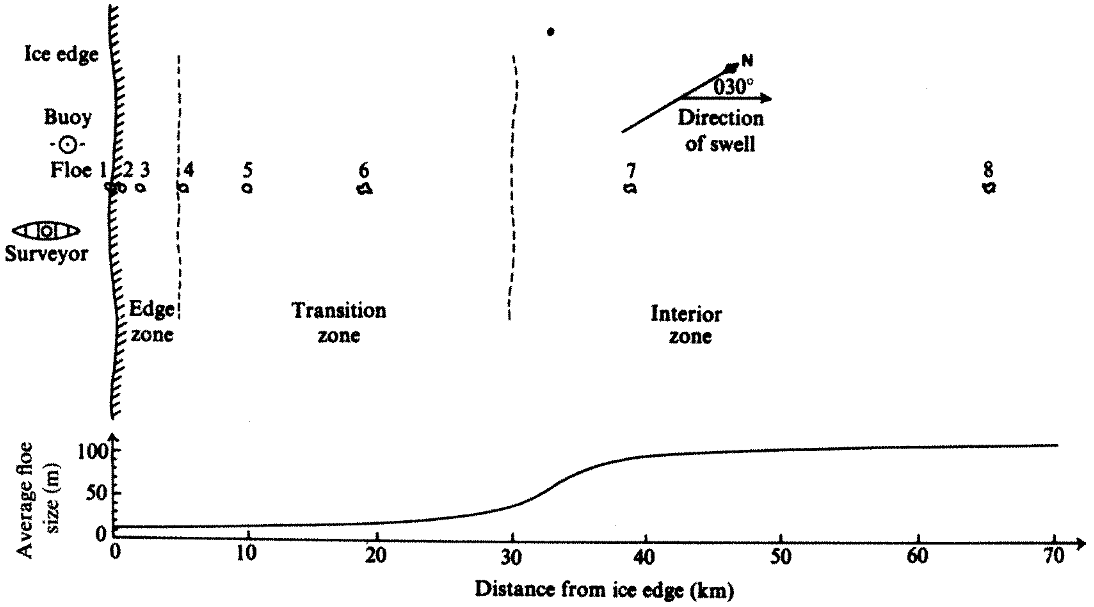

Fig. 1 Schematic diagram of attenuation experiment.

overcome this problem a Waverider buoy was deployed from Surveyor to monitor the open-water wave spectrum.

Routine ice observations were carried out during each helicopter flight. The ice margin was diffuse with an average concentration of four Oktas for tens of kilometres into the ice cover with occasional isolated bands of higher concentration. Floe diameter increased gradually from 10 m at the ice edge to 40 m some 30 km in. At 30 km, the floe size increased abruptly to more than 100 m in diameter, the typical size thereafter. From the air the ice cover could be divided into three distinct zones made up of floes of quite different character: the edge zone, which stretched from the ice edge some 5 km into the pack; the transition zone, which stretched a further 25 km; and the interior zone. This zonal structure had been observed earlier in the field trip and was the reason behind our choice of floe separation. The edge zone was made up of floes which had been buffeted together in waves of sufficient intensity to ridge, raft and fracture the ice. Floes were typically 10 m across, of uneven thickness, with heavily rafted perimeters. Floes within the transition zone were much smoother since the incoming waves had lost much of their energy in the extremely active edge zone. The penetrating waves were still able to fracture the ice, however, and the average floe diameter remained 10 m. Further into the ice cover, the incoming swell had been attenuated to such an extent that little or no fracturing took place and floes in the interior zone were typically smooth and >100 m across.

All the floes visited were between 10 and 20 m across, less than 0.5 m thick and relatively smooth. CTD casts had shown the underlying seawater to be well-mixed and well above the freezing point, and this together with several days of warm weather, had left the ice in a mushy and decaying condition. Twenty minutes of wave data were collected on each of the floe stations and it was noted that there were at least two components of swell present. There seemed to be a noticeable attenuation between floes but at this stage we could not be sure that the change in amplitude was not due to a decline in the open-water wave forcing. The wave records obtained at each site were digitised and, together with the Waverider buoy data, were calibrated and transferred to IBM digital tape for further analysis. All data processing was carried out on the IBM 370 at Cambridge University using the FFT/graphics package developed by the Sea Ice Group at the Scott Polar Research Institute (SPRI).

Table 2 The attenuation coefficients for energy decay at various central wave periods

Central period (s)	Attenuation coefficient ($m^{-1} \times 10^{-4}$)
12.2	0.272±0.054
9.4	0.438±0.036
7.6	0.855±0.049
6.4	1.087±0.037
5.5	1.214±0.192

The Waverider buoy data are presented in Fig. 2. Each power spectrum represents a 20-min sample of the open-sea wave conditions during the experiment. Records are between 1 and 2 h apart. Within the statistical errors generated by a frequency domain analysis[12], the smoothed power spectra show the wave conditions off the ice edge to be stable throughout the day. This being so, the wave forcing for the attenuation run may be assumed stationary and any comparison between wave data from individual ice floes is valid.

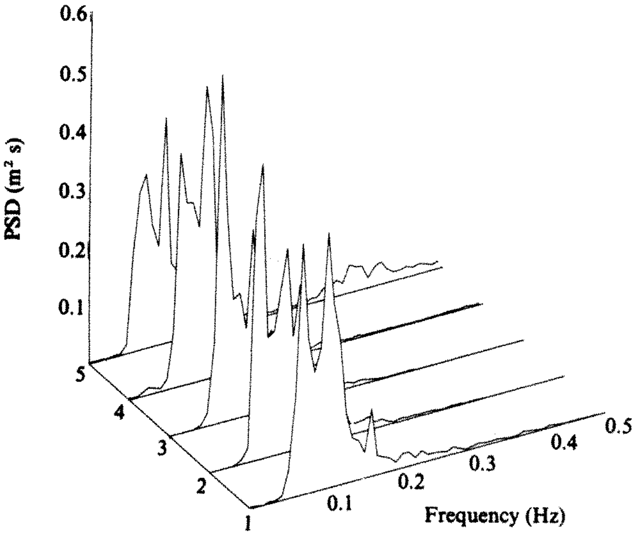

Fig. 2 Three-dimensional graph showing evolution of power spectra from Waverider buoy during the experiment.

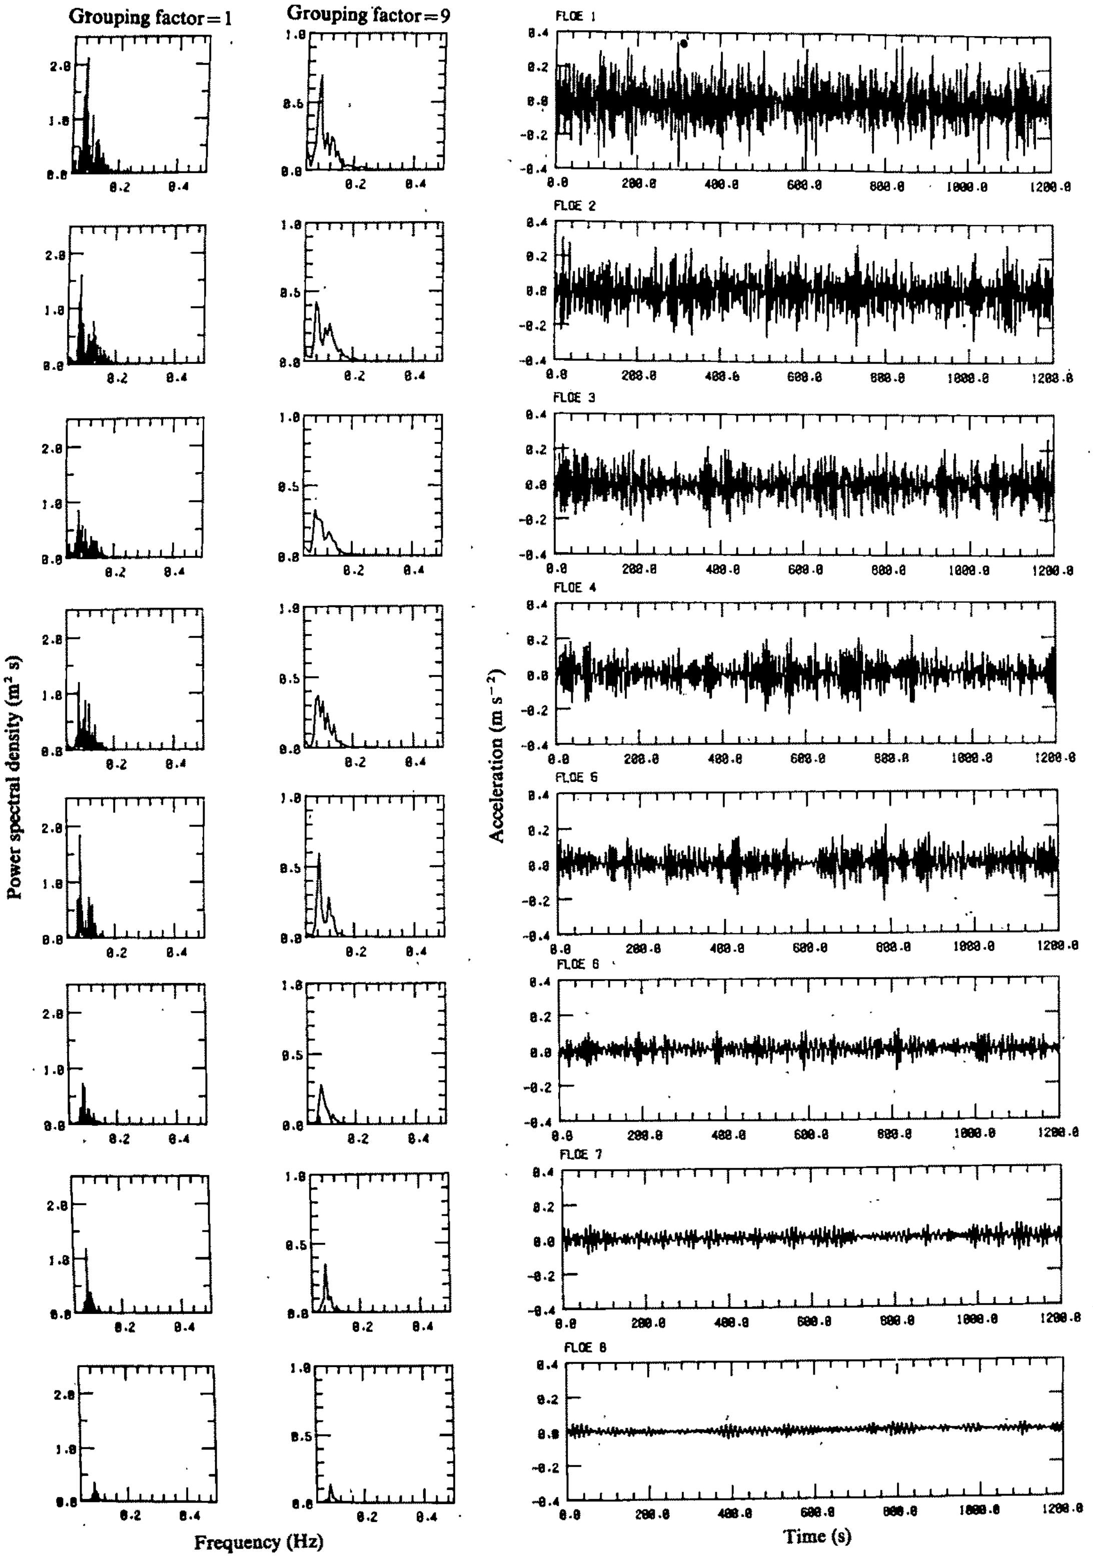

Fig. 3 The attenuation run showing time series at each floe and corresponding power spectra.

Figure 3 shows the time series and the unsmoothed and smoothed power spectra for the wave data recorded at each floe station. All records are 20 min (1,200 s) long and are plotted to the same scale so that a direct comparison may be made. Each time series represents the vertical acceleration at a point along the attenuation line. There is a clear attenuation with distance from the ice edge together with a noticeable filtering of the incoming waves in favour of longer wavelengths. The power spectra confirm these observations. Each pair of spectra, derived from the corresponding time series and corrected for acceleration, shows the power spectral density (PSD) as a function of frequency. The first spectrum of the pair is unsmoothed and is presented for completeness. The second has been frequency smoothed with a grouping factor of nine. There is a striking decay in the available wave energy as the reader proceeds from floe to floe. Furthermore,

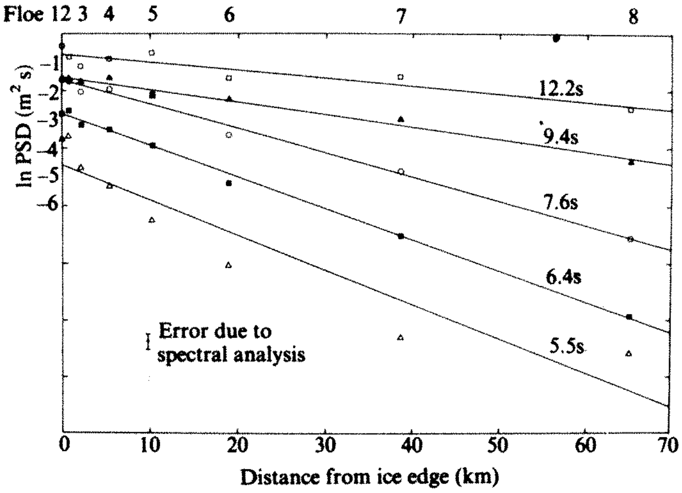

Fig. 4 Energy decay as a function of wave period.

waves of shorter period are attenuated more rapidly than long waves.

From the smoothed spectra, five central wave periods were selected at which significant wave energy was present. Figure 4 shows these wave energies plotted against distance from the ice edge. The energy decay is seen to be approximately exponential with the attenuation coefficient a function of wave period (Table 2). The line corresponding to a period of 5.5 s shows the most scatter. This is believed to be due to an increase in energy at shorter periods occurring late in the day (see Fig. 2). If the 5.5 s point for floe 8 is assumed to be an overestimate and is neglected, the best straight line between the remaining seven stations gives an attenuation coefficient of $(1.824 \pm 0.183) \times 10^{-4}\ \mathrm{m}^{-1}$. With this revised value for the energy decay at 5.5 s, the data fit the empirical inverse square relationship between attenuation coefficient and wave period found by Wadhams[2]. Similar studies carried out off the coast of East Greenland[13] by SPRI, the Cavendish Laboratory at the University of Cambridge, and the Technical University of Denmark promise attenuation runs for thicker floes and longer wave periods.

We thank Dr Seelye Martin who was chief scientist for the cruise, Dr David Halpern of the Pacific Marine Environmental Laboratory for the loan of the Waverider buoy, Ms Jane Bauer for preliminary analysis of the Waverider tapes, and the officers and crew of Surveyor. We thank the Office of Naval Research (contracts N00014-78-G-0003 and N00014-76-C-0234) and BP Co. Ltd for support. This study was part of a program managed by the Outer Continental Shelf Environmental Assessment Program Office, and was supported by the Bureau of Land Management through the National Oceanic and Atmospheric Administration.

KBS Tuff dating and geochronology of tuffaceous sediments in the Koobi Fora and Shungura Formations, East Africa

R. E. Drake*, G. H. Curtis*, T. E. Cerling†,

Plio–Pleistocene lacustrine and fluvial sediments of the Koobi Fora Formation along the east shore of Lake Turkana in northern Kenya (see Fig. 1) and thicker fluvial sediments of the Shungura Formation in the Lower Omo River Basin 100 km to the north have become widely recognised because of their rich hominid and artefact assemblages, together with associated vertebrate fauna[1–3]. Over the past decade, tuffaceous horizons within these two sedimentary formations have been mapped[4,5] and dated by K–Ar[6–11] and fission-track techniques[12] to provide chronologic control supporting studies of hominid and faunal evolution and archaeology. We report here new ^{40}K–^{40}Ar dates and revised values for previously published dates which give a mean age of 1.8±0.1 Myr for the KBS Tuff. This estimate suggests contemporaneity between the KBS Tuff and Tuff Units H2 and H4 in the Shungura Formation, lower Omo River Basin, Ethiopia, and with Bed I at Olduvai Gorge.

Although isotope dates for most of these tuffaceous horizons have been stratigraphically and palaeontologically consistent, some have remained uncertain. Of these, the KBS Tuff of the Koobi Fora Formation has been the most controversial, particularly because of its importance in placing an upper age limit on the important hominid skull KNM-ER-1470 with its associated vertebrate fauna, and on artefacts embedded in the tuff[13,14].

In 1975, we reported ^{40}K–^{40}Ar dates indicating the KBS Tuff and its correlative horizons contained at least three pumice populations with two different ages[9]. All dates from Area 105 (see Fig. 1) averaged 1.6 Myr, while those from Area 131 averaged 1.8 Myr. Both dates were significantly younger than the previously assigned age of 2.61 Myr based on a ^{40}Ar–^{39}Ar incremental heating date[6]. Even though the 2.61 Myr date was subsequently revised to 2.42 Myr (ref. 10), in apparent agreement with newly obtained fission-track dates on zircons separated from KBS pumices[12], a substantial age discrepancy still remained between our conventional ^{40}K–^{40}Ar results and those obtained by ^{40}Ar–^{39}Ar and fission-track dating techniques.

To resolve this problem, we dated a new group of KBS pumice samples that were collected in 1977. All of these new dates fell in the 1.8 Myr range, and none reproduced our previous 1.6 Myr dates. This result led to the discovery of a systematic error in potassium analyses for all KBS samples which had a given 1.6 Myr date. This error was traced to a defective balance. Recalculation using revised potassium contents obtained by re-analysis of the originally dated material increased all of the 1.6 Myr dates to 1.8 Myr, bringing them into agreement with the new dates, and completely eliminating the evidence of any KBS pumice 1.6 Myr old (see Fig. 2.)

With this revision, we now have 22 KBS dates; 16 on feldspars and 6 on glasses that were separated from a total of 13 different pumice samples collected within the KBS Tuff in Areas 131, 105 and 112. Fig. 2 shows that statistically, these dates give a mean of 1.8±0.1 Myr at the 95% confidence level. For correlation and interpretation, the dates of all of the pumices so far sampled must be treated as being indistinguishable in age, even though several geochemically distinct pumice types representing separate eruptive events occur together in the KBS Tuff horizon. As we can distinguish dates that are >100,000 yr apart,

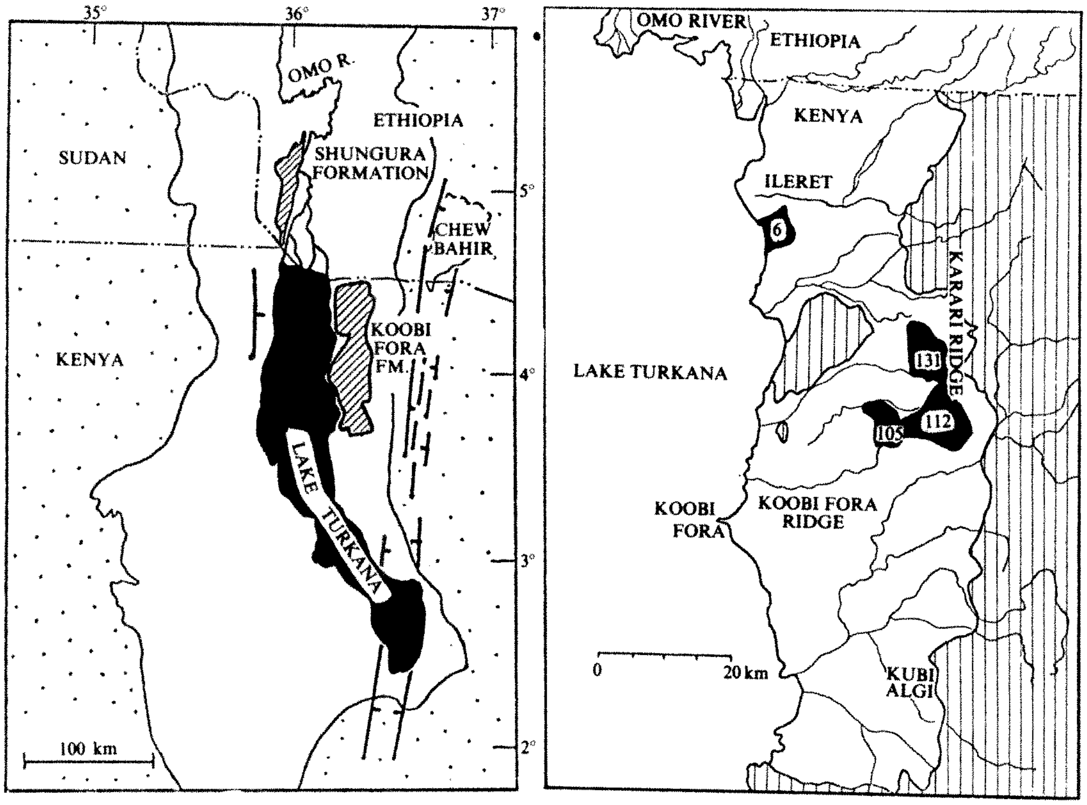

Fig. 1 Maps showing sample localities in the Koobi Fora Formation east of Lake Turkana and their geographic relation to the Shungura Formation in the lower Omo River Basin.

it seems reasonable to assume that several eruptive events which led to the accumulation of the various pumice fragments in the KBS Tuff took place within this time interval, and may contribute to the scatter of dates about the mean.

In 1970, the first K-Ar dates from the KBS Tuff were obtained on feldspars by Fitch and Miller using ^{40}Ar–^{39}Ar incremental heating and total degassing procedures[6]. Further work produced dates ranging from 0.52 to >200 Myr (ref. 8). As Fitch and Miller recognised, the extremely old dates resulted from detrital contamination with ancient crystalline basement rocks. Disregarding those old dates, one is still faced with a broad range of possible dates from which 2.61 ± 0.26 Myr was originally selected as the 'best apparent age' of the KBS Tuff. The subsequent revision to 2.42 ± 0.01 Myr using a different J value[10] did not reduce this scatter. We feel that the apparent discrepancy between our ^{40}K–^{40}Ar results and the date favoured

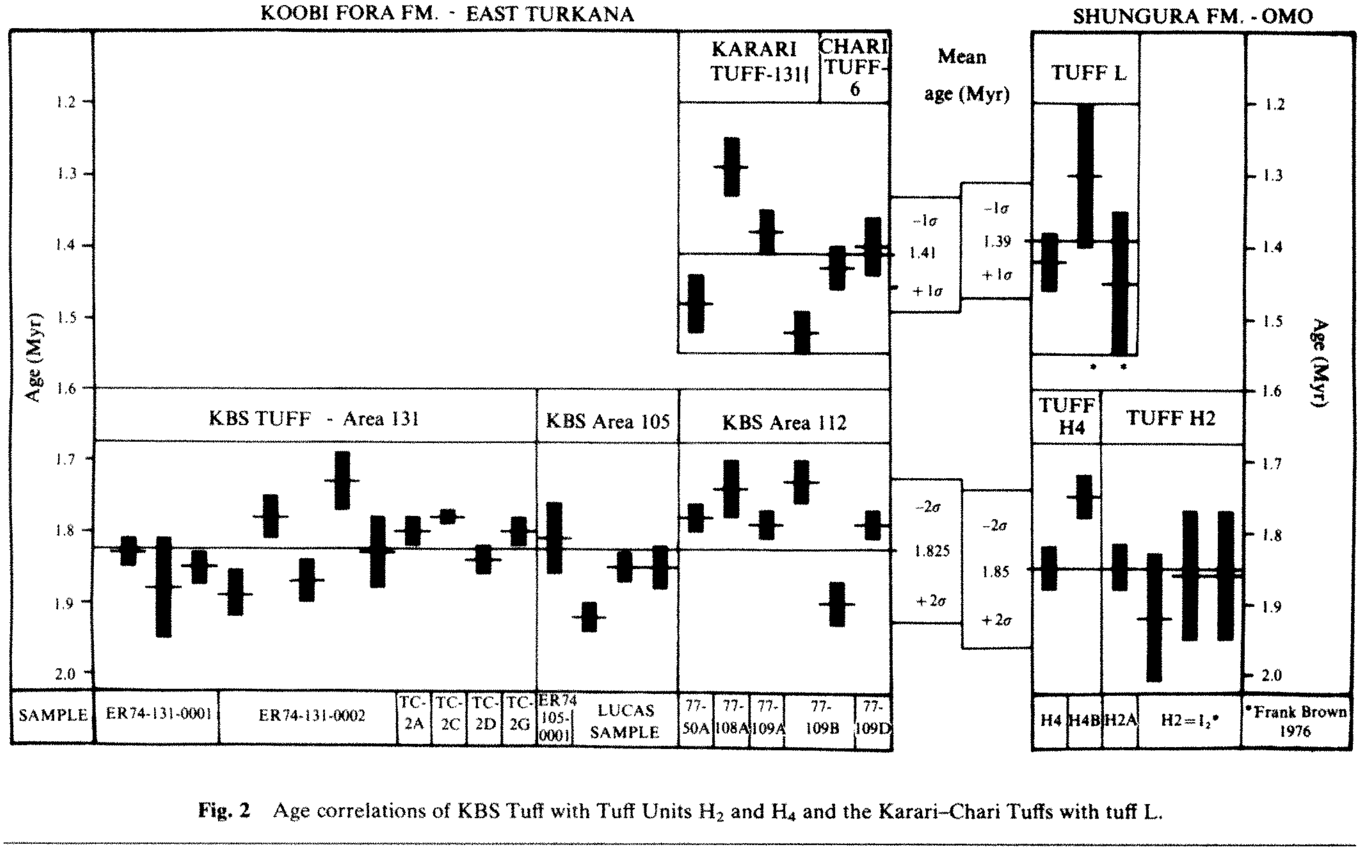

Fig. 2 Age correlations of KBS Tuff with Tuff Units H_2 and H_4 and the Karari–Chari Tuffs with tuff L.

by Fitch and Miller arises through their selection of a particular value from a scatter. Their criteria used for selecting this date are debatable. Based on their experience of interpreting ^{40}Ar–^{39}Ar release patterns of plutonic minerals known to have been thermally overprinted, they believed they could not only see effects of similar overprinting of feldspar from KBS pumices, but could also infer a geological age for these events. Such an interpretation for KBS pumice dates is not supported, however, either by our data or by theirs. Furthermore, many of those with ^{40}Ar–^{39}Ar dating experience support the conclusions of Lanphere and Dalrymple[15] that "it may be difficult or impossible to extract geologically meaningful information from the age spectrum of a disturbed sample."

We have demonstrated the repeated concordancy of dates on glass and feldspar taken from the same pumice clasts (Table 1). As glass devitrifies and loses argon much more readily than sanidine or anorthoclase feldspar, the concordancy of dates argues strongly against thermal overprinting. Such overprinting would manifest in significantly younger dates for glass with respect to coexisting feldspar.

To interpret Fitch and Miller's ^{40}Ar–^{39}Ar incremental heating data following a thermal overprinting model requires a different history of thermal events for almost every sample dated. Only in this way can many otherwise reasonable KBS dates be disregarded. (In fact, several of Fitch and Miller's better total degassing dates and at least one ^{40}Ar–^{39}Ar age spectrum support a 1.8 Myr age.) The inability to obtain reproducible results apparently led to special interpretations which are not satisfactorily supported by the data presented. We feel, therefore, that the 1.8 Myr mean of our tightly clustered ^{40}Ar–^{40}K dates provides a better estimate of the age of the KBS Tuff than the ^{40}Ar–^{39}Ar dates selected by Fitch and Miller.

Another aspect of the dating problem was brought to light by fission-track dates on zircons[12] from two KBS pumices which gave a mean of 2.44±0.08 Myr, apparently supporting the ^{40}Ar–^{39}Ar age advocated by Fitch and Miller[10], but differing from our 1.8 Myr ^{40}K–^{40}Ar mean of 1.8 Myr.

Although the mean of five dates yielded this statistically precise value, the individual dates have much larger error estimates because fission-track counting was done only on a few zircons which have very low track densities. Hence, any minor systematic error in technique could greatly bias the age, and a statistically derived estimate of precision may not be relevant to the accuracy of the mean of these dates. If this is so, the apparent discrepancy between our ^{40}K–^{40}Ar mean date of 1.8 Myr and the fission-track mean may be resolved by increasing the fission-track confidence interval to express the possibility that systematic errors may have yielded an excessive age. This apparent discrepancy between the fission-track age estimates of Hurford, Gleadow and Naeser[12] and the mean of our 22 tightly clustered ^{40}K–^{40}Ar dates deserves investigation, but for the present we contend that our mean date is an age estimate with much more clearly defined confidence limits than the fission-track age.

The mean value of 1.8±0.1 Myr for the KBS Tuff and a mean value of 1.4±0.1 Myr for the Chari–Karari Tuffs of the Koobi

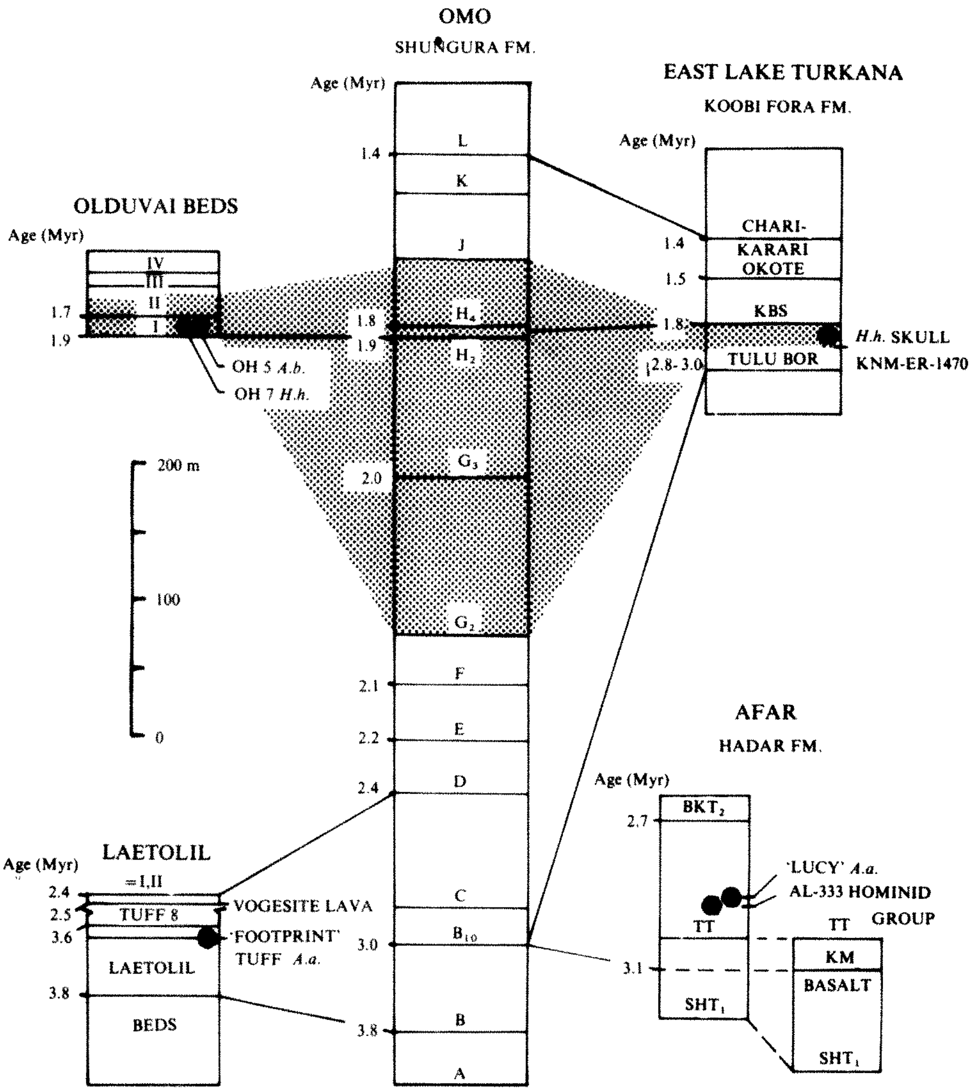

Fig. 3 Comparison of dated stratigraphic sections of the Koobi Fora Formation, Shungura Formation, Laetolil Beds, and the Hadar Formation in East Africa. The stippled area represents biostratigraphically contemporaneous units.

Fora Formation are indistinguishable from K–Ar dates on Tuff Units H_2 and H_4 and Tuff Unit L[11] respectively in the Shungura Formation (Fig. 2).

The results of extensive geochemical and geophysical analyses of pumices and tuffaceous matrix from these tuffs[19] have enabled the identification of unique pumice types in the KBS-H_2, H_4 horizons that are probably derived from the same eruptive event though they occur in sedimentary sections 100 km apart. As the Shungura Formation has yielded a long and consistent sequence of ^{40}K–^{40}Ar dates, this independent geochemical correlation of the KBS Tuff and Tuff Units H_2 and H_4 strengthens the case for a 1.8 Myr age for the KBS Tuff.

Figure 3 compares the generalised stratigraphic sections and dated horizons within the Olduvai Beds, the Shungura Formation, the Koobi Fora Formation, the Laetolil Beds, and the Hadar Formation to show the relationship of the ^{40}K–^{40}Ar time scales that have been established for each stratigraphic section[11,16–18].

Cooperative studies of the taxonomic composition of fossil vertebrate assemblages in the beds immediately below the KBS Tuff, between Tuffs Gi and J in the Shungura Formation and in Bed I at Olduvai Gorge suggest that all three are biostratigraphically indistinguishable units[1,2] as shown by the stippled area of Fig. 3. Further detailed studies of the stage of evolution of certain rapidly changing lineages, especially among the Suidae also suggest contemporaneity (see refs 20, 21).

Bed I at Olduvai Gorge has been dated by numerous ^{40}K–^{40}Ar dates as between 1.7 and 1.9 Myr (ref. 17). Member G between Tuff Units G and H in the Shungura Formation is dated by ^{40}K–^{40}Ar as between 1.8 and 2.0 Myr (ref. 11). These beds and those below the KBS Tuff exhibit a palaeomagnetic stratigraphy consistent with an Olduvai event age between 1.76 and 1.91 Myr (refs 22, 23). We consider it unlikely, therefore, that the KBS samples which also yield the same ^{40}K–^{40}Ar dates as the Olduvai and Omo localities could have been subjected to overprinting or other disturbances as are postulated by Fitch and Miller.

We thank Drs Glynn Isaac and Frank Brown for their assistance in this project which was supported by NSF grant EAR76-21833.

Wind velocities determined from the surface textures of sand grains

David Krinsley & William Wellendorf

Department of Geology, Arizona State University, Tempe, Arizona 85281

Krinsley and Smalley[1] suggested that 'upturned plates', a surface texture that is represented on quartz sand surfaces by a series of thin parallel plates, either continuous or discontinuous parallel to $r(10\bar{1}1)$ and $z(01\bar{1}1)$, cause the frosting observed on desert sand grains. As these plates depend on the extent of physical abrasion[2], the spacing between individual plates might be related to the velocity of the wind which last transported the grains. The technique described here attempts to relate experimental and modern aeolian sand grain surface textures to wind velocity via scanning electron microscopy (SEM)[3].

To test this hypothesis, we examined crushed Brazilian quartz abraded in a paddle wheel device at four effective wind velocities: 8, 24, 32 and 40 m s^{-1} (ref. 4). Two modern Saharan desert sands where the average wind velocity was known from meterological data, and a Permian eolian sand were also studied. The paddle wheel apparatus was driven by a variable speed motor that moves particles at a given rate and causes particle self abrasion; the apparatus was constructed to simulate aeolian action on Mars, as previous devices could not operate at the low pressures and high velocities presumably present on Mars[4]. At normal pressures and velocities, surface textures on experimental sand grains were identical to those produced by other devices used to simulate natural aeolian processes[5]. Upturned plates on grains were photographed using SEM; stereo photogrammetry was then used to measure separation between the plates.

Plate spacing measurements on the experimental samples (175–355 μm diameter) exhibit three significant characteristics: (1) spacing is constant across individual grain surfaces; (2) spacing on grains abraded at similar velocities is reasonably constant; and (3) grain size has little effect on spacing (two grain sizes averaging 200 and 300 μm diameter were used).

Plate spacing on the 20 experimentally produced aeolian grains was measured using stereo microscopy (Table 1). The results of a regression analysis of the plate spacing (y) plotted against the wind velocity (x) for this experimental material (Fig. 1) show that the best fit ($r = 0.94$) line for these data is described by the polynomial expression:

$$y = 0.000032x^3 - 0.0017x^2 + 0.0364x + 0.0016 \qquad (1)$$

The curve representing this equation is characterised by three zones (delineated by two slope changes) which were observed in the Sahara desert[6–8].

The first zone (from 0 to 7 m s^{-1}) is the velocity range in which grains have lost all of their sharp edges and have begun to round. The presence of frosting on edges indicates that these areas were the most susceptible to abrasion. Sand grains at this range of wind velocities have been observed to be mobile for only short distances in deserts.

The second zone extends from 7 to 27 m s^{-1}; the flattening of the curve here suggests that physical changes due to abrasion are linearly related to wind velocity. The calculated average daily wind velocity is from 5 to 8 m s^{-1} in the Sahara[6] and it has been observed that sand clouds form and sand actively migrates across the desert at velocities of 10–13 m s^{-1}; sandstorms begin to form at velocities from 13.7 to 15.7 m s^{-1} (refs 7, 8). Note that the maximum continuous wind velocities observed in the Sahara are represented in this zone.

The third zone (no measurements have been continuously recorded above 27 m s^{-1} shown on the curve ranges from 27 to 40 m s^{-1}. Here the slope increases very rapidly, suggesting rapid physical changes on sand grain surfaces; these have been observed with SEM on individual sand grains abraded at the two highest velocities (32 and 40 m s^{-1}). In this range, grain size seems to decrease rapidly; the grains become more spherical, and plastic deformation and/or partial melting may occur on surfaces[4].

Micron-sized quartz particles, after abrasion at 27–40 m s^{-1}, are structurally deformed and SEM observations indicate that rounding and smoothing occur on quartz sand grains at these velocities[4]. Calculations also show that the collision between two quartz grains at 15 m s^{-1} would raise the temperature of a microscopic feature (~5 μm diameter) on their surfaces to above the melting temperature of quartz[4].

Extrapolation of the curve past 40 m^{-1} suggests that it becomes asymptotic at some higher velocity. This indicates that there may be a limit or terminal velocity where either grains achieve total sphericity or break down into silt and clay-size fragments. The large population of fine silt-sized debris in the 40 m s^{-1} sample suggests that this limit probably results in grain destruction ('kamikaze grains' as in ref. 9), and not perfect sphericity. Note that when the fine silt particles from the 40 m^{-1} sample are studied at high magnification, some of them exhibit a finely abraded and rounded surface while other surfaces display conchoidal fracture. Thus, these particles may represent portions of rounded and frosted grains which subequently have been destroyed during the experiment.

Photomicrographs of 10 modern Saharan dune sand grains were studied (Table 2) first to determine if plate spacing could be measured on naturally occurring sand grains, and second to obtain a reasonable approximation of the maximum wind velocity which last moved them.

The Libyan grains fall into the lowest velocity zone; they were collected from an inactive interdune area. Solution and/or precipitation and small bits of debris sticking to grain surfaces suggest that the grains were not being actively abraded at the time of collection. The wind conditions of this sub-environment (5–8 m s^{-1}, (ref. 8)) are comparable to those calculated directly from aeolian plate spacings (6.33 ± 0.04 m s^{-1}, Table 2).

The Algerian sand was collected from an active dune. Here, solution and/or precipitation features can be recognised only in depressions on the grains with clean surfaces indicating that they have undergone recent active abrasion. The calculated wind velocity for this sample (13.53 ± 0.05 m s^{-1}) lies well within the values observed by Bagnold for actively saltating grains (10–15.7 m s^{-1}).

Plate spacing on Permian aeolian sands was then examined (Table 2). The Permian sandstone deposits of County Durham, UK have been interpreted as a hot, dry, Saharan type of aeolian deposit[10]. Minor quartz overgrowths and precipitation features are present, but do not obscure grain surfaces. Some of these features may even aid plate measurement; the aeolian plates seem to act as a growth site for secondary quartz. Measurements

Table 1 Measured average aeolian plate spacings from experimentally abraided Brazilian quartz grains

Velocity (m s^{-1})	No. of grains	No. of measurements	Grain size range (μm)	Average spacing (μm)
8	5	98	175–355	0.207 ± 0.041
24	5	78	175–355	0.338 ± 0.048
32	5	88	175–355	0.490 ± 0.073
40	5	71	175–355	0.777 ± 0.130

0028–0836/80/040372—02$01.00

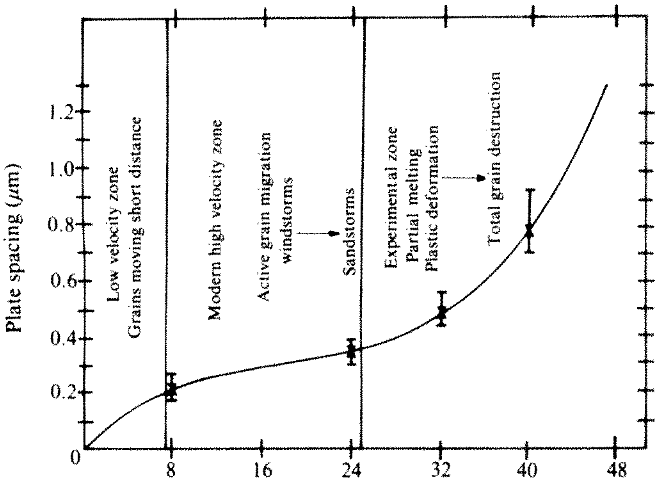

Fig. 1 Comparison between changes in slope of experimental data and wind velocity for various types of sand grain movements observed in deserts.

of plate spacing were substituted in the regression equation; the calculated wind velocity is 29 m s^{-1}, a value slightly higher than the strongest continuous wind velocities observed in the modern Sahara (22 m s^{-1} (ref. 6)). If the technique is valid, these sands could have been transported and deposited in a hot arid Saharan type desert by winds of higher velocities than those in the modern Sahara.

If the time required to remove a thickness equal to the relief of the plates is short enough, the spacing measured will represent the final abrasion episode. If the time is measured in days, weeks, or months, then the spacing must represent some average value related to the velocity of a number of storms.

Crushed Brazilian quartz averaging ~500 μm in diameter was abraded at a velocity of 8 m s^{-1} for three hours in the paddle wheel device. The grains were then removed and studied with the scanning electron microscope; >80% of all surfaces were covered with small abrasion markings. Upturned plates constituted a large portion of the abraded surfaces. Three hours is probably the maximum abrasion time necessary to cover almost completely the surface with abrasion markings; the only remaining non-abraded areas were those that were at least 5 μm below the general surface and thus were protected from immediate abrasion. Although the original starting material was fairly large and quite angular, the experiment suggests that times of the order of minutes or hours in a sandstorm would resurface natural sand grains.

Additionally, 500 g of natural quartz sand (sieved to between 125 and 180 μm) was fed into an aeolian whirling arm device[11] and used to abrade, in an aeolian mode, six quartz flats at 20 m s^{-1}. The sand stream struck the targets perpendicular to their surfaces for 23 min with 16 g of sand actually striking each target. Note that each grain of sand struck each flat only once. Finally the targets were weighed to an accuracy of five places before and after bombardment.

The time needed to remove completely a layer of quartz the height of an average plate (0.5 μm) was calculated and was 29 min. This is probably the maximum time needed to remove a significant fraction of the old plates and produce new ones; thus in a very short time a high velocity wind could reset the spacing over a large portion of grain surfaces. The experiment, of course, was conducted with a fixed target; natural aeolian grains are round and rotate, which would tend to create an isotropically eroded surface similar to the experimental targets. The two experiments give order of magnitude results, but even if the final answer were three times as large, plate spacing on aeolian grains probably represents the final windstorm velocity to which the grains were subjected.

Table 2 Sample locations, plate spacing and calculated wind velocities for Saharan and Permian sands

Sample location	No. of grains	No. of measurements	Average spacing (μm)	Calculated wind velocities (using equation (1))
Sehba Sand Sea, Libya (Sahara desert)	5	92	0.172 ± 0.045	6.33 ± 0.04 m s^{-1}
Great Western Erg, Algeria (Sahara desert)	5	102	0.262 ± 0.039	13.53 ± 0.05 m s^{-1}
Permian sandstone County Durham, UK	5	100	0.354 ± 0.047	29.34 ± 0.04 m s^{-1}

We stress that plate spacing results from the last abrasion event that occurred on a given sand grain; a change in velocity is assumed to eliminate previous plate spacing imprints and to superimpose the most recent velocity spacing on surfaces. The ability to determine ancient wind velocities could aid further understanding of the paleogeography and paleoclimatology of the vast continental aeolian sand deposits preserved in the geologic record. This research was supported by NASA consortium agreement 2-0R035-801 and 2-0R035-901, Office of Planetary Geology. Why do Bedouins wear black robes in hot deserts?

Amiram Shkolnik, C. Richard Taylor*, Virginia Finch* & Arieh Borut

Department of Zoology, Tel Aviv University, Tel Aviv, Israel

* Museum of Comparative Zoology, Harvard University, Cambridge, Massachusetts 02138

Survival in hot deserts has always posed a problem for man; Moses had to solve it in order to lead the children of Israel through the wilderness of the Sinai—a formidable hot desert. It seems likely that the present inhabitants of the Sinai, the Bedouins, would have optimised their solutions for desert survival during their long tenure in this desert. Yet, one may have doubts on first encountering Bedouins wearing black robes and herding black goats. We have therefore investigated whether black robes help the Bedouins to minimise solar heat loads in a hot desert. This seemed possible because experiments have shown that white hair on cattle[1,2] and white feathers on pigeons[3] permit greater penetration of short-wave radiation to the skin than black. In fact, more heat flowed inward through white pigeon plumage than through black when both were exposed to simulated solar radiation at wind speeds greater than 3 m s^{-1} (ref. 3). We report here that the amount of heat gained by a Bedouin exposed to the hot desert is the same whether he wears a black or a white robe. The additional heat absorbed by the black robe was lost before it reached the skin.

0028-0836/80/040373—03$01.00

Table 1 Radiation exchange and convective heat loss

	Radiation gain	Radiation loss	Net radiation gain	Convective loss	Net radiation gain–convective loss
Black robe	838±10	543±2	295±8	57±7	238±12
White robe	649±3	534±3	115±2	31±5	84±6
Tan army uniform	644±3	452±2	192±2	45±3	147±4
Shorts (semi-nude)	624±10	442±6	182±5	−2±4	184±7

The rate of net heat gain by radiation was more than 2.5 times as great in the black robe as in the white. The greater heat loss by convection from the black robe due to its higher surface temperature was not great enough to compensate for its higher net radiation gain. This leads us to postulate that additional heat was lost by convection through the robes through a bellows effect or a chimney effect. Values in W m^{-2} are the means of nine experiments ± s.e.

To quantify the effects of the colour of a robe on the heat load imposed by a hot desert, we measured and/or calculated the net heat gain by radiation, heat loss by convection, heat loss by evaporation, heat storage and metabolic heat production of a man standing facing the Sun in the desert at mid-day while he wore: (1) a black Bedouin robe; (2) a similar robe that was white; (3) a tan army uniform; and (4) shorts (that is, he was semi-nude). We used one individual as a calibrated heat exchanger, because we were interested in the effects of the coverings rather than in physiological differences among individuals. Robes were purchased from Bedouins and we used two layers of robes in the same manner as they did. Only the outer robe was changed when comparing black and white robes. We selected experimental conditions where both solar radiation and air temperature were high. The measurements were made during the summer at mid-day (1030–1430 h) at the Hatzeva Field School (in the Negev Desert at the bottom of the rift valley between the Dead Sea and the Gulf of Elat). During the measurements air temperatures ranged between 35 °C and 46 °C (average 38 °C) and wind speed between 0 and 4.1 m s^{-1} (average 1.3 m s^{-1}).

Table 2 Avenues of heat gain and loss of a subject facing the Sun in a hot desert at mid-day and in a temperature-controlled room at 48 °C

	$\dot{H}_{\text{gain}}$	=	$\dot{H}_{\text{evap}}$	+	$\dot{H}_{\text{stor}}$	−	$\dot{H}_{\text{metab}}$	T_{amb}
Desert								
Black robe	142±4	=	199±4	+	10±1	−	67±2	59.5
White robe	134±11	=	191±8	+	8±1	−	65±2	58.6
Tan army uniform	161±7	=	217±7	+	10±1	−	66±2	–
Shorts (semi-nude)	208±7	=	264±8	+	8±1	−	64±2	62.2
Temperature-controlled room at 48 °C								
Black robe	66±7	=	126±6	+	7±2	−	67±2	
White robe	65±9	=	123±9	+	6±1	−	64±3	
Shorts (semi-nude)	86±9	=	144±9	+	9±2	−	67±2	

Rates of net heat gain ($\dot{H}_{\text{gain}}$) from the environment, evaporative heat loss ($\dot{H}_{\text{evap}}$), heat storage ($\dot{H}_{\text{stor}}$) and metabolic heat production ($\dot{H}_{\text{metab}}$) are given in W m^{-2} and are the means of nine experiments ± s.e. To determine the temperature in our environmental room (T_{amb}) that would be necessary to simulate conditions of our hot desert at mid-day, $\dot{H}_{\text{gain}}$ was quantified when the room was set approximately 10 °C above average skin temperature. It was then assumed that $\dot{H}_{\text{gain}}$ would be directly proportional to the temperature gradient between the skin and room in order to calculate the room temperature required to obtain the same $\dot{H}_{\text{gain}}$ as we obtained in the hot desert.

Radiation exchange and heat loss by convection were calculated according to the procedures outlined for cattle[4] and goats[5] with the following minor modifications. (1) Swinbank's empirical formula[6] was used for calculating long-wave radiation from the sky; (2) surface area was calculated from Dubois' formula[7] when the subject wore the army uniform or was semi-nude (this area was multiplied by 0.85 when calculating diffuse radiation exchanges to correct for exchanges between the legs, arms and body); and (3) surface area for the subject wearing the robes was calculated by assuming he approximated a cylinder whose circumference was measured around the chest.

Rates of metabolic heat production (H_{metab}), evaporative heat loss ($\dot{H}_{\text{evap}}$), and changes of heat content of the body ($\dot{H}_{\text{stor}}$) were measured, then net heat gain by non-evaporative means ($\dot{H}_{\text{gain}}$) was calculated by applying the first law of thermodynamics where:

$$\dot{H}_{\text{gain}} = \dot{H}_{\text{evap}} + \dot{H}_{\text{stor}} - \dot{H}_{\text{metab}} \qquad (1)$$

All measurements were made during 30-min intervals. The techniques and their accuracies were the same as we have described in detail for similar measurements on the Bedouin's black goats[5].

The absorptivity of the black robes for radiation in the visible part of the spectrum (0.89) was more than 2.5 times as great as that measured for the white robe (0.35) and about 1.5 times as great as for the army uniform (0.72) or the semi-nude subject (0.66). The greater rate of absorption of visible radiation by the black robes was not accompanied by a greater rate of radiation loss (Table 1). Although convective heat loss from the black robe was greater than that from the white because of its higher surface temperature, the net inward flow of heat through the black robe (that is, net radiation gain − convective loss) was calculated to be almost three times as great as through the white (Table 1).

In spite of the greater net heat gain by the black robe, there was essentially no difference in rates of net heat gain ($\dot{H}_{\text{gain}}$) by the subject wearing black or white robes (Table 2). Rates of evaporative heat loss, heat storage, and metabolic heat production were essentially the same in the black and white robes.

How does one reconcile these seemingly conflicting results? The explanation must be greater convective transfer of heat through the air spaces beneath the black robe, either by a bellows action as the robes flow in the wind or in a manner analogous to the functioning of a chimney where the chimney in this case would be the air space between the robes and the skin. The air beneath the robe might rise and pass through the loosely woven fabric as it was warmed, pulling in cooler air from the bottom of the robe. Either explanation would be supported by our measurments of temperatures in the air space between the robes and the skin. The temperature of the air space beneath the inner robe was approximately the same as the temperature of the surrounding air when the outer robe was black or white, despite as much as a 6 °C difference in surface temperature of the different coloured robes (47 °C for the black and 41 °C for the white) (Fig. 1).

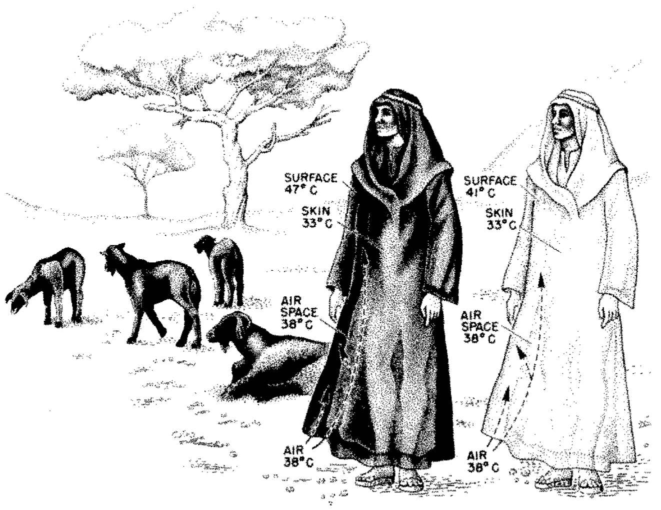

Fig. 1 Black Bedouin robes gain two to three times as much heat by radiation from the Sun as white robes, but enhanced convection of air beneath the robe carries this heat away before it reaches the skin. The temperature of the air space between the robe and the skin was the same for black and white robes and equalled the temperature of the surrounding air. The greater convection beneath the black robe might make it feel more comfortable. Mean temperatures of the robe surface, skin and air space (see text) are typical of temperatures observed when air temperature was 38 °C at mid-day, the sky was cloudless, and the subject was orientated facing the Sun.

Whether a bellows action, a chimney effect or some other mechanism explains the enhancement of convection beneath the black robes, it seems clear that the difference in radiation exchange at the outer surface of the robes is not affecting the heat exchange of the subject. Other authors have also observed that the colour of clothing has little effect on heat gain of a subject exposed to direct solar radiation[8,9].

Data from kinships of monozygotic twins indicate maternal effects on verbal intelligence

Richard J. Rose[*], Joann A. Boughman[†], Linda A. Corey[†], Walter E. Nance[†], Joe C. Christian[‡] & Ke Won Kang[‡]

[*] Department of Psychology, Indiana University, Bloomington, Indiana 47405
[†] Department of Human Genetics, Medical College of Virginia, Richmond, Virginia 23298
[‡] Department of Medical Genetics, Indiana University School of Medicine, Indianapolis, Indiana 46233

Familial resemblance in intellectual skills is well documented, but its interpretation is a source of continuing controversy. The critical problem is that a family's shared genes are confounded with its shared experiences, and controls possible in animal research (selective mating, cross-fostering, and uniform or randomised environments) do not directly apply to human subjects. Conventional twin and family methods reveal substantial genetic variance in intelligence quotient (IQ) test scores, but the same methods also document significant environmental influences. Research designs which can identify the nature of these environmental factors may effect progress in the 'IQ debate' (ref. 1). The families of monozygotic (MZ) twins provide a new research design[2] which permits a unique assessment of maternal influences in quantitative traits. We describe here initial applications of the design to verbal IQ, with results suggesting that maternal effects significantly contribute to familial similarity in verbal intelligence.

Maternal effects influence cognitive development in early childhood[3]. Observations of mothers of adopted infants, which eliminate the confounding of genetic transmission with maternal attributes, have identified specific maternal behaviour which fosters intellectual development in infancy[4,5]. Characteristics of maternal care and qualities of the home environment during early life predict pre-adolescent IQ[6], and longitudinal studies in London[7] and Kauai[8] document effects of the quality and intensity of early maternal stimulation. These and other data[9–11] suggest that a mother's sensitivity to her infant's needs facilitates early intellectual growth. In part, cognitive developmental differences in childhood may reflect differences in children's interactions with their mothers.

Mothers are not merely models for imitation. They establish the conditions and incentives for children's early achievement. This pervasive, but indirect influence may significantly affect a child's cognitive growth without increasing mother–child resemblance, because the relevant attributes of a mother's child-rearing may be attitudes and expectations which are uncorrelated with her IQ. Thus, the fact[12] that children's IQs exhibit no greater resemblance to their mothers than to their fathers does not preclude significant maternal effects, as such effects can[13] and do[14] occur in the absence of increased mother–child covariance.

A direct test of maternal effects on intelligence is possible within the kinships of adult identical twins. Because their twin parents are monozygotes, the children of identical twins are related to one another as conventional half-siblings; socially, they are cousins reared in different households. Because they derive from twin parents, MZ half-sibships have the same expected age and size, in contrast to conventional half-sibships resulting from death, divorce or illegitimacy. The offspring of female MZ twins form a unique group of maternal half-siblings who allow a direct measure of maternal effects on human traits. When such effects are present, the offspring of female twins will resemble one another more than do the offspring of male twins.

Table 1 Analysis of variance of offspring data from two Wechsler verbal scales

Mean squares	Information		Vocabulary	
Among paternal (MS_{Ap})	8.56	$F' = 1.56, P < 0.05$	11.12	$F' = 1.37, P < 0.10$
Among maternal (MS_{Am})	13.13		16.03	
Between paternal (MS_{Bp})	5.53		5.69	
Between maternal (MS_{Bm})	3.66		4.77	
Within paternal	3.64	NS	3.91	NS
Within maternal	4.01		3.80	
Correlations				
Paternal half-siblings	0.125	$P < 0.05$	0.200	$P < 0.10$
Maternal half-siblings	0.334		0.328	

[illegible] Library SCIENCE COLLEGE [illegible]

For the Information subtest, the analysis is based on 335 offspring in kinships of 71 MZ twin parents ($N_p = 34$, $N_m = 37$). The analysis of Vocabulary data is based on 397 offspring in 79 MZ kinships ($N_p = 37$, $N_m = 42$). Because the number of offspring within each sibship varies, coefficients of the between, within and among components of variation are calculated from observed distributions of family size[13,14]. The three coefficients do not differ for paternal and maternal families in the present data, permitting a direct evaluation of maternal influences by an F' test

$$F' = MS_{\mathrm{Am}} + MS_{\mathrm{Bp}}/MS_{\mathrm{Bm}} + MS_{\mathrm{Ap}}$$

$$\text{with d.f.} = \frac{(MS_{\mathrm{Am}} + MS_{\mathrm{Bp}})^2}{(MS_{\mathrm{Am}})^2/N_m - 1 + (MS_{\mathrm{Bp}})^2/N_p} \text{ for numerator and d.f.} = \frac{(MS_{\mathrm{Bm}} + MS_{\mathrm{Ap}})^2}{(MS_{\mathrm{Bm}})^2/N_m + (MS_{\mathrm{Ap}})^2/N_p - 1} \text{ for denominator}$$

In controlled matings of laboratory animals, each of a group of sires is mated to multiple dams, and the resulting litters of half- and full-sibling progeny permit a direct evaluation of maternal effects through a nested analysis of variance[15]. Figure 1 shows that the offspring of identical twins provide a human parallel to these conventional animal methods. Variation among the offspring of MZ twin parents may be partitioned by a nested analysis of variance[16] into components arising (1) among families, (2) between sibships within families, and (3) within sibships. Because the offspring of male twins are born to genetically unrelated mothers, maternal effects, when present, will inflate the variation arising between sibships within paternal families (MS_{Bp}). Conversely, maternal effects will inflate the variance arising among half-sibships in maternal families (MS_{Am}). Finally, because all offspring within each sibship are born to the same mother, maternal effects will not affect variation arising within sibships. Accordingly, a direct test of maternal effects can be made from the partitioned variance of offspring data.

To evaluate maternal effects in intellectual development, we administered the vocabulary and information subtests from the Wechsler intelligence scales to offspring of MZ twins. Of the 11 Wechsler subtests, Vocabulary and information are the most reliable, and factor analyses of the Wechsler scales suggest that Information and Vocabulary are consistently the best predictors of general intellectual functioning over the entire age range. In addition, because the focus of this report is on maternal effects, these two verbal scales are of special interest given evidence of the mother's dominant role in a child's early development of verbal skill[17].

Subjects were tested individually by trained examiners. Offspring of ages 4.0–5.11 yr were administered the Wechsler pre-school and primary scales; those aged 6.0–15.11 yr, the 1975 revision of the Intelligence Scales for Children, and those over age 16 yr were administered the Wechsler adult intelligence scale. For time intervals up to 1 yr, the inter-test correlations for vocabulary and information are as high as their test–retest stability on the individual Wechsler scales[18,19]. Some self-selection, expected in voluntary research, is evident in our study population and verbal scores of the sample reveal elevated means and restricted variances compared with national norms. However, means and variances do not differ between twins and non-twins, males and females, or children and adults; the family providers in maternal and paternal families are closely matched in educational attainment and social-class position and comparisons between their offspring are not invalid.

Results of the analysis of variance of offspring data are presented in Table 1. The analysis provides direct evidence of a maternal effect on verbal intelligence. For the information subtest, the intra-class correlation of maternal half-siblings, offspring of MZ twin mothers, significantly exceeds that of paternal half-siblings; comparison of the mean squares yields $F' = 1.56_{61,56}$, which enables us to reject ($P < 0.05$) the null hypothesis of no maternal influence. Results for the vocabulary subtest are similar, although the F' test does not achieve statistical significance in this preliminary sample.

The maternal effect suggested in these results could arise in any of several ways, some unique to kinships of twin mothers, some not. (1) Twin sisters may spend more time together during childhood than do twin brothers, and as a consequence of more similar childhood experience, may be more alike in their tested intelligence. We evaluated that possibility by comparing the IQ correlations of our male and female twin parents. No difference was found. (2) Female twins may maintain more frequent social contact in post-marital life and create more overlap in the IQ-relevant experience of their children. An adequate test of this possibility awaits collection of self-reported frequency of social interaction within kinships, but a crude test was made by comparing the geographical propinquity of maternal and paternal half-sibships. Again, no difference was found. (3) Assortative mating for IQ by MZ twin sisters may exceed that by MZ twin brothers. Asymmetric assortative mating was directly evaluated by comparing the resemblance of wives of twin brothers to husbands of twin sisters. The spousal correlations do not differ. (4) Identical twin sisters may provide more similar patterns of child-rearing than do the unrelated wives of twin brothers, such that the greater resemblance of their children reflects greater resemblance of relevant maternal behaviour. (5) The greater resemblance of maternal half-siblings may reflect

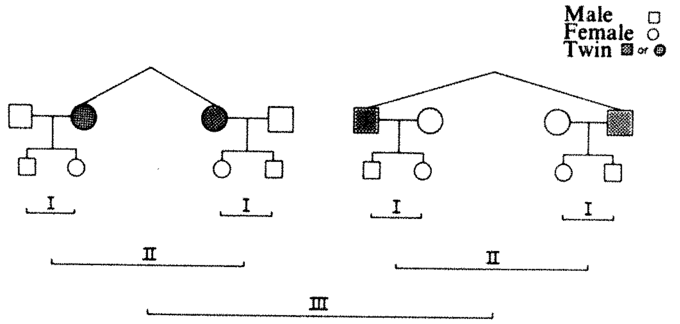

Fig. 1 Variation in offspring data in kinships of MZ twin parents. I, A component of variation arising within sibships; II, variation arising between sibships nested within families; III, variation arising among families.

the reduced variability of intra-uterine environment with which identical twin mothers provide their children. The last two possibilities reflect pre- and postnatal maternal influences not limited to kinships of twin parents, and, although we have no direct tests of them, research with mothers of singletons suggests their plausibility.

Maternal effects modulate the expression of familial mental retardation[20], and the data presented here, obtained from normal children reared by their biological parents in typical home environments, provide direct evidence of significant maternal influences on variation in tested IQ. Indeed, the correlation of maternal half-siblings approaches that typically reported for full siblings! We remain uncertain as to whether the source of these maternal influences is pre- or postnatal, but we emphasise that they are found in the context of significant genetic variance[21] to clarify a widespread confusion—that demonstrations of genetic variance in IQ test scores nullify social efforts to enrich early intellectual development. Heritability of IQ does not negate its social modifiability. Evidence of significant maternal effects may serve to redirect the polemical IQ debate towards constructive efforts to identify environmental factors in cognitive development.

We thank Professor Leon Kamin for helpful criticism of an earlier draft of this report and Frances H. Gabbay, Emily L. Harris, Nancy Holmes and Mary Munchel for their help in data collection. The study was supported by the Indiana University Human Genetics Center, GM 21054.

Distracting information, motor performance and sex differences

Judith I. Laszlo, Phillip J. Bairstow, Gary R. Ward & Hudson Bancroft

Departments of Psychology and Physiology, University of Western Australia, Nedlands, Western Australia 6009

It is often argued that, in general, men are superior to women in perceptual motor skills (for example, car driving). Extensive reviews of the relevant literature do not give convincing evidence of sex differences in manual dexterity[1] or motor skills in general[2]. However, in the studies reported here, variables have been isolated which demonstrate that sex differences do exist in two perceptual motor tasks. These studies showed that females are adversely affected by irrelevant stimuli while performing tasks permitting freedom in movements but perform as well as males when the movement is stereotyped.

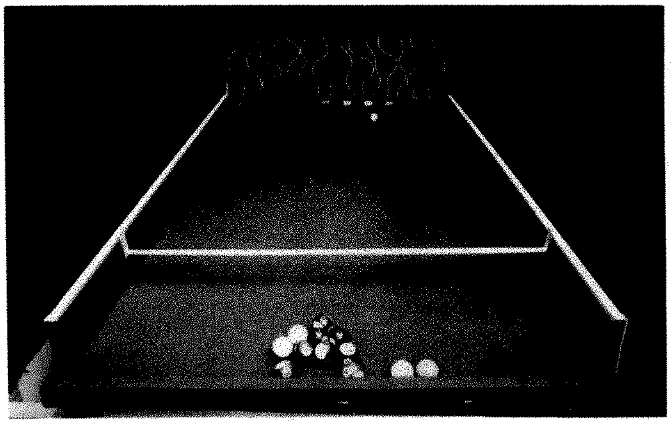

Fig. 1 The experimental set-up. The subject was to roll the ball at the target aiming at the centre flap. In Ward-games *a* and *b* the target comprised seven flaps—the centre flap scored 4; in Ward-game *c* nine flaps were used, the centre flaps scored 5. The landmarks shown were used in Ward-game *c*. In the no-landmark condition the lines were absent.

We first established the performance variables that have direct relevance to motor programming in an aiming task, without considering sex differences. The task was carried out on a Ward table 213 × 114.5 cm (see Fig. 1). At one end was a target consisting of seven 5-cm-wide flaps, either stationary in the middle of the table, or moving from side to side at 20 excursions per min. Subjects had to hit the target with a billiard ball. The score depended on the accuracy of the hit. Target missed scored 0; the outer two flaps scored 1 each; the middle flap scored 4, with increasing scores for the second and third flaps. Several variables were tested in a between-subjects, randomised block design, but for the present purposes, only motor programming demands and sensory information are considered. Motor programming demands varied from simple stereotyped to complex movements, involving temporal and/or spatial organisation. (1) The subject was required to 'shoot' the ball out of a spring-loaded 'gun' at the moving target. The subject had to make the temporal decision when to press the button to release the ball. (2) The subject rolled the ball manually at the stationary target, requiring a directional decision only. (3) The ball was rolled manually at the moving target, necessitating both spatial and temporal programming.

Sensory information was varied by the presence or absence of landmarks. Above the target was a matt blackboard in the no-landmark condition, and four regularly placed vertical white lines were displayed on the blackboard in the landmark

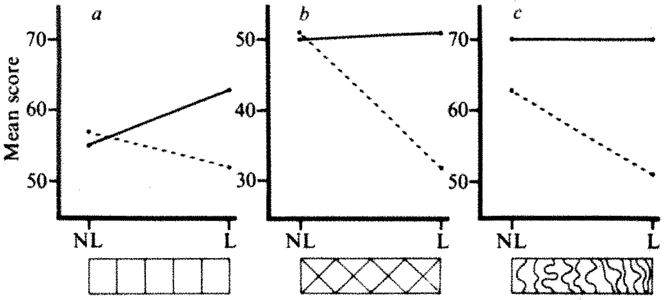

Fig. 2 Results of three Ward-games with the ball manually rolled at the moving target. Maximum score for: Ward-game *a* [condition (3)], 30 trials = 120; Ward-game *b*, 25 trials = 100; Ward-game *c*, 25 trials = 125. Males: ——; females: - - -. L, landmark; NL, no landmark. The patterns below each graph denote the visual stimuli used as landmarks.

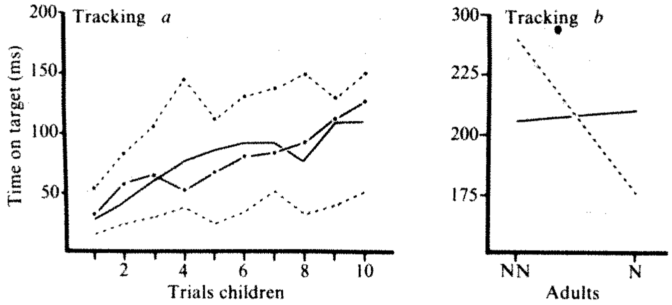

Fig. 3 Results of tracking studies in adults and children. Males: ——; females: - - -. Tracking *a*, noise: no dots; no noise: dots marking data points. Tracking *b*, N: traffic noise through earphones; NN: no noise.

condition. These landmarks were expected to aid in the timing of the movement.

The experiment was conducted as the 'Ward-game' championship and we noticed that males dominated the finals. The results showed that in none of the movement conditions did the landmarks assist male performance, whereas females performed significantly worse with landmarks than without landmarks in conditions (2) and (3) [(2) $t(32) = 3.52$, and (3) 3.92, $P < 0.01$], although in (1) no significant difference was found. Thus, landmarks affected females only, and were irrelevant for the performance of males (Fig. 2).

We carried out two further experiments with the subjects manually rolling the ball at the moving target [condition (3) Ward-game *a*], but varied the visual patterns (Fig. 2). The results confirmed the findings of Ward-game *a*. [Ward-game *b*: landmark main effect $F(1, 36)$ 5.102, $P < 0.03$; sex main effect $F(1, 36)$ 7.662, $P < 0.01$; interaction 9.072, $P < 0.005$; Ward-game *c*: with planned comparison: males versus females with landmark $F(1, 36)$ 9.84, $P < 0.01$; males versus females without landmarks $F(1, 36)$ 0.28, not significant.]

To establish that sex differences were not task specific and relevant to visual stimuli only, two pursuit tracking studies were run. In these, a triangular track (33 r.p.m.) was used, with recorded traffic noise as the irrelevant stimulus. For the control groups the noise was omitted. In the tracking *a* study, the subjects were 7–12-yr-old children, and in tracking *b*, adults were used. The Ward-game results were confirmed [tracking *a*: auditory main effect $F(1, 28)$ 6.96, $P < 0.01$; sex main effect not significant; interaction 5.81, $P < 0.01$; tracking *b*: ANOVA results not significant, *t*-test on female performance with versus without auditory noise: $t(22) = 4.214$, $P < 0.001$] (see Fig. 3).

In a further three experiments with stereotyped aiming movements[3] and visual distractors, no sex difference was found.

Thus, it seems that, as a group, females from the age of 7 yr are adversely affected by irrelevant stimuli in the performance of motor skills in which spatial freedom of movement programming is possible. It can be argued that the input which is processed preceding and determining the motor programme[4] is over-inclusive in females, but selective in males.

The implications of these findings are: (1) contradictory results in the literature on sex differences in motor skill may be due to stimulus configuration in the experimental situation and/or to motor programming demands of the task; (2) most females might be adversely affected by distracting stimuli when operating complex machinery and in car driving; (3) industrial training and driver education may need to be re-examined.

This research was supported by the University of Western Australia Research Grants Committee. We thank Judith Cullity and Jocelyn Brown for their assistance in running some of the experiments, and Peter Bourn, Michael Caracciolo, Chris Edwards, Claire Fletcher, Mike Jones, Rhonda King, Shelagh Morgan, Hanja Sambrailo and Keith Wise, who acted as experimenters in some of the studies.

Origin of the mammal-like reptiles

T. S. Kemp

University Museum, Parks Road, Oxford, UK

The first major adaptive radiation of reptiles consisted of the Synapsida, or mammal-like reptiles, which are now totally extinct, but which dominated the terrestrial fauna from the late Pennsylvanian, throughout the Permian and for much of the Triassic periods. The mammals arose from advanced synapsids in the Upper Triassic, at which time the dinosaur reptiles were rapidly replacing the mammal-like reptiles as the principal terrestrial forms. The orthodox view[1,2] of the ancestry of this important stage in vertebrate history is that the synapsids arose from a hypothetical stem-reptile of the family Romeriidae, the group closest to the ancestry of all the other reptile lineages. The principal difference between romeriids and the primitive synapsids is the development of a space, or temporal fenestra in the cheek region of the skull of the latter. However, the structure of this part of the skull of the romeriids cannot satisfactorily be considered ancestral to the synapsid temporal region on either comparative anatomical or functional grounds. As I propose here, the kind of skull which would be expected to evolve into that of a synapsid is the type possessed by the archaic 'quasi-reptile' *Limnoscelis* and its possible relative *Romeriscus*.

The typical synapsid temporal fenestra is already fully developed in the earliest known skull[3], that of the pelycosaur *Archaeothyris* from deposits of Westphalian D age, in the Pennsylvanian of Nova Scotia (Fig. 1*b*). The fenestra is bounded above by the postorbital and squamosal bones, and the parietal bone is not in contact with the squamosal. Another point to note is that the supratemporal bone, although small, still contacts the postorbital. In contrast, the romeriid skull (Fig. 1*a*) has the postorbital restricted anteriorly, so that there is a long line of contact between the parietal and squamosal, while the supratemporal is reduced to a small, superficial bone right at the back of the skull. The only explanation offered[4] for the difference in bone configuration is that when the temporal fenestra formed in a romeriid-like skull, there was a secondary extension of the postorbital bone backwards, above the new fenestra, to strengthen this part of the skull. It is not clear, however, why the temporal region of the skull should be strengthened in this way. If fenestration of a romeriid skull were to occur, then the space would inevitably develop between the parietal bone above and the squamosal bone below, yet these are two of the largest, most robust bones of the skull, and their mutual contact both in front of and behind the supposed new fenestra would have provided adequate strength. Indeed, this is probably what happened in certain other reptile lines where the fenestra is bounded dorsally by the parietal and squamosal. An alternative view of the origin of the synapsid skull is that the ancestral condition of the temporal region consisted of a large supratemporal bone which was in contact anteriorly with the postorbital. This condition is found in the skull of the limnoscelids, which are early reptile-like forms best known as *Limnoscelis* itself[5]. *Limnoscelis* occurs in the Lower Permian of North America and is a relatively large animal. The skull is unique among early reptiles, for the supratemporal bone is very large and extends far enough forwards to make a broad contact with the postorbital (Fig. 1*c*). The supposed remnant[6] of the old crossopterygian fish hinge-line

0028-0836/80/040378—03$01.00

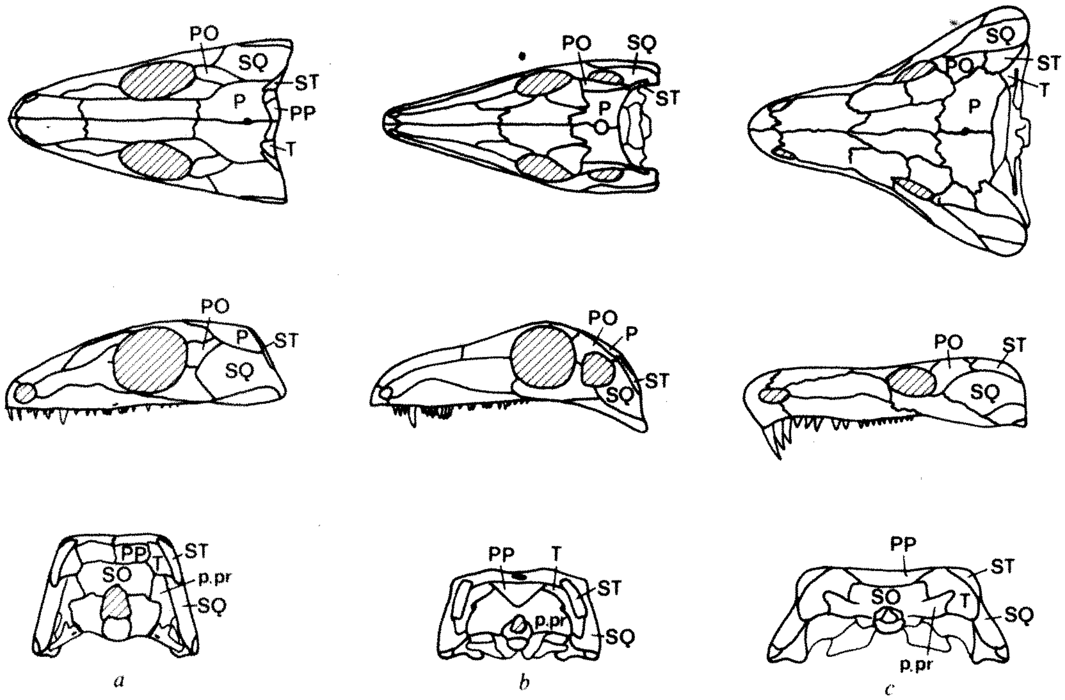

Fig. 1 *a*, Skull of the primitive romeriid *Paleothyris* in dorsal (top), lateral (centre) and posterior (bottom) views. Note the extensive contact between the parietal (P) and squamosal (SQ), the short postorbital (PO) and small supratemporal (ST). No temporal fenestra is present (after Carroll and Baird). *b*, Skull of pelycosaur synapsids, *Archaeothyris* in dorsal view (top) and lateral view (centre); *Varanops* in posterior view (bottom). Note the contact between the postorbital (PO) and supratemporal (ST) and postorbital and squamosal (SQ) above the temporal fenestra (after Romer and Price, and Reisz). *c*, Skull of the primitive reptile-like *Limnoscelis* in dorsal (top), lateral (centre) and posterior (bottom) views. Note the large contact between the postorbital (PO) and supratemporal (ST) bones above the line of weakness between these two bones and the squamosal (SQ) (after Romer). m, adductor mandibuli muscle; P, parietal; PO, postorbital; PP, postparietal; p.pr, paroccipital process; SO, supraoccipital; SQ, squamosal; ST, supratemporal; T, tabular; t.ap, temporal aponeurosis.

persists in the form of a failure of the squamosal to unite firmly with the supratemporal and postorbital above. Thus the cheek and skull table must have been held together by soft connective tissue, probably to allow a slight intracranial kinesis at this point. Another, much earlier form *Romeriscus* has been described as a limnoscelid by Baird and Carroll[7] (Fig. 2*a*), on the basis of a similar configuration of the temporal region. In fact, the skull is very incomplete and badly crushed, but certainly the supratemporal is large, and extends anteriorly sufficiently for it to be presumed to meet the missing postorbital. And there is no apparent suture between the supratemporal and squamosal, indicating the presence of a line of weakness. Whether *Romeriscus* is a limnoscelid or not is doubtful[6], but it does suggest that the basically limnoscelid type of temporal region of the skull existed early, for it dates from the Westphalian A, earlier than any of the true reptiles.

The arrangement of the skull bones of *Limnoscelis* offers a good model for the ancestral state leading to the fenestrated synapsid condition. The classic view that a temporal fenestra is a window out of which the contracting jaw muscles can bulge has been discredited by the observation that in modern fenestrated reptiles the muscles do not so bulge, and that the muscle fibres tend to attach to the edges of the fenestra and to connective tissue covering it. A more acceptable view is that of Frazzetta[8], who suggested that the role of the fenestra is to provide bony edges, to which the muscles can be more strongly anchored. In the line leading to pelycosaurs, an increase in body size appears to have occurred, for all the early forms are larger than other contemporary reptiles[3]. Therefore a relative increase in the mass of the adductor jaw musculature would be expected. If the ancestral, unfenestrated skull was similar to that of limnoscelids, some of the muscle fibres would tend to become attached to the connective tissue between the skull table and cheek (Fig. 2*b*, top). In effect, these particular fibres would be attached to the lateral edge of the postorbital and supratemporal bones, giving them a stronger anchorage than other fibres which merely attached to the internal surfaces of the skull bones. An increase in the area of the connective tissue between cheek and table so that increasing numbers of muscle fibres could attach to it would be expected, leading to the development of a gap, or fenestra, between the postorbital and supratemporal above and the squamosal below (Fig. 2*b*, bottom), covered over by an aponeurotic sheet. The weakest point of the temporal region would have been the supratemporal bone, for it is small and not strongly attached posteriorly. Expansion of the postorbital posteriorly, below the supratemporal, to meet and brace against the squamosal followed, thereby strengthening the post-fenestral region of the skull, and giving rise to the characteristic form of the synapsid postorbital bone.

Two further arguments support this hypothesis of the origin of the synapsid skull. The first concerns the occipital structure of the skull. In the romeriids, the tabular bone is small and restricted to the dorsal part of the occiput, and therefore makes at best a very limited contact with the paroccipital process (Fig. 1*a*, bottom). In contrast, the pelycosaurs possess a large tabular which extends ventrally to make a massive, bracing contact with the paroccipital process (Fig. 1*b*, bottom). Panchen noted this point[6], and concluded that the common ancestor of romeriids and pelycosaurs was more primitive than any known form. In fact, the limnoscelid tabular and paroccipital process have a relationship very similar to that of the pelycosaurs (Fig. 1*c*, bottom). Functionally, retention of the tabular-paroccipital process brace in pelycosaurs would be expected, as a further manifestation of the need for strengthening devices in the potentially weak post-fenestral region of the skull. The second argument is that in certain generally primitive pelycosaurs such as *Eothyris*[1] (Fig. 2*c*) and *Oedaleops*[9] the supratemporal is a large bone, making extensive contact with the postorbital directly above the temporal fenestra. It is not unreasonable therefore to suggest that a large supratemporal bone, quite unlike that of the romeriids, is actually the primitive synapsid condition.

The conclusion is, therefore, that the synapsid skull evolved from a limnoscelid-like skull rather than from that of a romeriid, and that the temporal fenestra of the mammal-like reptiles evolved directly from the remnant of the crossopterygian hinge line. This is not to say, of course, that taxonomically the limnoscelids are the ancestors of the synapsids, merely that the limnoscelids have retained the ancestral configuration of the temporal region of the skull. It has long been supposed that a fundamental reptilian feature is the parietal lappet, which is the lateral process of that bone which contacts the squamosal and replaces topologically the intertemporal bone of early labyrinthodont amphibians. This arrangement contrasts with those labyrinthodonts which themselves lost the intertemporal, for here the area occupied by that bone is taken over by the postorbital and supratemporal. On the argument presented here, the synapsid line at least never possessed a parietal lappet. Whether the parietal lappet of the romeriids and other primitive reptiles does indeed indicate a separate loss of the intertemporal, or whether it reflects a subsequent reduction of the postorbital and supratemporal bones is not known. The latter seems the more probable in view of the many points of similarity that do exist between limnoscelids, romeriids and pelycosaurs.

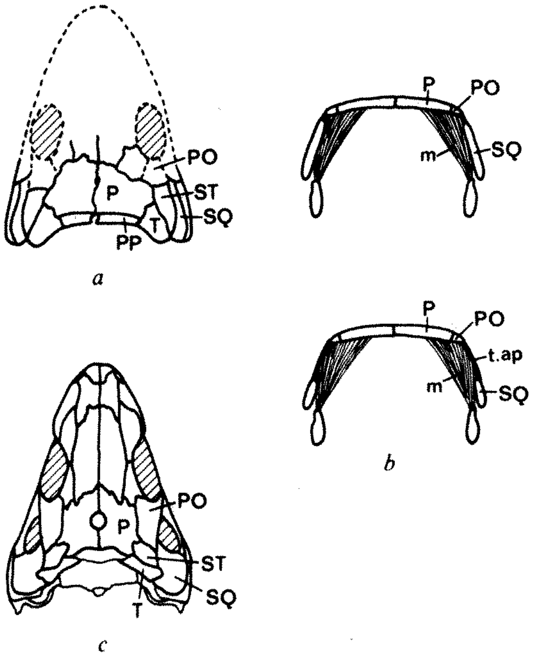

Fig. 2 *a*, Skull of the possible early limnoscelid *Romeriscus* in dorsal view (after Baird and Carroll). *b*, Above, diagrammatic cross-section through the temporal region of the skull of a limnoscelid-like form, in which the adductor jaw muscles (m) are beginning to gain an attachment to the connective tissue binding the postorbital (PO) of the skull roof to the squamosal (SQ) of the cheek. Below, further development of this trend, with enlargement of the gap to form a temporal fenestra, covered by a large connective tissue aponeurotic sheet (t.ap), leading to the synapsid skull pattern. *c*, Dorsal view of the skull of a very primitive pelycosaur synapsid *Eothyris*. Note the retention of a large supratemporal in contact with the postorbital (after Romer and Price).

Juvenile ceratopsians from Mongolia—the smallest known dinosaur specimens

Walter P. Coombs Jr

Department of Biology, Western New England College, Springfield, Massachusetts 01119

Among dinosaurs collected by the Third Asiatic Expedition of the American Museum of Natural History (New York) are two juveniles each of which is smaller than any hitherto reported dinosaur specimen. Their overall anatomy resembles that of the type specimen of *Psittacosaurus mongoliensis* (AMNH 6254)[1], which was collected from the same horizon and locality: the Lower Cretaceous Oshih Formation, Artsa Bogdo Basin, Mongolian Peoples' Republic. The anatomy of the new specimens confirms *Psittacosaurus* as a ceratopsian, not an ornithopod, and their minute size precludes both post-hatching parental care and endothermy.

Of the two specimens, AMNH 6535 includes a skull and partial mandibles and AMNH 6536 includes a skull, mandibles, partial pes in articulation and numerous postcranial elements (Fig. 1). Important cranial features include: skull triangular in dorsal view; short deep snout with parrot-like beak; small nostrils far dorsal; massive jugal with small ventrolateral flange

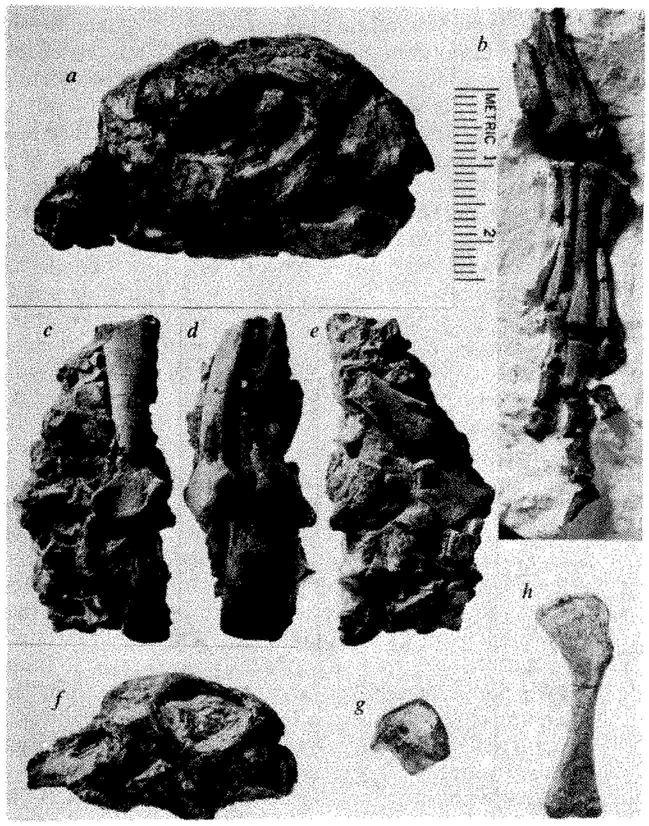

Fig. 1 Representative material of the two smallest known dinosaur specimens. *a–e*, *g* and *h*, AMNH 6536; *f*, AMNH 6535. *a*, Skull and mandibles. *b*, Left pes with distal ends of tibia and fibula, astragalus, calcaneum, metatarsals II, III, IV, and partial metatarsal V, and a partial set of phalanges. *c*, *d*, And *e*, three views of a block of bone containing two scapulae, partial ilium, partial ischium, proximal end of a femur, several vertebrae, and sacral ribs. *f*, Skull and partial mandible. *g*, Right coracoid. *h*, Left humerus. Scale divisions in mm (shown approximately natural size).

0028-0836/80/040380—02$01.00

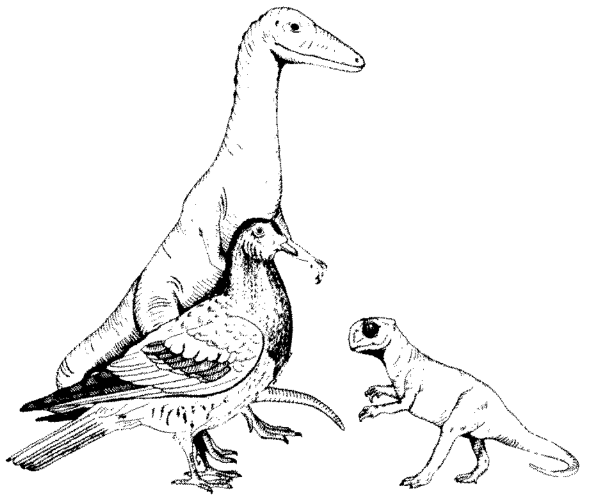

Fig. 2 Restoration of the smallest known dinosaur, a juvenile *Psittacosaurus mongoliensis*, based on AMNH 6535. Included for size comparison (on the left) are *Compsognathus longipes* and a common pigeon (*Columba livia*). Illustration by Matthew Hyman.

or spike; and massive curved mandible with triangular coronoid process. A rostral bone, present on both juvenile skulls and the type specimen of *Psittacosaurus mongoliensis*, is a synapomorphic character diagnostic of the suborder Ceratopsia. Wear on the teeth of both juvenile skulls indicates a diet of abrasive vegetation, and suggests that a newly hatched *Psittacosaurus* would have been smaller than either of these specimens. Pedal conformation, humeral shape, elongate tapering scapulae and femora with cylindrical heads and curved shafts (Fig. 1) all indicate a gracile, tridactyl biped. That these specimens are juvenile is indicated by the enormous orbits, relatively large braincase, arched cranial roof, short snout and neural arches not fused to centra. Using basicranial length for comparison, the smallest known dinosaur specimens include the following: *Lesothosaurus diagnosticus*, 94 mm; two juvenile *Protoceratops andrewsi*, 76 mm and 62 mm; *Compsognathus longipes*, 70–75 mm, and *Bagaceratops rozhdesvenskyi*, 47 mm (refs. 2–6). The juvenile *Psittacosaurus* skulls measure 42 mm (AMNH 6536) and 28mm (AMNH 6535). Estimated total body length, snout to tail tip, obtained by scaling down the complete skeleton of *P. mongoliensis* (AMNH 6254) is 395 mm for AMNH 6536, and 265 mm for AMNH 6535. These values make no allowance for allometric changes in proportions, and insofar as the skull is relatively larger in juveniles, the actual total length for AMNH 6535 is probably between 230 and 250 mm. The latter juvenile was smaller than a common pigeon (*Columba livia*) and less than one-third the length of *Compsognathus longipes* (750–810 mm)[6], also a juvenile specimen and often cited as the smallest known dinosaur (Fig. 2).

Dinosaur egg morphology indicates a pattern of nest construction similar to that of crocodilians and megapodes (chicken-like, terrestial birds of Australasia)[7], and parental attendance of such nests is reasonably inferred for dinosaurs. The usual thickness of dinosaur eggs may have reduced breakage by attendant parents of large size and fully upright stance. However, the minute size of these juvenile *Psittacosaurus* compared with the adult (body mass of juvenile about 0.7% of adult mass) makes post-hatching care by parents virtually impossible, both because the parent could not effectively feed so tiny a juvenile, and because the young would be liable to crushing at the least misstep of the adult. Tooth wear and well-ossified limb bones point to precocial self-feeding by hatchling *Psittacosaurus*. The surface area to body mass ratio of these juveniles would promote heat loss at a much higher rate than in adults. Exceptionally small neonates of modern endotherms are commonly ectothermic at birth, with endothermic physiology developing together with a more favourable surface area to body mass relationship[8,9]. Egg volumes of *Protoceratops* and *Hypselosaurus* infer a hatchling to adult size discrepancy even greater than that of *Psittacosaurus*[10]. Regardless of adult physiology, it is unlikely that such relatively tiny juvenile dinosaurs were endothermic in a mammalian-avian sense.

Male and female visual neurones in dipterous insects

N. J. Strausfeld

European Molecular Biology Laboratory, Postfach 102209,
6900 Heidelberg, FRG

In many insects some visually guided behaviour patterns differ between the sexes. For example, male hoverflies and houseflies chase females in the air using visual cues but are not chased by females[1–3]. Presumably information processing by nerve cells also differs. The genetic and histochemical identification of a brain area in *Drosophila* that must be male for male behaviour to occur[4] suggests that circuits for sexual behaviour are localised. Recent anatomical studies of houseflies (*Musca domestica*) have demonstrated certain visual neurones present only in males[5]. I report here results from another species (the blowfly, *Calliphora erythrocephala*) demonstrating another kind of sexual difference of neural architecture in the visual system. In this fly dimorphism is expressed by differences in the shapes of analogous neurones in males and females, as well as by the presence of some cells in only one sex. The sexually dimorphic neurones of both sexes 'view' a region of the visual field coinciding with the region of binocular overlap.

The structures described here are from the lobula, the third visual neuropil. In this neuropil, columnar arrangements of small neurones precisely represent the facet organisation of the retina, and any dendritic field in the lobula can be represented as a map on the retinal surface[5,6]. Assemblies of nerve cells in the lobula are revealed by silver intensification of cobalt ions introduced either from a pool of cobalt chloride over a cut in the thoracic ganglion or from a smaller pool diffusing from a micropipette inserted into the brain. In the first case cobalt ions pass 'trans-synaptically' from dendrites of descending neurones into presynaptic relay cells originating in the lobula (Fig. 1*a*, *b*)[7]. In the second case cobalt appears to be taken up directly by one or more populations of visual interneurones[8]. The same neuronal arrangement can be revealed reproducibly in different brains. The results reported here are obtained from examination of 80 males and 60 females.

The shapes of many neurones do not significantly differ in males and females and comprise similarly structured networks. These are not described here; instead the emphasis is on morphologies characteristic of one or the other sex.

Lobulae of male blowflies have certain prominent neurones, each with characteristic shape, dendritic domain and axonal destination. Three of these are the male lobula giants[5] (MLG 1–3) illustrated in Figs 1 and 2. Two (MLG 1, 2) reside in the upper frontal lobula where their unistratified dendritic fields interact with relays from upper frontal ommatidia of the eye

0028–0836/80/040381—03$01.00

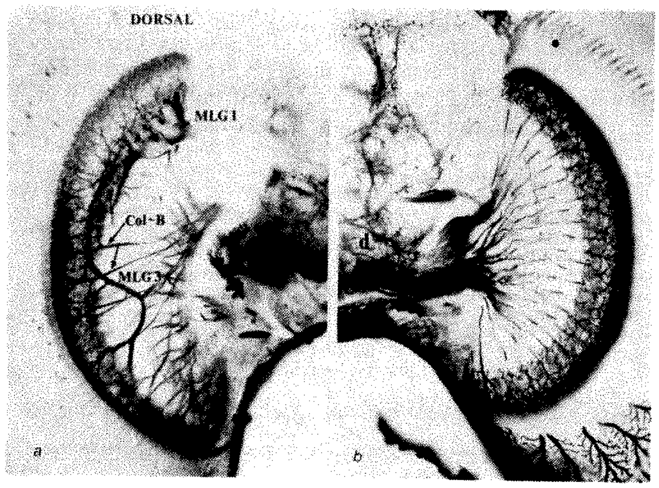

Fig. 1 Silver intensified neurones in male (*a*) and female (*b*) lobulae of *Calliphora erythrocephala*. The two pictures illustrate palisades of Col A neurones, parts of two male lobula giant neurones (MLG 1 and 3), and some Col B neurones which have taken up cobalt after its initial introduction into cut thoracic ganglia (×100).

(Fig. 3). Their cell bodies lie as a pair posteriorly above the upper margin of the lobula plate. The axon of MLG 1 passes to the rear of the contralateral mid-brain, ending among dendrites of descending neurones. The axon of MLG 2 ends at the equivalent ipsilateral region. Terminal branching patterns of MLG 1 and MLG 2 are similar. The third giant neurone (MLG 3) has a lyre-shaped profile. Its dendritic branches invade the anterior lobula along a strip that is narrow dorsally and wider ventrally (Fig. 3). The location of its cell body has not been identified. Its axon projects to the vicinity of a descending neurone in the medial ipsilateral protocerebrum.

In the female lobula there are four special neurones (female lobula giants; FLG 1-4). The dendrites of two of these (FLG 1, 2) invade the upper frontal lobula. FLG 1 is characterised by a unistratified field of spiny dendrites and, like MLG 1, its axon ends among dendrites of descending neurones in the rear of the contralateral mid-brain. The dendrites of FLG 2 are multistratified and distal to FLG 1 in the lobula. Like MLG 2, its axon passes to the rear of the ipsilateral mid-brain. The cell bodies of FLG 1 and 2 lie as a pair between the upper margin of the lobula and the upper margin of the lobula plate. A small lyre-shaped neurone (FLG 3) invades a narrow anterior strip of the lobula both above and beneath its equator. Like MLG 3, its axon projects ipsilaterally to the medial protocerebrum. FLG 4 invades a fronto-ventral strip of the lobula. Its axon projection has not been followed and the cell body locations of FLG 3 and 4 are not known.

Sexual dimorphism is also expressed among palisades of columnar neurones common to both sexes. Type A columnar cells (Col A)[5] are distributed throughout male and female lobulae and their axons project to the same region of the medial ipsilateral protocerebrum as MLG 3 and FLG 3. Col A shapes and distributions are similar in the two sexes (Fig. 2). However, in the upper region of the male lobula, where they overlie MLG 1 and 2, Col A cells show a graded change of dendritic morphology from multistratified to bistratified. In females, Col A neurones are uniform over the whole lobula, including the region occupied by FLG 1 and 2.

Both sexes of blowfly have in the lobula an upper-frontal row of columnar neurones serving exclusively the extreme frontal retina. In males, this row consists of two cell types: Col B ventrally, and Col C dorsally. In females the row consists only of Col B cells, ventrally and dorsally (Fig. 2). Col B cells have multistratified dendrites and long oval dendritic domains. Their axons project dorsally to ipsilateral protocerebrum in both sexes. Col C cells are distinguished by flattened dendritic expansions emitting numerous thin processes. Col C axons

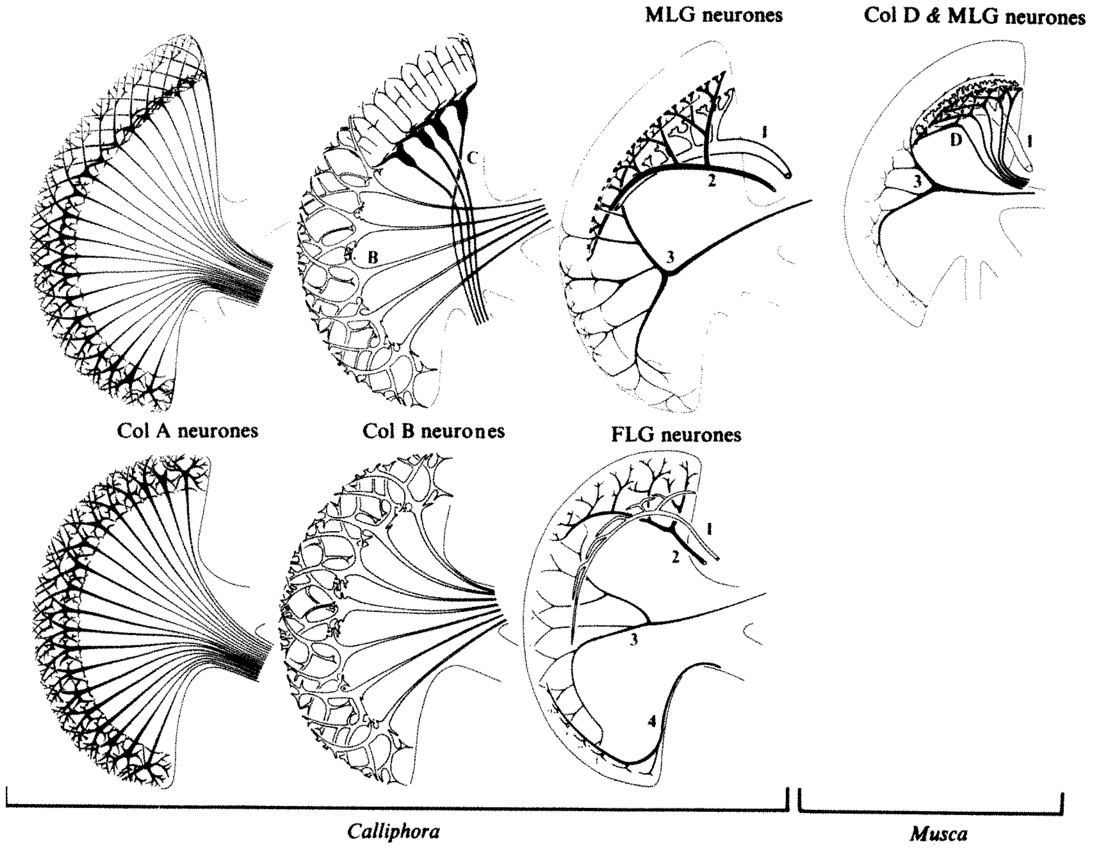

Fig. 2 Diagram of neurones in the lobula of male blowflies (upper row) and females (lower row) as seen in vertical sections of the lobula. Dorsal is to the top, with the midline to the right. Type A columnar neurones (Col A) are found throughout the lobula and are identical between the sexes except in the upper frontal zone of the male lobula. Col B neurones are found in the anterior of the lobula in both sexes. However, in males they are absent from an upper region. Col C neurones are found only in the anterior upper male lobula. Three unique male lobula giant neurones (MLG 1-3) and four unique female lobula giant neurones (FLG 1-4) are also found. Although termed female giants the diameters and processes of FLG neurones are usually much smaller than those of MLG neurones. The inset (upper right) shows the homologues of the MLG 1-3 neurones in the housefly, where a palisade of columnar cells (Col D) appears to substitute the single MLG 2 of *Calliphora* (see ref. 5).

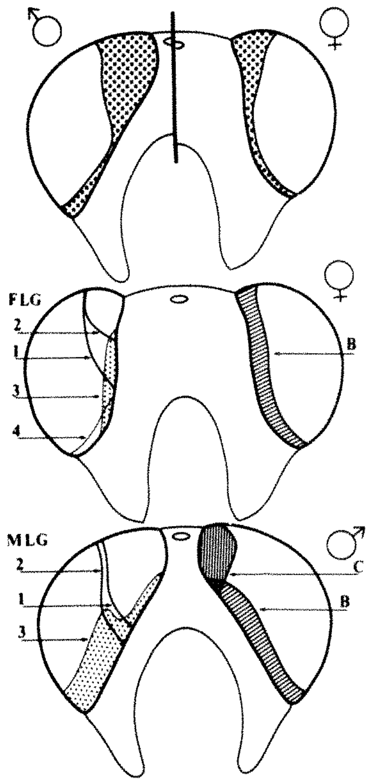

Fig. 3 Maps of dendritic fields demonstrate the sexual dimorphism. The top figure juxtaposes front views of male and female half-heads to show differences in eye position and zones of binocular overlap[9] (indicated by heavy dots). The middle figure shows the domains of FLG neurones mapped on to the retina to the left. The domains of FLG 1 and FLG 2 are above the lines indicated; the domain of FLG 3 is dotted and the domain of FLG 4 is below the line indicated. The domain of female Col B cells is shown in hatching on the right. The lower figure illustrates the domains of MLG 1-3 and male Col B and Col C neurones. Note the general correspondence between the zones of binocular overlap and the domains of Col B, Col C, MLG and FLG neurones.

project ventrally to a median locus in ipsilateral protocerebrum.

The styles of sexual dimorphism in the blowfly and housefly show interesting differences. Neurones analogous to MLG 1, MLG 3 and Col C are found in the lobulae of male houseflies[5]. However, there is no single element corresponding to MLG 2: instead, the housefly has a small cluster of columnar cells (Col D[5], Fig. 2) collectively covering the same domain of the lobula. Like MLG 2 of *Calliphora*, their axons project ventrally into the ipsilateral rear protocerebrum. No neurones corresponding to FLG 1-4 were found in female houseflies although they were sought with the cobalt method, with reduced silver stains, and by reconstruction from serial 3-μm Araldite-embedded sections stained with methylene blue[5].

Comparisons between the sexes of *Calliphora* lead to the following conclusions. Three unique neurones in the male and female are probably analogous. The location of dendrites is similar and the cell body locations of two cells (MLG 1, 2 and FLG 1, 2) are similar. Similarly shaped neurones in males and females send axons to the same regions. Comparable neurones differ with respect to morphology, axon diameter, dendritic domain and layer relationships. These differences may reflect different synaptic connections in males and females. Other neurones (FLG 4 and Col C) are present in one sex but apparently have no analogue in the other sex.

The sexual dimorphism of lobula neurones can be summarised by projections of their dendritic domains out to the retinal surface, as in Fig. 3. This figure also compares regions of binocular overlap in males and females[9]. The overlap is greatest in the upper frontal retina of the male where there is also an extra zone of ommatidia not present in the female[10-12]. The MLG 1 and 2 fields, and the Col C assembly, correspond to this zone (Fig. 3). In the female, FLG 1 and FLG 2 cover slightly more of the retina than the female binocularity zone. In both sexes the strip of Col B neurones corresponds to the binocular overlap zone more ventrally. In females, FLG 3 and 4 lie within this zone whereas in males the ventral part of the MLG 3 domain is significantly wider than this zone.

It has been suggested that the upper front part of the eye of male houseflies may play a significant role in visually guided sexual behaviour[3]. Are the sexually dimorphic neurones important in sexually dimorphic behaviour? Their large size should permit exploration of this question by electrophysiological methods.

I thank Dr Duncan Byers for critical reading of the manuscript and Drs Byers, K. Hausen and D. Nassel for discussions of the results.

Feeding behaviour of tsetse flies infected with salivarian trypanosomes

L. Jenni*, D. H. Molyneux†, J. L. Livesey‡ & R. Galun§

* Swiss Tropical Institute, Socinstrasse 57, CH-4051, Basle, Switzerland
† Department of Biology, Salford University
‡ Department of Aeronautical and Mechanical Engineering, Salford University, Salford, UK
§ Department of Zoology, Hebrew University, Jerusalem, Israel

Although much is known about factors which determine infection rates of salivarian trypanosomes (subgenera *Nannomonas*, *Duttonella* and *Trypanozoon*) in the tsetse fly *Glossina*[1,2], it is not clear why infection rates of *Trypanozoon* are high in mammalian hosts but low in wild-caught *Glossina*[3,4] and why trypanosomiasis occurs where *Glossina* is not readily detectable. We report here that the feeding behaviour of trypanosome-infected *Glossina* differed from that of uninfected control flies. Infected flies probed more frequently and fed more voraciously. We describe a specific relationship between trypanosomes and the mechanoreceptors responsible for detecting the rate of blood flow[5-7], and show how infection affects that rate in the labrum. We suggest that the observed differences in feeding behaviour result from impaired function of the labral mechanoreceptors in infected *Glossina*.

Glossina m. morsitans and *Glossina austeni* were obtained as pupae. Teneral *G.m. morsitans* were fed on mice (ICR) infected with *Trypanosoma* (*Trypanozoon*) *brucei* subsp. (ST1B 247) isolated in Serengeti, Tanzania, from *Alcelaphus buselaphus* (hartebeest) in 1971 and cryopreserved after one passage in the rat. Control flies received an uninfective blood meal at the same time and all flies were subsequently maintained as described previously[8]. Infected flies were detected by inducing individuals to probe on warmed slides 14 days after the infective feed and then feeding them on mice to verify their infectivity.

Forty infected and forty uninfected flies (20 males and 20 females in each group) were placed individually in glass tubes

0028-0836/80/040383—03$01.00

Table 1 Probing and feeding patterns of infected and uninfected *Glossina m. morsitans*

	Starving for 24 h			Starving for 48 h		
State of flies	No. feeding	No. feeding on first probe	Mean no. of probes ± s.e. before feeding	No. feeding	No. feeding on first probe	Mean no. of probes ± s.e. before feeding
40 Infected flies	40	3	5.08 ± 0.40	40	4	4.68 ± 0.37
40 Uninfected flies	28	13	1.89 ± 0.21	38	24	1.53 ± 0.13

The flies were 20–35 days old.

Table 2 Factors by which the required pressure drop $-\Delta\bar{P}$ would need to be increased for a given proportion of length colonised by trypanosomes $m(L)$ and for a given proportionate reduction in diameter $n(D)$ as a result of trypanosome infection if the same flow rate in the labrum was to be maintained

Proportion of diameter unoccluded	Proportion of length infected									
$n(D)$ \ $m(L)$	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
1.0	—	—	—	—	—	—	—	—	—	1
0.9	1.052	1.10	1.16	1.21	1.26	1.31	1.37	1.42	1.47	1.52
0.8	1.14	1.29	1.43	1.58	1.72	1.86	2.01	2.15	2.30	2.44
0.7	1.31	1.63	1.95	2.27	2.58	2.90	3.22	3.53	3.85	4.16
0.6	1.67	2.34	3.01	3.69	4.36	5.03	5.70	6.37	7.04	7.72
0.5	2.5	4	5.5	7	8.5	10	11.5	13	14.5	16
0.4	4.81	8.61	12.42	16.23	20.03	23.84	27.64	31.45	25.26	39.06
0.3	13.25	25.49	37.74	49.98	62.23	74.47	86.72	98.97	111.21	123.4

0.1	1,000.9	2,000.8	3,000.7	4,000.6	5,000.5	6,000.4	7,000.3	8,000.2	9,000.1	10,000

with netting at one end. Mice were anaesthetised with Nembutal before being used as the source of a blood meal. We first counted the number of probes by individual uninfected and infected flies (previously starved for 24 and 48 h) which pierced the skin with the haustellum before they were gorged. Table 1 shows that infected flies probed significantly more frequently than uninfected control flies, and suggests that infected flies were more voracious, for all 40 infected flies took blood after 24 h whereas only 28 of 40 uninfected flies did so.

We then offered 10 infected flies (5 male, 5 female) a series of mice on which to probe. If an individual fly failed to engorge after probing and withdrawing its haustellum, it was offered another mouse. Of a total of 41 probes by 10 infected flies, 38 proved to be infective to mice; the highest number of infective probes by an individual fly was 6. There was no significant difference between male and female fly behaviour in the above experiment.

The labrum of two *T.* (*T.*)*brucei*-infected *G.m. morsitans* were successfully prepared for scanning electron microscopy (SEM) out of a total of eight flies with mature infections examined with the light microscope. All eight flies had groups of trypanosomes in the proximal part of the labrum and SEM examination of two infected labra demonstrated a specific association between parasites and LCl mechanoreceptors (Fig. 1). We know the subgenera *Nannomonas* and *Duttonella* colonise the labrum where LCl mechanoreceptors are located[5] and are in close association with them[9,10].

We then applied principles of fluid mechanics[11–15] to predict the behaviour of blood in the labrum of *Glossina* to evaluate the likely effects of colonies of trypanosomes on the rate of blood flow. The data, units and sources which allow calculations of the predicted effects of parasites on flow in this system are available from the authors. The flow is characterised by the Reynolds number[12], and a frequency parameter[13–15] for the pulsating flow and non-newtonian viscosity effects are considered[11]. From these calculations, the pressure drop ($-\Delta\bar{P}$) below atmospheric required to obtain the same flow rate, $\bar{Q}$, for the meal is obtained. Table 2 indicates the factors by which $-\Delta\bar{P}$ would need to be increased for a proportion of the length mL (for m, 0.1–1.0) infected with trypanosomes and the proportionate unoccluded diameter $n\bar{D}$ (for n, 0.1–1.0) if the same meal flow rate were to be obtained. Alternatively, if $-\Delta\bar{P}$ remained constant, the flow rate would be inverse to the factors in Table 2. To illustrate the effect of occlusion due to *Nannomonas* and *Duttonella*[9,10], Table 2 shows that colonies of trypanosomes will be significantly invasive hydrodynamically, affecting blood flow rate through the labrum. Such changes would be detected by LCl mechanoreceptors[5]. Table 2 is also applicable to the trypanosome-infected hypopharynx, where a greater proportionate reduction in diameter would apply due to the smaller internal diameter of the hypopharynx; thus, the pressure required to expel saliva would be greater in infected than uninfected flies.

Table 3 The relationship between viscosity and feeding rate in *Glossina austeni* fed 24–48 h after emergence through bat or mouse skin membrane

Diet	Viscosity (cP)	Meal weight (mg)	Average feeding time (s)	Feeding rates (mg s^{-1})
10^{-3}M ATP saline	0.68	18	36	0.500
10^{-3}M ATP saline 3% dextran	1.36	18.6	48	0.387
10^{-3}M ATP saline 6% dextran	2.64	16.5	55.5	0.297
10^{-3}M ATP saline 12% dextran	6.78	18.1	82.25	0.220
Defibrinated sheep blood	3.10	16.5	63.3	0.26
Sheep plasma + 10^{-3}M ATP	1.15	16	37.1	0.431

Twenty flies were used for each diet and duration of feeding was measured electronically as described in ref. 6. Blood meal size was determined by weighing the fly before and immediately after feeding, before primary excretion took place. Viscosity was measured in a Cannon–Lebbelohde semi-microviscometer, size 200 at 38 °C

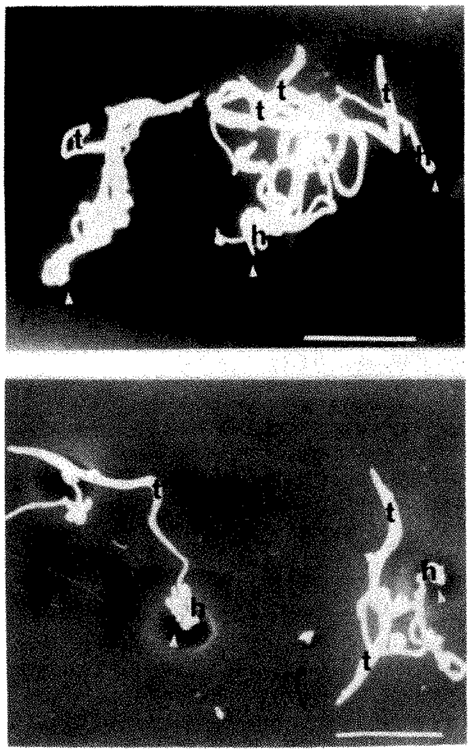

Fig. 1 Upper, scanning electron micrograph of *T. b. brucei* parasites (t, procyclic trypomastigotes) associated with two LCl mechanoreceptors (basal pits arrowed) in the proximal part of the labrum of *G. m. morsitans* 19 days after an infective feed. The preparation was fixed in 0.2 M glutaraldehyde in cacodylate buffer, critically point dried and examined in a Cambridge stereoscan. Scale bar, 10 μm. Lower, two procyclic parasites (t) associated with one LCl mechanoreceptor in the labrum of *G. m. morsitans* (and a single parasite associated with a second LCl). Scale bar, 10 μm.

However, if the viscosity of the blood meal was increased in membrane feeding experiments with *G. austeni*, there was a reduction in the rate of feeding of approximately 50% for a 10-fold increase in viscosity (Table 3). We have shown that there will be a need to increase either pump frequency or capacity by the factors given in Table 2 if the flow rate is to remain constant for any given occlusion in effective diameter by trypanosomes. However, we also know the pump performance is limited in its capacity to respond to an experimentally increased viscosity. Thus, to obtain the same blood meal size the infected fly would take longer to engorge or, if it did not take sufficient blood, would need to feed more frequently.

We know[5-7] that the feeding and gorging responses of *Glossina* are determined by chemo- and mechano-sensilla located in the labellum, labrum and cibarium. The LR7 sensilla of the labellum initially detect a suitable food source in their role as ATP detectors; probing continues until there is (1) sufficient stimulus of the LCl mechanoreceptive sensilla of the labrum and of the LC2s of the anterior cibarial wall by an adequate blood flow rate, at which time (2) the four LC4 sensilla of the posterior cibarial wall are stimulated by the ATP present in the meal to begin the gorging phase of the feeding cycle. Thus, impairment of the LCl mechanoreceptor function will affect sensory input and modify the feeding behaviour of infected flies as described above. Such behaviour indicates an advantageous adaptation by parasites that may have profound epidemiological and epizootiological implications. In particular, the significance of salivarian trypanosome infection rates in *Glossina* will require re-examination if studies on the behaviour of different tsetse species in the field confirm our laboratory findings.

This work was supported by Swiss NSF grant no. 3.346-0.78 (to L.J.), by the UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases and Overseas Development Administration Research Scheme R3495 (to D.H.M.) and by the International Atomic Energy Agency (to R.G.). We thank Dr A. M. Jordan for the supply of *Glossina* pupae and Mr K. F. Schell, Miss M. Kauffman, Mr D. R. Lavin and Mr D. V. Roscoe for technical assistance.

Larval hatching from vitellogenin-deficient eggs developed in male hosts of the silkworm

Okitsugu Yamashita & Ken Irie

Laboratory of Sericultural Science, Faculty of Agriculture,
Nagoya University, Chikusa, Nagoya 464, Japan

Egg production in insects is generally considered to require the availability of the yolk precursor, vitellogenin. In most insects, the synthesis of this protein in the female fat body and its uptake into the ovaries are under the control of the hormones, juvenile hormone and ecdysone[1], which is somewhat analogous to the oestrogenic control in oviporous vertebrates[2]. Indeed, vitellogenin constitutes ~90% of total egg proteins in the cockroach, *Leucophaea maderae*[3], and ~40% in the silkworm, *Bombyx mori* (unpublished data). However, in some insects[4-9], rudimentary ovaries transplanted into male hosts are known to develop to mature eggs with chorion but lacking vitellogenin. *Drosophila melanogaster* is exceptional in that the ovaries themselves can produce vitellogenin, which accounts for its accumulation in ovaries transplanted into males[8]. Vitellogenin is believed to represent a reserve for use during embryogenesis[10,11]. However, experiments on *D. melanogaster*[12] and *B. mori* (unpublished data) demonstrated that vitellin was not used rapidly during embryonic development and persisted at a considerable level in the newly hatched larvae. These facts suggest that vitellogenin may not be essential for ovarian development or for embryonic development. Therefore, the present experiments were carried out in order to establish whether the vitellogenin-deficient eggs that matured in male hosts, if activated by artificial parthenogenesis[13], can compute embryonic and further post-embryonic development. We have found that they can.

Silkworms of a bivoltine race (Shunrei and Shogetsu) were programmed to produce diapause eggs by incubating the parental embryonic stage at 25 °C under continuous illumination. On the third day of the fifth instar, ovaries were transplanted into males, the testes of which had just been extirpated. The operated larvae metamorphosed into pupae in 9 days and into adults after a further 14 days, as did non-operated control animals. Mature eggs with chorion were taken from the newly emerged adults. Table 1 compares various characteristics of these eggs with those of eggs matured in females. The eggs from males were less numerous and slightly light in weight. The contents of amino acids, RNA and lipids were almost the same but the glycogen content was clearly higher in the eggs from males, and the protein content was about 20% lower than that of controls.

Polyacrylamide disc gel electrophoresis of the proteins of eggs from males demonstrated eight bands comparable with those

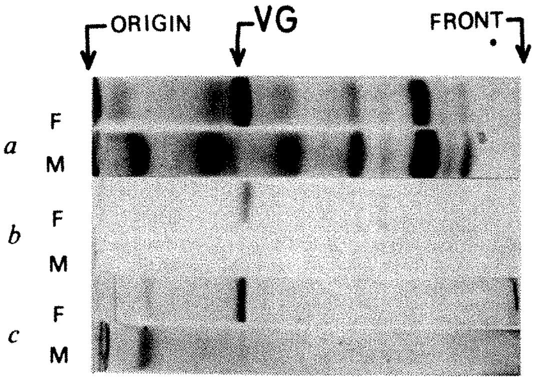

Fig. 1 Polyacrylamide gel electrophoresis of soluble proteins from eggs from females (F) and male hosts (M). Eggs (about 200 mg) obtained as described in Table 1 legend were homogenised in 5 vol of 0.4 MKCl in 50 mM phosphate buffer, *p*H 6.0. The homogenate was centrifuged at 15,000*g* for 15 min at 4 °C and 10–20 μl of the supernatant containing 0.002% bromphenol blue and 20% glycerol was applied to a 5% polyacrylamide gel (*p*H 8.5) and run at a constant current of 2 mA per gel[18]. Gels were stained[19] for protein with amido black 10B (*a*), for glycoprotein with Schiff's reagent (*b*), and for lipoprotein with Sudan black (*c*). VG, vitellogenin.

Table 1 Comparison of weight and composition of eggs developed in normal females and in male hosts

	Eggs developed in	
	Females	Male hosts
Wet weight (μg per egg)	600 ± 30	556 ± 11
Dry weight (μg per egg)	231 ± 1	188 ± 1
Amino acids (mg per g eggs)	2.3 ± 0.1	2.5 ± 0.2
RNA (mg per g eggs)	2.4 ± 0.8	3.0 ± 0.7
Lipids (mg per g eggs)	85.4 ± 2.4	87.8 ± 9.3
Glycogen (mg per g eggs)	26.5 ± 1.5	35.3 ± 2.5
Proteins (mg per g eggs)	105.2 ± 7.5	84.7 ± 10.7

Ovaries from fifth instar larvae were transplanted into males of the same stage. At the emergence of adults, ovaries were dissected out and mature eggs with chorion were collected by squeezing from ovarioles through a layer of gauze. After brief air drying, the eggs were weighed, then dried three times at 80 °C for 3 h to constant dry weights and weighed again. Fresh eggs were homogenised in cold water with an agate mortar and the homogenates were passed through a cotton pad to remove chorion residues. The filtered sample was used for determination of amino acids, RNA, lipids, glycogen and proteins. Amino acids were extracted three times with cold 5% $HClO_4$. After neutralisation with KOH, the solution was applied to a column of Dowex-50 (H^+ form) and eluted with 1 M NH_4OH. The pooled eluate was used for determination of total amino acids by the ninhydrin reaction, with leucine as standard[14]. From the acid-insoluble residues RNA was extracted with hot 5% $HClO_4$ and determined by the orcinol reaction, with yeast RNA as standard[15]. Protein was extracted from the residues with 0.5 M NaOH and determined by the method of Lowry *et al.*[16], with bovine serum albumin as standard. Lipids were extracted from fresh homogenates with methanol/chloroform (3:1) and the evaporated residues were then extracted with chloroform, washed with 0.5 M NaCl, dried and weighed[17]. For glycogen, the homogenate was digested with 30% KOH at 100 °C for 30 min, and glycogen was precipitated with 4 vol of ethanol overnight. In some experiments a cold $HClO_4$ soluble fraction was used directly for glycogen determination. Glycogen was determined with the phenol–sulphuric acid or concentrated H_2SO_4 method with glucose as standard[17]. Values are means ± s.e.m. from three to five determinations on different pools of eggs (about 350 eggs, 200 mg).

from normal eggs, but one normally major band corresponding to vitellogenin was lacking or at a trace level (Fig. 1). This was supported by staining for glycoprotein and lipid which are characteristic components of vitellogenin[1], and further by immunochemical assay (data not shown). Therefore, eggs from male hosts seem to differ from those produced in females chiefly in deficiency of vitellogenin.

To initiate embryogenesis in the eggs developed in male hosts, artificial parthenogenesis by a heat-shock treatment was carried out according to the method of Astaurov[13], who applied it to eggs from ovaries in females. The parthenogenetic development was easily detected in eggs by a reddish-brown pigmentation which reflected the formation of the serosal cells and entry into diapause (Fig. 2). The treatment induced parthenogenetic development in 63.1 ± 16.2% of the eggs from male hosts, and in 59.7 ± 0.8% of normal eggs from females. Thus, there was no appreciable difference in capacity for parthenogenetic response.

Because these eggs were programmed for diapause, diapause was then prevented artificially in the usual way by HCl treatment (Fig. 2). Embryonic development progressed and larvae of hatching size appeared in about 21.0 ± 4.2% of the coloured eggs 8 days after the HCl treatment. Hatching occurred in about 5.7 ± 2.7% of the parthenogenetic eggs, which is comparable with that in normal eggs from females[13]. The larvae appeared to be rather pale in colour but moved actively. When raised on fresh mulberry leaves, the larvae moulted to the second instar 4 days later, continued to grow succssfully and reached maturity to spin cocoons on day 25 at 25 °C.

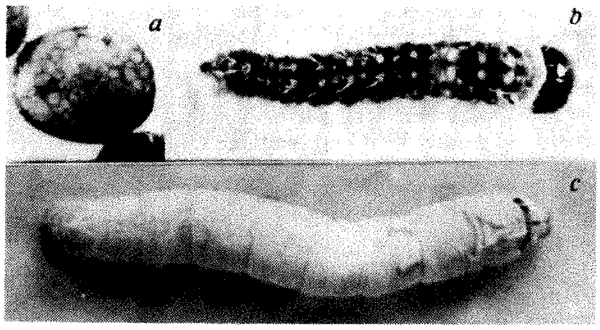

Fig. 2 Egg (*a*), newly hatched larva (*b*), and the fifth instar larva (*c*) from parthenogenetically activated eggs which had developed in male hosts. Ovaries dissected out from newly emerged males were immersed in water at 46 °C for 16 min and cooled abruptly in tap water for 10 min. After drying in air, the eggs were kept at 20 °C for 4 days to ensure parthenogenetic development[13]. The eggs with a reddish-brown colour were then soaked in HCl solution (specific gravity, 1.075 at 15 °C) at 47 °C for 3 min to prevent diapause[20]. They were kept at 25 °C and 75% relative humidity thereafter. After 12 days, larvae hatched and were raised on mulberry leaves. Egg and newly hatched larva, ×20; fifth instar larva, ×1.5.

We believe that the completion of embryogenesis and subsequent larval growth from the eggs that developed in male hosts is the first such case reported in insects as well as in other classes of animals. The results demonstrate that vitellogenin or vitellin is not essential for egg maturation and embryonic development. In addition, such a biological system should open a new field in reproductive and embryonic studies.

We thank Professor S. Kawase for his encouragement.

Adult newts regenerate functional limbs after amputation[1,2]. This process normally depends on the trophic influence of nerves on the regenerating limbs, particularly in the early stages before differentiation of the regeneration blastema[3], when it stimulates growth by maintaining high rates of macromolecular synthesis[4]. The sequence of biochemical events involved is unknown, but it has been suggested that intracellular cyclic AMP may be a second messenger within the blastema[5–10]. Many studies have indicated that the neural agent(s) involved might be protein[4,11–16]. The recent finding that blastemata contain high levels of catecholamines[17], however, has implicated noradrenaline (NA) as the neurotrophic agent, and suggested that it works via stimulation of β-adrenergic receptors on the blastemal cells, thereby raising the intracellular concentrations of cyclic AMP[10]. To test this hypothesis we studied the ability of NA alone and in combination with α-and β-adrenergic antagonists to increase cyclic AMP levels and to mimic the effects of nerves by maintaining high rates of protein synthesis[13,14] and high mitotic indices (MI)[15,16] in denervated blastemata in organ culture. We find that although NA raises cyclic AMP levels through a β-adrenergic effect, it does not maintain high rates of protein synthesis or high MI in cultured blastemata. It is unlikely therefore, that this hypothesis applies.

The rate of protein synthesis and the mitotic index in blastemata decrease after denervation[3,11]. Similar changes occur after blastemata are denervated and explanted into organ culture[13–16]. The addition of extracts of newt brains to the culture medium mimics the trophic effects of nerves by preventing these post-denervation decreases[13–16]. We cultured cone stage blastemata[18] from newts (*Notophthalmus viridescens*) in the presence of brain extracts, NA, and NA together with either an α- or β-adrenergic antagonists and determined the effects of these treatments on the cyclic AMP levels[10] rates of protein synthesis[13,14] and MI[15,16] in the blastemata. Histological examination revealed a normal, viable regenerate[16]. In confirmation of our previous findings, blastemata cultured in the presence of chick embryo or adult newt brain extracts had rates of protein synthesis and mitotic indices that were significantly greater than those in control blastemata cultured in their absence. In contrast to the effects of brain extracts on the blastemata, NA (at concentrations ranging from 10^{-6} to 10^{-4} M) did not elevate the MI and caused a small but significant decrease in the rates of protein synthesis below control values (Fig. 1). This indicates that, under the present experimental conditions, contrary to the hypothesis proposed by Taban *et al.*[10], it is unlikely that NA is an important neurotrophic agent since it does not mimic at least two important neurotrophic effects: maintenance of high rates of protein synthesis and high MI in the blastemata.

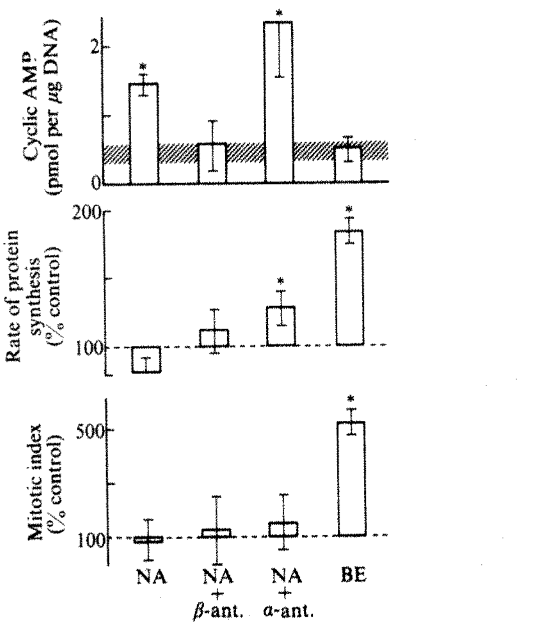

Fig. 1 Effects of NA, adrenergic antagonists and brain extracts on the cyclic AMP concentration, mitotic index, and protein synthesis of blastemata cultured *in vitro*. Cone stage blastemata were explanted and cultured as described previously[14–16]. Control cultures contained no addition to the medium; there were four treatment groups; NA = medium containing 10^{-4} M NA; NA + α-ANT = medium containing 10^{-4} M NA + either 10^{-4} M phenoxybenzamine or 10^{-4} M phentolamine; NA + β ANT = medium containing 10^{-4} M NA + 10^{-4} M propranolol; BE = medium containing an aqueous extract of adult newt brain (0.3 mg ml^{-1}) or embryonic chick brain (1.0 mg ml^{-1}) (refs 14–16). Blastemata were cultured in the presence of the various agents and the levels of cyclic AMP (at 10 min), rates of protein synthesis (at 12 h) and MI (at 24 h) were determined. At these time periods, the maximal effects of the treatments on various parameters occurred. Each value is the mean ± s.e.m. of six determinations. Cyclic AMP was determined using a radioimmunoassay[22] as modified by Harper and Brooker[23]. The rate of protein synthesis in the blastemata[14] and mitotic indices[15,16] were determined as described elsewhere. Differences in cyclic AMP concentrations, mean MI and rate of protein synthesis between experimental blastemata and controls from contralateral limbs were analysed for significance by the *t*-test for non-independent samples[24]. $^*P \leq 0.05$. The cross-hatched area on the cyclic AMP graph represents control values ± 1 s.e.m. The control values were as follows: MI = 0.64 ± 0.06% (s.e.m.). Rate of protein synthesis = 2.33 ± 0.05 (s.e.m.) pico atoms of carbon per g protein per 12 h. Cyclic AMP = 0.478 ± 0.06 (s.e.m.) pmol per μg DNA.

Unlike NA alone, NA in combination with the β-adrenergic antagonist propranolol had no effect on the rate of protein synthesis in the blastemata, or on their MI, both of which were the same as in control cultures (Fig. 1). Conversely, the addition to the cultures of NA plus either of the α-adrenergic antagonists, phenoxybenzamine or phentolamine, significantly increased the rate of protein synthesis in treated blastemata, while MI was unaffected. The increase in protein synthesis due to this β-adrenergic effect was far smaller however, than that produced by brain extracts (Fig. 1). This small increase in protein synthesis observed when the α-adrenergic effects of NA are inhibited, leaving only the β-adrenergic effects, is of particular interest. It is unlikely that the selective stimulation of β-adrenergic receptors is responsible for the neurotrophic effects on blastemata *in vivo* however, since there is no evidence that naturally occuring α-adrenergic antagonists exist. Furthermore, when the β-adrenergic effects of NA are blocked, protein synthesis in blastemata is not inhibited. It appears, therefore, that the inhibitory effects of NA on the rate of protein synthesis may be due to the combined simultaneous activation of α- and β-adrenergic receptors.

Although NA stimulated increases in cyclic AMP in cultured blastemata (and thus confirmed the report of Taban *et al.*[10]), it failed to stimulate increases in the rates of protein synthesis or

0028–0836/80/040387—02$01.00

mitosis, two neurotrophically regulated processes of the nerve-dependent growth phase of limb regeneration[3,11]. Previous studies have shown that the effects of brain extracts on protein synthesis and mitosis in cultured blastemata are similar to the effects of nerves on these processes *in vivo*[14,16]. Thus, the failure of NA to mimic the neurotrophic effects of brain extracts *in vitro* on these two processes would argue against this catecholamine as an important trophic effector during the early stages of regeneration. The possibility remains, however, that NA may play a significant role during the later nerve-independent stages of redifferentiation. Indeed, pharmacological studies on regeneration *in vivo* support such an hypothesis[7]; treatment with anti-adrenergic agents does not prevent blastema formation (a nerve-dependent process) but retards or represses subsequent morphogenesis (a nerve-independent process).

Additionally, crude brain extracts were ineffective in stimulating increased cyclic AMP levels in cultured blastemata. These results demonstrate that the elevation of intracellular cyclic AMP in blastemal cells is not invariably associated with increases in the rates of protein synthesis and mitosis in the blastemata. Consequently, the previously described stimulation of DNA and protein synthesis and mitosis by exogenous dibutyryl cyclic AMP[5,16,19] may be mediated through a different mechanism.

We have previously found that stimulation of α-adrenergic receptors increases cyclic GMP levels in newt tissues, and that β-adrenergic stimulation inhibits such increases[20]. It has been suggested that the ratio of cyclic AMP to cyclic GMP may play an important role in the response of tissue muscle to neurotrophic influences[10,21]. If true, this might explain the observed failure of NA to elevate protein synthesis and MI. This interpretation is not supported by observations of the effects of denervation on the levels of cyclic nucleotides in blastemata *in vivo* (M.P.R. Liversage and McLaughlin, unpublished observations); it appears likely that any alterations in cyclic AMP and cyclic GMP levels after denervation are not induced directly by the neurotrophic stimulus, but rather reflect a more general metabolic alteration in the blastemata that is part of the overall metabolic response associated with the increased growth stimulated by the neurotrophic influence.

Thus our findings are inconsistent with the hypothesis[10] that nerves transmit trophic information to blastemal cells via β-adrenergic receptor mediated stimulation of adenylate cyclase with subsequent production of cyclic AMP. Studies are currently in progress to determine the nature of the neurotrophic influence and to elucidate the molecular mechanisms involved in the response of blastemata to neurotrophic stimuli.

Cigarette smoke-induced DNA damage and lung cancer risks

J. M. Hopkin* & H. J. Evans

Medical Research Council, Clinical and Population Cytogenetics Unit, Western General Hospital, Edinburgh, UK

Epidemiological studies have firmly established that cigarette smoking causes almost all cases of anaplastic and squamous cell bronchial carcinomas[1]. It is equally well known, however, that many smokers do not develop lung cancer and, although the amount of tobacco smoked is undoubtedly the dominant risk factor, it seems possible that other factors may also be involved[2]. There is increasing evidence to support Boveri's[3] old hypothesis that somatic mutation is an important event in the development of cancer[4,5] and we have recently shown that cigarette smoke condensate (CSC) produces many dose-related lesions in the cellular DNA of cultured human lymphocytes as measured by sister chromatid exchange (SCE) induction[6]. Cytogenetic studies[7,8] had previously shown an increase in chromosomal aberrations in blood lymphocytes of heavy smokers relative to non-smokers, but little[9] or no[8,10] increase in SCEs. We have now measured basal and CSC-induced SCE rates in lymphocytes from different individuals and report that smokers have higher rates than non-smokers and that smokers with untreated lung cancer have consistently higher rates than their matched heavy smoking controls. These results are in keeping with the somatic mutational hypothesis and the epidemiological evidence, but also raise questions related to difficulties in smoking dosimetry and to possible variation among different individuals' responses to a common insult.

The responses of cultured lymphocytes from four groups of people to four doses of smoke condensate were examined by the visual scoring of induced SCEs. We used the same methods as in our original report[6] and, as before, samples were coded and scored 'blind'. Smoke condensate produced from a standard brand of British cigarette was dissolved in dimethylsulphoxide at serial dilutions and stored in small aliquots at −20 °C. This condensate, together with single stocks of culture medium and fetal calf serum, were used throughout the series. Four cultures, each of 10 ml and containing 0.8 ml of whole blood with an average of 10^6 lymphocytes, were set up from each individual. The four groups studied were: *A*, 10 healthy smokers, none of whom to our knowledge had been unduly exposed to any mutagen other than cigarette smoke. *B*, 10 healthy non-smokers who were examined in pairs matched for age and sex with members of group *A*. *C*, 12 patients with histologically proven but untreated non-disseminated anaplastic or squamous cell bronchial carcinomas, in whom diagnostic biopsies had been obtained by fibreoptic bronchoscopy under local anaesthetic. Ten of these patients were continuing to smoke at the time of testing (C_1), but two had stopped smoking 2 and 5 yr previously (C_2). *D*, 10 control patients with other disorders, but none with any form of cancer, who were on average 10 yr older and had smoked similar numbers of cigarettes per day, but for 10 yr longer, than our lung cancer patients. All individuals in groups *C* and *D* were inhaling smokers and smoked their cigarettes to comparable butt lengths. Only one individual had been exposed to a recognised occupational risk factor (asbestos). All were hospital inpatients, none of whom was acutely ill, and individuals from both groups had received similar exposure to X rays and drugs.

From our results, shown in Tables 1 and 2, it may be seen that cigarette smoke condensate (CSC) present in small quantities

---

‖ Mean (s.e.) ≥ 20 cigarettes per day.

¶ Mean (s.e.) < 20 cigarettes per day.

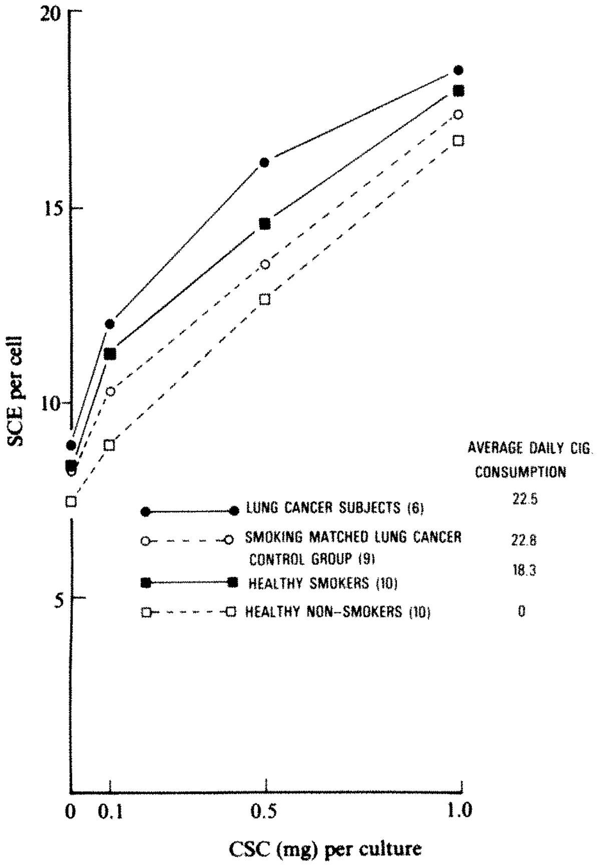

Fig. 1 Within group pooled mean SCEs (that is, the mean of individuals' means), at different dose levels of CSC, for the various groups.

produced dose-related increases in SCEs in lymphocytes from all individuals. Basal and induced SCE rates did, however, differ significantly among individuals.

Healthy smokers (*A*) had, relative to healthy non-smokers (*B*), higher mean basal and also higher induced SCE rates (following exposure to 0.1 mg of CSC, $P<0.05$) and the heaviest smokers had the highest SCE rates. A comparative study on cultured whole blood cells of two smokers and two non-smokers showed that these differences between smokers and non-smokers are maintained even in the absence of autologous plasma; we conclude, therefore, that the greater number of SCEs produced by condensate in smokers' cells in comparison with non-smokers must reflect some cellular alteration dependent on previous exposure to smoke *in vivo*.

For patients with lung cancer who were continuing to smoke (C_1), SCE rates were significantly higher at all levels of testing than for the smoking matched cancer controls (*D*). During final analysis, we found that there were more plain cigarette (middle or high tar) smokers at the time of testing in our lung cancer group than in the matched controls and this might have introduced a bias. However, exclusion of these plain cigarette smokers from both groups does not influence the result and smoking lung cancer subjects continue to have higher SCE rates at all levels of testing (0.1 or 0.5 mg of CSC, $P<0.01$). The two ex-smokers with lung cancer (C_2) had responses indistinguishable from those of healthy non-smokers, suggesting that high SCE rates are not secondary to the development of cancer. Furthermore, the overlapping of responses between the healthy smokers (*A*), the smoking matched non-cancer patients (*D*) and the smoking lung cancer patients (C_1), supports this conclusion.

Figure 1 presents mean basal and induced SCE frequencies for filter cigarette smokers in groups *A*, *C* and *D* (that is, smokers exposed to comparable levels of smoke *in vivo*) and for

non-smokers (*B*) and shows specifically that there is a consistent ordering of our four groups at all levels of testing. Superficially, the almost parallel dose–response curves in Fig. 1 might imply that the increased SCE rates following *in vitro* induction may simply emphasise *in vivo* differences, with similar increments being added for all four groups for each *in vitro* unit dose. This cannot be ruled out, but at lower CSC doses the relative response is not uniform between groups and more data would be needed to distinguish between these two possibilities. More important, however, is the fact that *in vitro* induction highlights the differences between the four groups. Highest responses were found for smokers with lung cancer (C_1). Among smokers, the lowest responses were found for the older heavy-smoking non-cancer patient group (*D*), and this is in keeping with our selection of these individuals as a 'relatively low risk' group. An unselected group of healthy and younger smokers (*A*) who might reasonably be expected to contain individuals of varying risk for lung cancer show a mean response intermediate between the lung cancer subjects (C_1) and their controls (*D*). This association of risk with extent of DNA damage supports the possibility that somatic mutation may be important in initiating malignant transformation in cells.

Although we have shown that cigarette smoking and the number and type of cigarette smoked significantly influence SCE rates, it is also clear that smokers seemingly exposed to similar amounts of cigarette smoke *in vivo* can have significantly different SCE rates (groups C_1 and *D*). These differences might simply result from discrepancies in actual amounts of tobacco smoked—certainly, all smoking histories describe only alleged amounts—or from varying patterns of inhalation or of airflow in the bronchial tree, both of which would clearly influence the dose of carcinogen delivered to bronchial mucosa and peripheral lymphocytes. Alternatively, if real smoke dosage *in vivo* was equivalent in both groups—and there is no way of determining this precisely—these differences might reflect the influence of other factors on the extent of measured DNA damage. In the context of Tokuhata and Lilienfield's[11] finding of significant familial aggregation of lung cancer not extending to spouses, it seems possible that some of these factors might be genetic and this would not be surprising for complex events resulting in DNA exchange, where presumably many enzymatic processes are involved, particularly in a species like man, where high rates of protein polymorphism are known to exist[12].

We thank the physicians and surgeons at the City Hospital for making their patients available for study, the Research Department of Imperial Tobacco Ltd for the loan of the smoking apparatus, and Mr A. Carothers for his help with statistical analysis.

Peptide-containing neurones connect the two ganglionated plexuses of the enteric nervous system

The enteric nervous system (ENS) of the mammalian gut consists principally of two ganglionated plexuses, the myenteric and submucous, which are embedded in the gut wall[1]. Little is known about the anatomical and functional connections between the two plexuses and further clarification of their relationship is of central importance for the understanding of the ENS. In the present study we have approached this problem in a new way, using methods we have previously developed for maintaining the myenteric and submucous plexuses separately *in vitro* for several weeks[2,3]. In an immunohistochemical study of these preparations and also of sections from normal and extrinsically denervated gut wall, we have found evidence for reciprocal projections between the myenteric and submucous plexuses, by nerve fibres containing two putative neurotransmitters, vasoactive intestinal polypeptide (VIP)[4] and substance P (ref. 5) (see Fig. 1). Our observations were supported by radioimmunoassay of tissue extracts. These results suggest that one of the roles of these peptides in the gut is to coordinate the function of the two enteric plexuses.

The normal distribution of VIP and substance P immunoreactivity in sections through the wall of the guinea pig caecum underneath and including the taenia coli is illustrated in Fig. 2. The VIP antiserum revealed a dense network of mostly varicose nerve fibres surrounding the ganglion cells of the myenteric plexus. Fibres were also frequent in the longitudinal and circular muscle, running parallel to the long axis of the muscle bundles, as well as in the ganglia of the submucous plexus. In the submucosa outside these ganglia and in the mucosa, VIP immunofluorescent fibres were present, but infrequent. Occasionally immunofluorescent nerve cell bodies were seen in the ganglia of the submucous plexus. The distribution and density of substance P immunoreactivity was similar to that of VIP, except that the density of substance P immunofluorescent fibres in the ganglia of the myenteric plexus was somewhat higher than that of VIP fibres. Substance P immunofluorescent fibres were not seen in the mucosa and no nerve cell bodies were detected with certainty.

It is recognised that neuronal perikarya of peptide-containing neurones are difficult to visualise, even if the axons to which they give rise contain demonstrable peptide stores[6,7]. To identify unambiguously the intrinsic source of the peptide-containing fibres we used our ability to immunostain tissue culture preparations of the myenteric and submucous plexus. The plexuses were removed from the gut wall and maintained separately *in vitro* for 1–2 weeks as described previously[2,3]. This enabled us to study peptide immunoreactivity in varicose axons which grow out from the neurones of each plexus during the culture period; these plexuses are free of axons extrinsic to the gut and also of those intrinsic axons, which *in situ* might run between them. Immunostaining of the cultures revealed that no VIP immunofluorescence could be detected in the myenteric plexus, whereas explants of submucous plexus contained numerous intensely fluorescent varicose fibres, which could often be traced for long distances in the outgrowth zone around the explants, as well as being observed among the neuronal cell bodies inside the explant (Fig. 3*a*). Conversely, substance P immunofluorescence was absent from the explants of the submucous plexus but was found in abundance in varicose fibres of the myenteric plexus cultures, both in the outgrowth zones and inside the explants (Fig. 3*b*). It is unlikely that our inability to observe VIP immunoreactivity in the myenteric plexus cultures is due to the failure of VIP-containing neurones to grow *in vitro*, or to technical difficulties in demonstrating VIP stores in nerve fibres in culture, because of the large numbers of VIP fluorescent fibres found in the cultures of the submucous plexus. The same argument applies to the absence of substance P immunoreactivity from the submucous plexus cultures. We therefore suggest that the guinea pig caecum contains intrinsic systems of both VIP-and substance P-containing neurones, the intrinsic VIP fibres originating exclusively from cell bodies located in the submucous plexus and the intrinsic substance P fibres emanating only from cell bodies in the myenteric plexus.

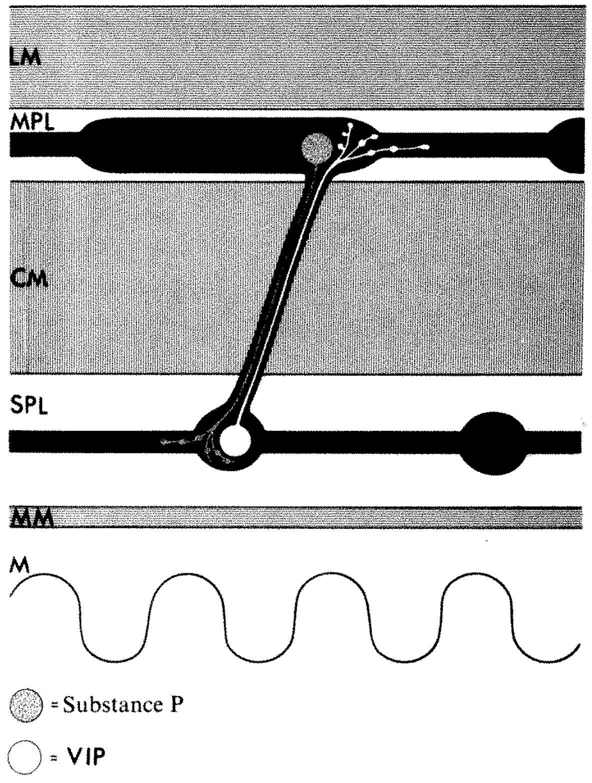

Fig. 1 Schematic drawing of a section through the wall of the caecum including the taenia, showing VIP- and substance P-containing neurones connecting the myenteric and submucous plexuses. LM, longitudinal muscle—this muscle layer constitutes the taenia coli. MPL, myenteric plexus—one whole ganglion and part of another are illustrated together with interconnecting strands. CM, circular muscle—the longitudinal and circular muscle layers are together referred to as the external muscle layer. SPL, submucous plexus—two ganglia and interconnecting strands are shown. MM, mucosal muscle. M, mucosa.

In the intact gut, however, we found VIP and substance P fibres densely surrounding cells in the myenteric and submucous plexuses respectively. There are two alternative explanations for these observations: (1) these fibres are extrinsic, originating from cell bodies outside the gut; or (2) the VIP fibres in the

0028–0836/80/040391—03$01.00

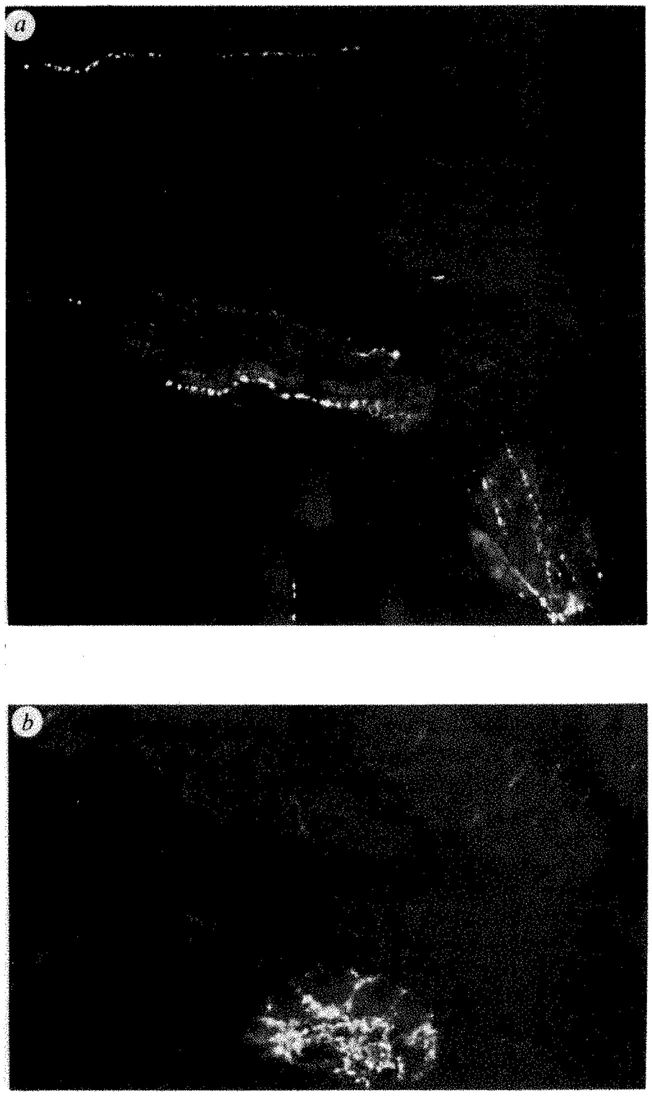

Fig. 2 Immunostaining of nerve fibres in sections from the caecum. *a*, VIP antiserum; *b*, substance P antiserum. In (*a*) immunoreactive beaded fibres can be seen among non-immunoreactive cell bodies in two ganglia of the myenteric plexus. A long beaded fibre is also visible in the longitudinal muscle above the ganglia and a short segment of a stained fibre can be seen associated with transversely cut bundles of the circular muscle below the ganglia (× 175). In (*b*) immunoreactive fibres can be seen surrounding non-reactive neuronal cell bodies in a ganglion of the submucous plexus. Above the plexus faint immunoreactivity can be seen in transversely cut fibres in the muscle bundles of the circular muscle layer (×250). Both VIP and substance P antibodies were raised in rabbits using purified porcine VIP or synthetic substance P coupled to bovine serum albumin by the carbodiimide method. The VIP antibody was directed to the C-terminal of the molecule and was used at a dilution of 1/400. The substance P antibody was directed to the whole molecule and was used at a dilution of 1/2,000. Neither antibody showed any significant cross-reactivity with other known neuropeptides. Staining was carried out by the indirect immunofluorescence method[14]. Tissue cultures or 10-μm thick cryostat sections of benzoquinone-fixed[15] specimens from the caecum were incubated with the peptide antibodies overnight at 4 °C. A second layer of fluorescent isothiocyanate conjugated anti-rabbit globulin was applied for 1 h at room temperature. In control experiments sections or cultures were incubated with nonimmune serum or VIP and substance P antisera which had been incubated with purified VIP or substance P respectively; no immunostaining was observed in these experiments.

myenteric plexus originate from the submucous plexus and the substance P fibres in the submucous plexus originate in the myenteric plexus. To distinguish between these possibilities we denervated the caecum of extrinsic nerve fibres by crushing the mesenteric nerves with fine forceps 3 weeks before killing, or, in some cases, by freezing them with a freeze probe. The effectiveness of the denervation was ascertained by noting the disappearance of the extrinsic adrenergic fibres from the gut wall (see ref. 8). No change in the amount or distribution of VIP or substance P immunofluorescent fibres was seen in the ganglia of the enteric plexuses in four experiments in spite of complete disappearance of adrenergic fibres. Furthermore, no significant change in VIP content, as measured by radioimmunoassay[9], was observed when denervated segments of gut wall underneath and including the taenia were compared to normally innervated segments from the same animal or from other control animals; the values for normal segments were 14.8 ± 4.2 pmol per g wet weight of tissue ($n = 6$) and for denervated segments 12.7 ± 4.3 pmol per g wet weight of tissue ($n = 4$). It is conceivable that nerve fibres may reach the caecum by running inside the gut

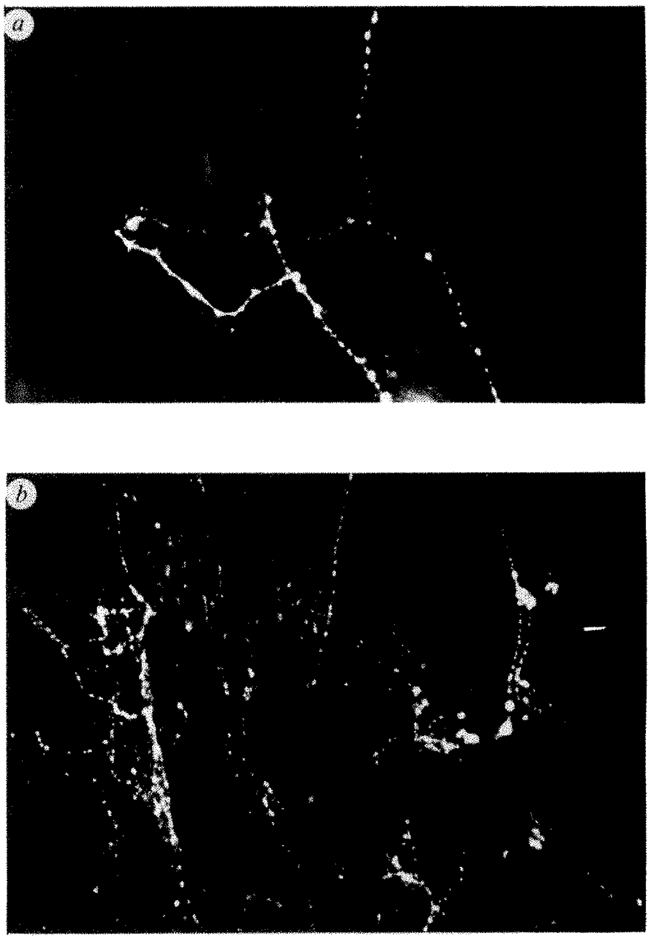

Fig. 3 Immunostaining of nerve fibres in tissue culture preparations of the enteric plexuses, *a*, VIP antiserum applied to a culture of the submucous plexus; intensely stained, apparently single, beaded nerve fibres, lying on top of non-immunoreactive, flattened, non-neuronal cells in the outgrowth zone of a culture which had been maintained for 7 days *in vitro* (×700). *b*, Substance P antiserum applied to a culture of the submucous plexus; several immunostained nerve fibres lie either apparently singly or in bundles in the outgrowth zone of a culture which has been maintained *in vitro* for 11 days. Under the nerve fibres lie flattened non-neuronal cells which show no immunoreactivity (×500).

wall, originating either from extrinsic nerves which enter the gut above or below the caecum or from the enteric plexuses of the small intestine or proximal colon, although the existence of such fibres has never been demonstrated. These fibres would not be affected by our denervation procedures. We therefore made a circumferential cut through the external muscle of the guinea pig caecum in the region just below the site of entry of the small intestine and proximal colon. The incision extended to the submucosa without penetrating it. In this way all nerve fibres which might reach the myenteric plexus of the caecum via the muscle layers or via the myenteric plexus were severed. The animal was killed 18 days later and sections from the caecum were immunostained, revealing VIP and substance P immunostaining which was identical both in distribution and density to that of normal material. Taken together these experiments demonstrate that the caecum receives no significant extrinsic innervation by VIP- or substance P-containing fibres.

We thus conclude that the submucous plexus of the caecum contains VIP neurones which provide most or all of the VIP innervation found in all layers of the intestinal wall in this area of the gut, including the dense network of fibres in ganglia of the myenteric plexus. In contrast, the substance P immunoreactive fibres of the gut wall, which are present in highest density in the ganglia of the myenteric and submucous plexuses, originate mostly or exclusively from the neurones located in the myenteric plexus. We have shown that in the caecum no VIP fibres originate from the myenteric plexus, and no substance P fibres emanate from the submucous plexus. This provides evidence for a VIP-containing pathway running from the submucous plexus to innervate neurones in the myenteric plexus as well as for a substance P-containing pathway providing innervation by the myenteric plexus of the submucous plexus as shown schematically in Fig. 1. A suggestion that there might be nerve connections between the two plexuses has been made previously on the basis of light microscopial findings[10], and has since received some support from physiological experiments[11]. Note, for comparison, that enkephalin immunofluorescent fibres do not span the two ganglionated plexuses but originate in the myenteric plexus and are confined to its ganglia and the external muscle layer[12,13]. A detailed account of the distribution of VIP, substance P and enkephalin neurones in the guinea pig small and large intestine is in preparation[13].

Although variations of the pattern described here may exist in other parts of the gut (for instance, some VIP-containing fibres originate from the myenteric plexus of the ascending colon and small intestine[13]) and in other species, these observations warrant pharmacological and physiological investigations into the possibility that one of the roles of VIP- and substance P-containing neurones in the gut is to provide functional connections between the two enteric plexuses.

We thank Dr G. Gabella for performing denervations with a freeze probe, Dr M. Costa for demonstrating denervation by crushing, and Ms Joan Woolveridge, Mr Stuart Waterman and Mr George Barrett for technical assistance. This work was supported by the Wellcome Trust and the MRC.

Substance P increases membrane conductance in parotid acinar cells

D. V. Gallacher* & O. H. Petersen†‡

* Glasgow Dental Hospital and School, 211 Renfrew Street, Glasgow, UK
† Department of Physiology, The University, Dundee, UK

Substance P, a naturally occurring polypeptide of mammalian origin[1], has been implicated both as a neurotransmitter and a neurohormone[2]. However, little is known of the ionic mechanisms underlying the postsynaptic response to substance P. In myenteric neurones Katayama and North[3] reported substance P-evoked depolarisations (of varying latency) associated, surprisingly, with a decrease in membrane conductance. A direct measurement of reversal potential in normal ionic conditions was not achieved but it was suggested that substance P acts by reducing membrane potassium conductance. In contrast, work on salivary glands suggests that substance P evokes an increase in potassium conductance[4,5]; however, electrophysiological work has not been carried out to verify this. We report here that substance P evokes a marked increase in rat parotid acinar cell membrane conductance associated with a potential change (latency 1.7 s) that reverses at about −65 mV. The reversal potential for substance P is shown to be identical to that obtained in the same cells for acetylcholine (ACh) and adrenaline. The identical membrane action of ACh, adrenaline and substance P, mediated by three separate receptor sites, suggests activation of a common effector mechanism.

Isolated segments of rat parotid gland were mounted in a tissue bath through which oxygenated physiological saline solutions were circulated at 37 °C. Single microelectrodes were used to record both membrane potential and input resistance of surface acinar cells[6]. Substance P (Peninsula Lab.) was applied both by iontophoresis[7,8] and by addition to superfusion media. The iontophoretic application of ACh and adrenaline has been described previously[9].

The mean resting membrane potential was -73.3 ± 0.8 mV ($\pm$s.e.m., $n = 62$) and the mean input resistance of the unstimulated cell was 4.8 ± 0.3 MΩ ($\pm$s.e.m., $n = 38$). Responses to iontophoresis of substance P were recorded in 42 cells from six rats. In 21 of these cells, responses to iontophoresis of ACh were also recorded, and in 12 responses to iontophoresis of three agonists, substance P, ACh and adrenaline, were recorded. Figure 1 shows the similar nature of the responses to the three stimuli in a single cell. Each agonist evokes a marked decrease in input resistance associated with an initial depolarisation. This depolarisation is followed by a delayed hyperpolarisation during which the input resistance returns to the resting level. At less negative resting membrane potentials the initial potential change becomes a hyperpolarisation, but in any one cell the responses to all three stimuli are the same. Such biphasic potential changes have been reported previously in response to iontophoresis of the two autonomic agonists[9]. Only the substance P response was resistant to autonomic blockade by a combination of atropine (10^{-6} M), phentolamine (10^{-5} M) and propranolol (5×10^{-6} M). Responses were recorded in 11 cells and in the presence of all three blockers.

Figure 2 demonstrates the marked reduction in input resistance induced by substance P even in the presence of autonomic blockade. Although there was no detectable change in either the magnitude or duration of the substance P response on introduction of the blockers, the latency of the response was affected. In the control solution the latency of the response was 608 ± 122 ms (mean$\pm$s.e.m. $n = 6$). On introduction of the blockers this latency became $1{,}737 \pm 165$ ms (mean$\pm$s.e.m., $n = 4$),

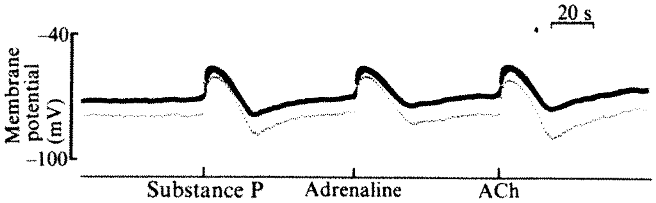

Fig. 1 Recording of membrane potential and input resistance from acinar cell of rat parotid. Responses are seen to iontophoretic application of substance P, adrenaline and ACh. The substance P micropipette contained 3.5 mM of peptide in 20 mM acetic acid (*p*H 5–7). The ejection current was 200 nA applied for 500 ms. Responses were recorded to ejection charges as low as 10 nC. Iontophoresis of a control solution (20 mM sodium acetate acidified to *p*H 5.7) never evoked any response. Adrenaline iontophoresis was achieved at 500 nA for 200 ms; ACh at 100 nA for 1 s. Hyperpolarising current pulses (2 nA, 100 ms) were repetitively injected through the recording microelectrode to obtain input resistance.

suggesting that in the absence of blockade an indirect effect of substance P is manifested at least as a shortened latency. The latency of the direct effects is nevertheless one of the shortest so far recorded for iontophoresis of substance P, variable latencies of between 1 and 30 s having been reported previously[3,7].

Responses could also be evoked by inclusion of substance P in the superfusion media in concentrations of 10^{-7} to 10^{-9} M. Changing the superfusion medium to one containing the drug induced a marked decrease in input resistance, this time associated with a slow monophasic hyperpolarisation. Such responses were obtained in nine cells from eight rats. In five experiments the superfusion medium also contained all three autonomic blockers.

Application of substance P (15 nmol) directly to the tissue bath as a single-shot injection (0.1 ml) evoked responses resembling those induced by iontophoresis. The similar, even repetitive, application of either of two other active polypeptides caerulein or bombesin (0.1 ml containing 1.5 pmol and 3.0 pmol, respectively) failed to evoke a response in any of 12 cells from five preparations. These concentrations are known to be effective in evoking responses from pancreatic acinar cells[10]. This demonstrates that the peptide receptor is not accessible to all active polypeptides and is in agreement with the previous finding[11] that these gastrointestinal hormones cannot evoke salivary secretion.

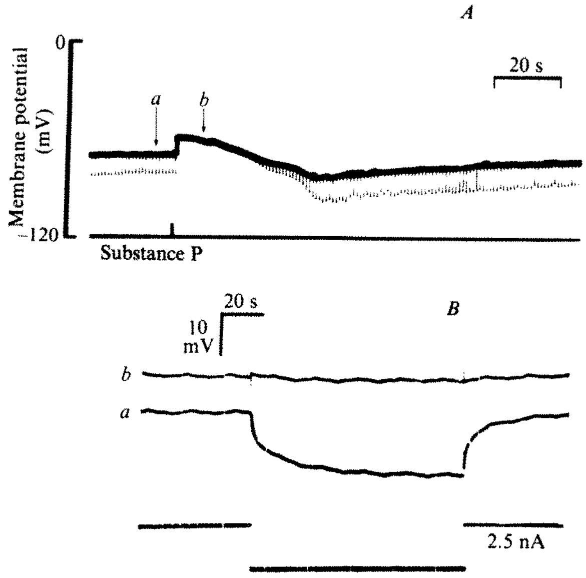

Fig. 2 Substance P response in the presence of full autonomic blockade; that is atropine (10^{-6} M), phentolamine (10^{-5} M) and propranolol (5×10^{-6} M). *a*, Response to iontophoresis of substance P (200 nA for 500 ms); *b*, oscilloscope picture showing amplitudes of the electrotonic potential changes due to injection of current pulses (2.5 nA hyperpolarising, 100 ms) at times *a* and *b* indicated in trace *A*. This demonstrates the marked reduction in input resistance at point *b* as a consequence of the iontophoretic application of substance P. This decrease in input resistance is not due to rectification as the current–voltage relationship of these cells is linear as previously shown in mouse parotid[9].

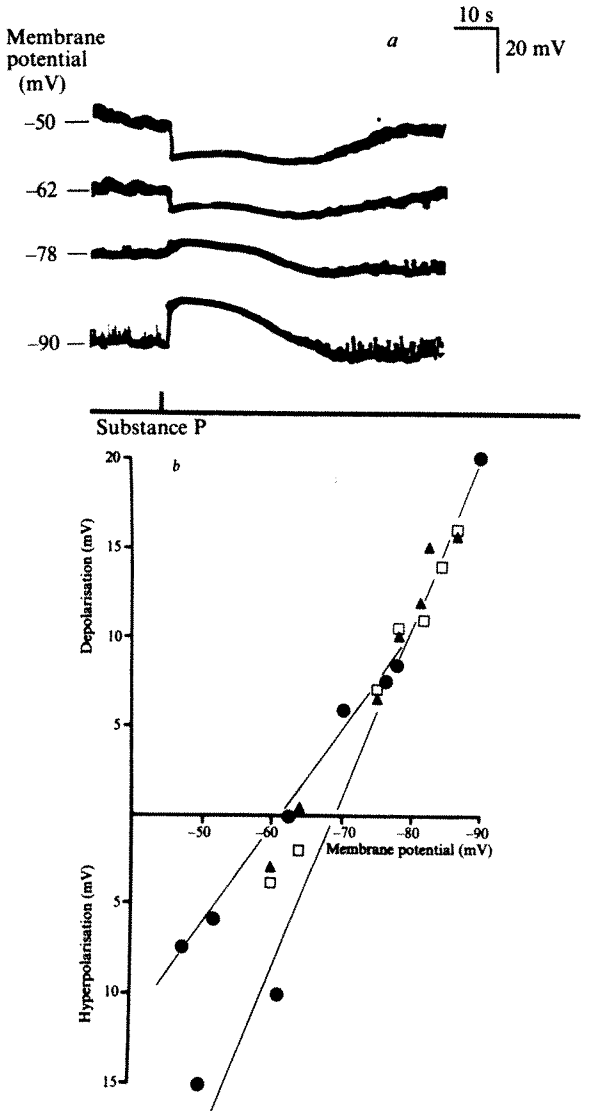

Fig. 3 *a*, Family of traces showing the nature of the substance P response at different levels of membrane potential in the same cell. The membrane potential is varied by applying direct current through the recording electrode. The superfusion medium contained all three autonomic blockers. The response changed from a depolarisation to a hyperpolarisation (reversal) as the membrane potential became less negative. In *b* the amplitudes of substance P responses are plotted as a function of membrane potential (●). Two plots are shown for substance P responses from different preparations and these are compared with plots of ACh (▲) and adrenaline (☐) responses in a third preparation. The reversal potentials of the responses, the intersection with the abscissa, for all three stimuli are between −60 and −70 mV. (Substance P, 100 nA for 1s; ACh, 100 nA for 1s; adrenaline 500 nA for 1 s.)

The reversal potential of the substance P response was determined by two methods. Trautwein and Dudel[12] describe how the 'transmitter equilibrium potential' can be determined by analysis of the changes in both membrane potential and input resistance induced by an agonist. This analysis was carried out for 58 responses to substance P, 35 responses to ACh and 17 responses to adrenaline. The mean reversal potentials were: substance P, −64.4 ± 0.9 mV (±s.e.m.); ACh, −64.5 ± 1.3 mV (±s.e.m.); adrenaline −65.7 ± 2.2 mV (±s.e.m.). The values of the reversal potential for substance P and adrenaline had not been previously determined, but the ACh reversal potential is in very close agreement with the value of −63 mV previously reported[13].

Figure 3 demonstrates the second method used. The amplitude of the responses from a single cell is recorded at different levels of membrane potential. The amplitude of the response is then plotted as a function of membrane potential and the intersection with the abscissa represents the reversal potential. Figure 3*b* shows two plots of responses to substance P and compares them with responses to ACh and adrenaline. Responses to all three stimuli undergo reversal between −60 and −68 mV. Thus both methods of estimating reversal potential give comparable values and illustrate that the reversal potentials for all three stimuli are the same, that is about −65 mV.

Our observations reveal that in a salivary gland substance P evokes changes in membrane potential and input resistance which are resistant to autonomic blockade, probably due to direct activation of a peptide receptor. A degree of specificity of the peptide receptor is indicated by the inability of two other active polypeptides, caerulein and bombesin, to evoke any response. The ionic mechanisms underlying the acetylcholine response has been extensively investigated[13]. The demonstration that substance P and adrenaline share the same reversal potential strongly suggests that responses to the three stimuli, although mediated by separate receptors, are the consequence of activation of the same effector mechanism primarily an increased potassium and sodium conductance.

Dual action of ototoxic antibiotics on sensory hair cells

Alfons B. A. Kroese & Joep van den Bercken

Institute of Veterinary Pharmacology and Toxicology, University of Utrecht, Biltstraat 172, 3572 BP Utrecht, The Netherlands

All aminoglycoside antibiotics in clinical use are ototoxic in that they can cause permanent malfunctioning of the cochlea and vestibule[1–3]. It is generally assumed that these ototoxic antibiotics primarily affect the sensory hair cells in the inner ear and that degeneration of secretory and neural elements comes later[2–5]. Most experimental work on aminoglycoside antibiotic ototoxicity has concentrated on the irreversible effects on inner ear functioning and hair cell morphology[2,3]. Little is known about their mode of action on the hair cells. Interference with hair cell protein synthesis, in analogy with the antimicrobial mechanism, has been ruled out as the primary cause of the high selective[6] toxicity of the aminoglycosides[3,5]. Recent evidence indicates that these antibiotics may interfere with membrane phospholipid metabolism[7]. Morphological studies have demonstrated that early on in the ototoxic process the membrane of the sensory hairs is already damaged[4]. The aminoglycoside antibiotics are reported to have a direct and reversible[8,9] effect on hair cell functioning in organs of the acoustico-lateralis system of lower vertebrates[8–11]. Hence, the primary site of action is probably the hair cell membrane. We have now therefore examined reversible effects of ototoxic antibiotics on single fibre afferent nerve activity and extracellular receptor potentials in the lateral-line organ of *Xenopus laevis.* Our results show that the antibiotics, in concentrations similar to those measured in the cochlear fluids[3], have a dual action on the hair cells. They not only increase the spontaneous afferent nerve activity, probably by an effect on the hair cell membrane, but also severely impair the mechano-electric transduction process, resulting in a large phase lag of the receptor potentials. The latter effect, which is antagonised by Ca^{2+}, may be due to interference of the antibiotics with the mechanical properties of the sensory hairs.

The experiments were carried out on isolated preparations of the lateral-line organ of the clawed frog, *X. laevis.* The organ was stimulated by small-amplitude sinusoidal water movements. Activity of single afferent nerve fibres was computed in period histograms, from which gain and phase were determined as previously described[12]. Amplitude and phase of extracellular receptor potentials were measured as described elsewhere[13]. The effects of the antibiotics were constant within 5 min of application and for concentrations up to 25 μg ml^{-1} were reversible.

Figure 1*a* shows that dihydrostreptomycin in concentrations between 2.5 and 17.5 μg ml^{-1} enhanced spontaneous afferent nerve activity. An increase in spontaneous afferent activity has recently been predicted by Gallais *et al.*[11] from behavioural observations on frogs injected in one ear with streptomycin. It is tempting to conclude that the transient symptom of tinnitus,

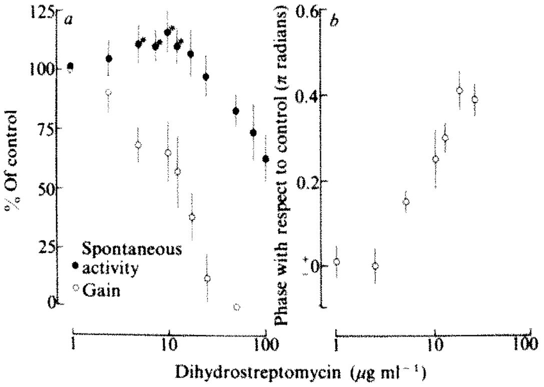

Fig. 1 Effect of different concentrations of dihydrostreptomycin (K & K Laboratories) on spontaneous afferent activity (*a*), and on gain (*a*) and phase (*b*) of the afferent nerve response to stimulation of the lateral-line organ of *Xenopus laevis.* A piece of skin containing several lateral-line organs was placed in an experimental chamber. The inner side of the skin was in contact with Ringer's solution, the outside was covered with tap water, which was replaced every 15 min. Temperature was 18 °C. Each 15-min period with tap water was followed by a 15-min period with fresh tap water to which the antibiotic had been added. Controls were taken before and after each period in which the antibiotic was applied. Stable control values could be obtained from the preparations for a period of more than 2 h. At 7 and 12 min, respectively, after each replacement of the tap water, the lateral-line organ was stimulated for 30–70 s with local, sinusoidal water movements (20 Hz) induced by a small glass sphere. Period histograms of single fibre afferent nerve activity were computed and analysed by means of Fourier analysis. The gain was expressed as per cent modulation of mean afferent activity per μm sphere displacement. The phase of the response was measured with respect to sphere displacement and expressed in radians. Spontaneous activity was measured before each stimulation over 1,000 intervals as the mean number of impulses per s. Further details of recording, stimulation and data analysis can be found elsewhere[12]. The values for spontaneous activity and gain obtained in the presence of dihydrostreptomycin were expressed as a percentage of control. The phase of the response in the presence of dihydrostreptomycin was expressed as phase shift with respect to control. Spontaneous activity was measured in 31 preparations; each point represents the mean ±s.d. of 10 measurements. Gain and phase were measured in 12 preparations; each point represents the mean ±s.d. of six measurements. Asterisk denotes spontaneous activity significantly higher than control (Student's *t*-test; $P < 0.05$)

0028-0836/80/040395—03$01.00

which is known to occur soon after administration of ototoxic antibiotics[1], is due to an increase in spontaneous afferent activity of the auditory nerve fibres. Additional experiments showed that blocking of the cholinergic efferent synapse[14] by curare or atropine (5×10^{-5} M) did not prevent the increase in spontaneous activity induced by 10 μg ml^{-1} dihydrostreptomycin. Thus, it is unlikely that the increase in spontaneous activity was brought about by an effect of the antibiotics on the efferent synapse[15]. Apparently, the antibiotics act directly on the hair cell membrane and cause an increase in spontaneous transmitter release[16] from the hair cells.

With higher concentrations of dihydrostreptomycin (>17.5 μg ml^{-1}), spontaneous activity was depressed (Fig. 1*a*). Depression of afferent activity by aminoglycoside antibiotics has been demonstrated previously in the mammalian cochlea[2,3] and in the semicircular canal organ of the frog[9,11]. This effect is consistent with other known effects of high concentrations of aminoglycoside antibiotics, that is, the inhibition of transmitter release[17,18] and postsynaptic blockade[19,16] in the neuromuscular junction, and interference with action potential generation in frog myelinated nerve[20].

The afferent nerve response to stimulation at 20 Hz was markedly depressed by dihydrostreptomycin (Fig. 1*a*). The gain decreased gradually with increasing concentration of the antibiotic and 50 μg ml^{-1} abolished response to stimulation. In addition, dihydrostreptomycin caused a progressive phase lag in the afferent nerve response up to a value of 0.4 π radians at 25 μg ml^{-1} (Fig. 1*b*). Figure 1 clearly illustrates the dual action of dihydrostreptomycin: low concentrations increased the spontaneous activity, but at the same time impaired the mechanical sensitivity.

Other aminoglycoside antibiotics produced a similar dual effect. Streptomycin was about as effective as dihydrostreptomycin (maximum increase in spontaneous activity at 7.5 and 10 μg ml^{-1}, respectively), whereas gentamycin was somewhat less effective (maximum increase at 17.5 μg ml^{-1}). Detailed results will be published elsewhere.

Figure 2 shows that dihydrostreptomycin induced a decrease in amplitude and a phase lag of the receptor potentials almost identical to that measured in the afferent nerve response. A similar phase lag of the receptor potentials was observed at 1 and 5 Hz. The similarity between the effects of dihydrostreptomycin on the afferent nerve response and on receptor potentials demonstrates that the antibiotics primarily affect the hair cells and not the afferent nerve fibres. Further, the antibiotics did not affect the sinusoidal shape of the afferent nerve response[12] or the characteristic dead time in the spontaneous activity.

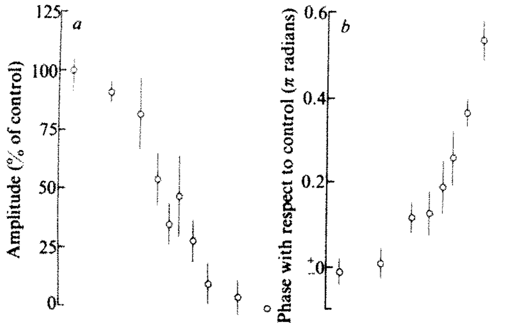

Fig. 2 Effect of different concentrations of dihydrostreptomycin on amplitude (*a*) and phase (*b*) of extracellular receptor potentials recorded from the sensory hair cells in one neuromast of the lateral-line organ of *Xenopus laevis*. Temperature was 22 °C. Preparation and application of the antibiotic were as described in Fig. 1 legend. At 7, 10 and 13 min, respectively, after each tap water replacement, the neuromast was stimulated for 60 s with short sequences of sinusoidal water movements (20 Hz; 8 periods per sequence). Extracellular receptor potentials were recorded by means of Pt–Ir microelectrodes. The response to 30 stimulus sequences was digitised, averaged and plotted. Amplitude and phase with respect to sphere displacement of the extracellular receptor potentials were computed by means of Fourier analysis of the averaged response. Details of recording, stimulation and data analysis can be found elsewhere[13]. Values for amplitude and phase of the response obtained in the presence of dihydrostreptomycin were expressed, respectively, as a percentage of control and as phase shift with respect to control (radians). Results were obtained from nine preparations; each point represents the mean ±s.d. of six measurements.

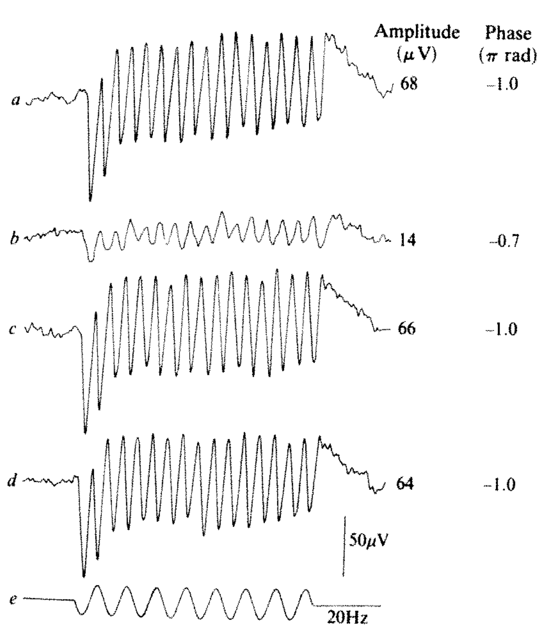

Fig. 3 Prevention of the effect of dihydrostreptomycin on extracellular receptor potentials from the lateral-line organ of *Xenopus laevis* by 5 mM $CaCl_2$. Preparation and application of the antibiotic were as described in Fig. 1 legend. At 13 min after each tap water replacement, the neuromast was stimulated for 60 s with short sequences of sinusoidal water movements (20 Hz; eight periods per sequence) induced by a small glass sphere. Each trace is the averaged response to 30 stimulus sequences. The lowest trace (*e*) denotes the displacement of the glass sphere. *a*, Control; *b*, during application of 17.5 μg ml^{-1} dihydrostreptomycin; *c*, during application of 17.5 μg ml^{-1} dihydrostreptomycin and 5 mM $CaCl_2$; *d*, control. The control recording between *b* and *c* has been omitted. Amplitude and phase with respect to sphere displacement were computed by means of Fourier analysis of the averaged response. To exclude any transient effects, the first two stimulus periods of the averaged response were discarded. Values for amplitude (μV) and phase (radians) are shown on the right side of each trace. Details of recording, stimulation and data analysis can be found elsewhere[13]. The normal Ca^{2+} concentration in the tap water was about 1 mM. Addition of 5 mM $CaCl_2$ alone had no noticeable effect on the receptor potentials.

Aminoglycoside antibiotics are known to interfere with Ca^{2+}-dependent membrane phenomena[7,17,21]. In the present study, the effects of dihydrostreptomycin on receptor potentials were fully prevented by 5 mM $CaCl_2$ (Fig. 3). There is evidence that Ca^{2+} ions are essential for hair cell transduction[22,23], although their precise role remains unclear[23,24]. It has been suggested that Ca^{2+} modulates the permeability of the hair cell membrane to K^+ ions[24], which are thought to carry the receptor current[24,25]. However, the time delay corresponding to the phase lag, particularly at low stimulus frequencies, is too large to be accounted for by an effect on the conductance mechanism underlying the receptor current.

A possible explanation for such a large phase lag is that the antibiotics alter the mechanical properties of the sensory hair bundle. Aminoglycoside antibiotics can cause sensory hair fusion and it has been postulated that they reduce the fixed negative charge on the sensory hair membrane, thereby diminishing the electrostatic repulsion between the hairs[4,26]. The effects reported here were easily reversible, which implies that we have studied an early stage in the ototoxic process. It is conceivable that before sensory hair fusion the antibiotics increase the coupling between the sensory hairs, resulting in a reduced mobility of the hair bundle. An alternative hypothesis is that the antibiotics affect the stiffness of the individual hairs, which depends on their fibrillar core, rather than on their membrane[26]. As the filaments in the core are composed of actin[27], it can be speculated that the antibiotics alter their mechanical properties by interfering with Ca^{2+}. Further work on the action of aminoglycoside antibiotics may lead to a better understanding of the role of Ca^{2+} in the transduction process.

Hypolipidaemic hepatic peroxisome proliferators form a novel class of chemical carcinogens

J. K. Reddy & D. L. Azarnoff

Department of Pathology, Northwestern University Medical School,
303 East Chicago Avenue, Chicago, Illinois 60611

C. E. Hignite

Research Division, Veterans Administration Hospital,
Kansas City, Missouri 64128

Several drugs, including clofibrate (ethyl-*α*-*p*-chlorophenoxyisobutyrate)[1], are now available for the treatment of hyperlipidaemias[2,3] and others are in the process of preclinical or clinical evaluation[4,5]. Clofibrate, the most widely used hypolipidaemic drug in Europe and the US[2], as well as other potent hypolipidaemic agents, cause massive hepatomegaly when administered to rats[6–8], mice[7,8] or hamsters (J.K.R., unpublished). This hepatomegaly is characteristically associated with a marked increase of peroxisomes (Fig. 1) in the liver cells of all three species[6–8]. These ubiquitous cytoplasmic organelles[9,10] contain catalase, several hydrogen peroxide-generating oxidases, carnitine acetyltransferase[11] as well as enzymes involved in the *β*-oxidation of long-chain fatty acids[12]. The activities of these enzymes in liver are elevated in association with peroxisome proliferation[8,13]. As hepatomegaly and peroxisome proliferation persist for as long as these drugs are administered to the animals, we initiated chronic toxicity studies with selected hepatic peroxisome proliferators in CS^{b} mice and F344 rats. Liver tumours were observed in both rats and mice fed nafenopin (2-methyl-2[*p*-(1,2,3,4-tetrahydro-1-naphthyl)phenoxy]-propionic acid)[14–16] or Wy-14,643 ([4-chloro-6-(2,3-xylidino)-2-pyrimidinylthio]acetic acid)[17], two structurally unrelated compounds (Fig. 2, compounds 2 and 3) which are several times more potent than clofibrate in inducing peroxisome proliferation and hypolipidaemia[8]. Recent evidence indicates that clofibrate (Fig. 2, compound 1) is also carcinogenic when fed to rats at a concentration of 0.5% in the diet[18,19]. We report here that BR-931 ([4-chloro-6-(2,3-xylidino)-2-pyrimidinylthio(*N*-*β*-hydroxyethyl)-acetamide])[20] and tibric acid (2-chloro-5-(3,5-dimethylpiperidinosulphonyl)benzoic acid)[8], two potent hypolipidaemic hepatic peroxisome proliferators (Fig. 2, compounds 4 and 5) induce hepatocellular carcinomas in CS^{b} mice and/or F344 rats. Thus, the development of liver tumours, in animals fed five structually diverse hypolipidaemic compounds (Fig. 2) supports our hypothesis that potent hepatic peroxisome proliferators as a class are carcinogenic.

The cumulative data in Table 1 indicate that BR-931 given at 0.2% dietary level caused a significant increase in the incidence of liver tumours in female CS^{b} mice and male F344 rats. The tumours were multiple and measured 0.5–3.5 cm in diameter. Histologically, these tumours were hepatocellular carcinomas, some of which metastasised to the lungs. BR-931 at 0.05% level induced tumours in 7 of 10 rats; there were few tumours per liver when compared with the liver tumour load in rats fed the higher dose. Tibric acid treatment of rats as outlined in Table 1 also resulted in a significant increase in the incidence of hepatocellular carcinomas. No liver tumours were encountered in the control groups of mice or rats. The ultrastructural appearance of BR-931- and tibric acid-induced hepatocellular carcinomas in rats and mice was characterised by the presence of many peroxisomes in tumour cells, as noted previously in liver tumours induced by nafenopin[14] or Wy-14,643 (ref. 17).

Table 1 Cumulative data on liver tumour incidence in female CS^{b} mice and/or male F344 rats fed hypolipidaemic hepatic peroxisome proliferator BR-931 or tibric acid

Group	Sex	Treatment	No. of animals Initial	No. of animals Effective*	No. of animals with liver tumours (%)	
CS^{b} mice	F	BR-931 (0.2% for 19 months)	15	12	11†	(92)
CS^{b} mice	F	—	15	15	0	(0)
F344 rats	M	BR-931 (0.2% for 16 months)	20	20	20‡	(100)
F344 rats	M	BR-931 (0.05% for 19 months)	10	10	7†	(70)
F344 rats	M	Tibric acid (0.2% for 7.5 months, 0.1% for 4 months and 0.05% for 5 months: total 16.5 months)	35	31	30‡	(97)
F344 rats	M	—	30	30	—	(0)

CS^{b} mice (4–6 weeks of age) derived from a colony maintained in our laboratory (JKR) and F344 rats (weighing 60–90 g) obtained from ARS, Sprague-Dawley, were used. The hypolipidaemic drugs BR-931 (LPB Istituto Farmaceutico) and tibric acid (Pfizer) were added to powdered chow at the concentrations (w/w) shown and fed *ad libitum*. Autopsies were carried out on dead or moribund animals. All surviving animals at the end of the treatment periods shown were killed under light ether anaesthesia.

* The effective number of animals was the number of survivors at the time the first tumour was observed.

† P (one-sided) < 0.001 when compared with the controls by Fisher's exact test.

‡ $P < 0.001$ when compared with the controls by χ^2 test corrected for continuity.

0028-0836/80/040397—02$01.00

There was a significant increase in carnitine acetyltransferase activity in the tumours and normal portions of tumour-bearing livers in the BR-931 fed rats, but as expected[18], the activity of peroxisomal marker enzyme catalase was not elevated (data not shown). Similar enzyme changes were previously observed in liver tumours induced by the peroxisome proliferator Wy-14,643 (ref. 17).

These experiments form part of an investigation to test the hypothesis that hypolipidaemic drugs capable of inducing hepatic peroxisome proliferation are carcinogenic. The experiments reported here with BR-931 and tibric acid and previous studies with nafenopin[14,16], Wy-14,643 (ref. 17) and clofibrate[18,19] strongly favour this hypothesis, which can be tested further experimentally because of the availability of several other potent hypolipidaemic agents possessing hepatomegalic and peroxisome proliferative properties. This group comprises structurally diverse chemicals which share unique biological properties, including the ability to induce marked hepatomegaly, hepatic peroxisome proliferation and hypolipidaemia.

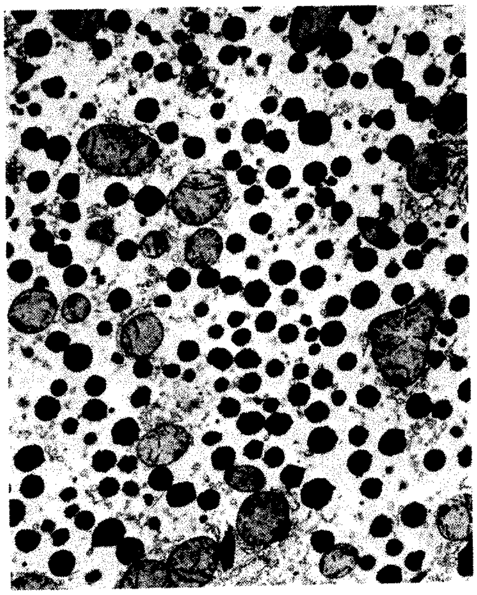

Fig. 1 Treatment with hypolipidaemic drugs causes proliferation of peroxisomes in liver parenchymal cells of rats, mice and hamsters. Many peroxisomes (electron dense bodies) are present in this electron micrograph, which represents a portion of a liver cell of a male rat fed a hypolipidaemic drug at a dietary concentration of 0.1% (w/w) for 4 weeks. The hepatomegaly and peroxisome proliferation persist for as long as the drug is administered. The hypothesis that chemicals capable of inducing hepatic peroxisome proliferation are carcinogenic is supported by the observation that five structurally diverse peroxisome proliferators are carcinogenic in mice and or rats.

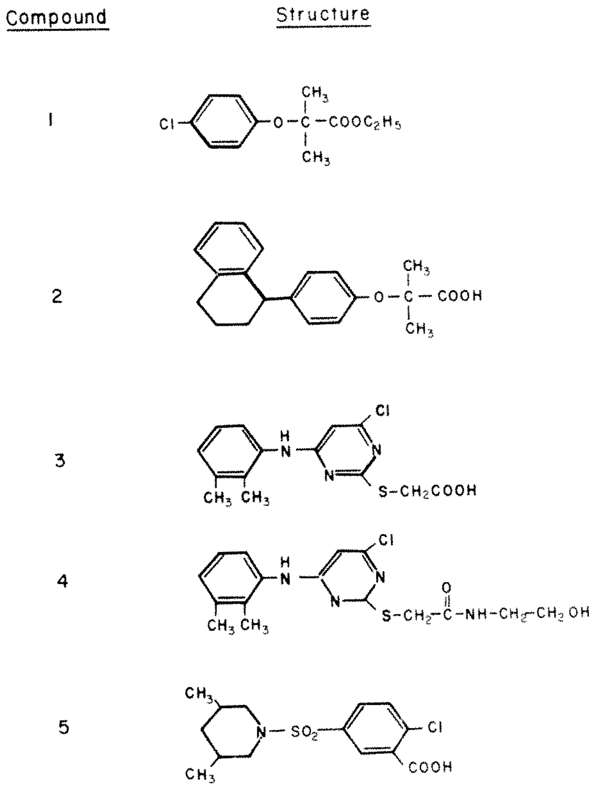

Fig. 2 Chemical structures of selected hypolipidaemic hepatic peroxisome proliferators tested for carcinogenicity. Compound 1: ethyl-α-p-chlorophenoxyisobutyrate (clofibrate, Atromid-S); Compound 2: 2-methyl-2-[p-(1,2,3,4-tetrahydro-1-naphthyl)-phenoxy]propionic acid (nafenopin); Compound 3: [4-chloro-6-(2,3-xylidino)2-pyrimidinylthio]acetic acid (Wy-14,643); Compound 4: [4-chloro-6-(2,3-xylidino)-2-pyrimidinylthio(*N*-*B*-hydroxyethyl)-acetamide] (BR-931); Compound 5: 2-chloro-5-(3,5-dimethylpiperidinosulphonyl)benzoic acid (tibric acid). All these compounds induced a significantly high incidence of hepatocellular carcinomas in mice and/or rats.

For these reasons, the hepatic peroxisome proliferators may be considered as a unique class of chemical carcinogens. Furthermore, unlike most known chemical carcinogens which inhibit DNA synthesis[21], the carcinogenic hepatic peroxisome proliferators identified thus far seem to stimulate DNA synthesis and cell division in intact liver without causing any antecedent necrosis[8,17,20]. Finally, none of these compounds caused detectable mutagenic activity in the *Salmonella*/microsome assay, or produced DNA damage in the lymphocyte ^{3}H-thymidine incorporation assay[22]. The mechanism by which these drugs induce liver tumours and the role, if any, of peroxisomal enzymes in, for example, excessive production and/or breakdown of H_2O_2 (ref. 17) or hypolipidaemia, and in the initiation of carcinogenesis such as that invoked for lysosomal DNase in inducing chromosomal aberrations[23], remain to be examined. Whatever the mechanism(s) involved, the morphological finding of hepatic peroxisome proliferation seems a good indication for selecting a potential hypolipidaemic chemical for long-term carcinogenicity testing.

Viroid synthesis: the question of inhibition by actinomycin D

L. K. Grill & J. S. Semancik

Department of Plant Pathology and Cell Interaction Research Group, University of California, Riverside, California 92521

Viroids, pathogenic, low molecular weight (10^5) single-stranded circular RNA molecules, represent a unique class of minimal infectious agents. Physical characterisation has culminated in the primary sequence of the 359 nucleotides comprising the potato spindle tuber viroid (PSTV)[1]. However, other than the dramatic expression of disease symptoms in plants[2], little is understood of the synthesis and biological activity of the viroid RNA. Molecular hybridisation techniques resulted in the detection of both viroid complementary RNA[3] and DNA[4] sequences. The putative template role of the DNA sequences was reinforced by the reported inhibition of viroid synthesis by actinomycin D[5–7]. However, viroid-specified proteins do not seem to function in replication or pathogenesis, for *in vitro* translation has not been accomplished[8,9]. Furthermore, no AUG initiation triplets have been found in the primary sequence of PSTV or in the hypothetical complementary sequence. Viroid synthesis, therefore, may be characterised as a markedly host-dependent process and consequently potentially very sensitive to inhibition of DNA-directed functions by agents such as actinomycin D. The accumulation of viroid progeny in nuclei[5,10] and nuclear-rich subcellular fractions[11] has provided clues to the mechanism of viroid synthesis. What was reported as a viroid complementary DNA sequence from DNA-rich extracts of *Citrus exocortis* viroid (CEV)-infected tissue[6] has subsequently been positively identified as complementary RNA[3] that may be associated with DNA-rich preparations. With further purification and treatment, no significant levels of viroid-complementary DNA can be detected in diseased *Gynura aurantiaca* or tomato. Therefore, we feel an RNA intermediate must assume a predominant role in any scheme for CEV replication and/or pathogenesis. We now report that synthesis of CEV and PSTV are not inhibited by actinomycin D concentrations which reduce host 5S RNA synthesis by 80%. Thus, the primary role of actinomycin D in viroid synthesis may reflect either inhibition of a host-specified function or a general toxic effect on cell metabolism, and not evidence for the replication through a DNA intermediate.

Because actinomycin D produces toxic conditions in infiltrated tissue[6] as well as protoplast[7] systems, we have used a range of actinomycin D concentrations coupled with the monitoring of host nucleic acid as an internal control to produce a dose–response curve to evaluate actinomycin D sensitivity. Either foliar tissue of *Gynura aurantiaca* infected with CEV or potato tuber sprouts infected with PSTV were vacuum infiltrated with actinomycin D and ^{32}P in a Barth's solution (88 mM NaCl, 1 mM KCl, 0.83 mM $MgSO_4$, 0.41 mM $CaCl_2 \cdot 2H_2O$, 0.34 mM $Ca(NO_3)_2 \cdot 4H_2O$, 2.4 mM $NaHCO_3$, 1.5 mM Tris-HCl, *p*H 7.6) and incubated overnight before the extraction of nucleic acid by the phenol method[12]. Using the parameter of incorporation of ^{32}P into DNA, it is possible to differentiate between sublethal doses of actinomycin D (0–10 μg ml^{-1}) at which DNA synthesis is not affected and higher doses (10–40 μg ml^{-1}) at which the inhibition of DNA synthesis may reflect general cellular impairment (Fig. 1). Incorporation of ^{32}P into total RNA decreased in a linear manner over the entire actinomycin D dose range.

RNA species were analysed by electrophoresis on 5% polyacrylamide vertical slab gel (Figs 2, 3)[13]. Samples were equalised by ^{32}P content so as to monitor only metabolically active cells containing ^{32}P. The intensity of the RNA bands on the autoradiograph was quantitated by direct scanning of the X-ray film at 600 nm.

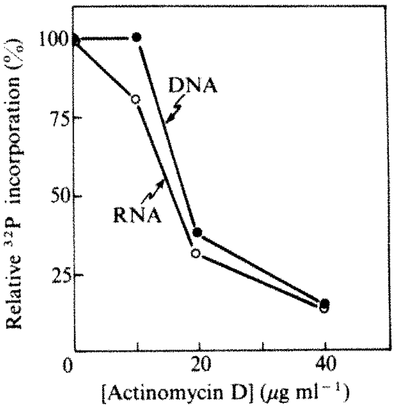

Fig. 1 Relative amounts of ^{32}P incorporation into RNA and DNA as determined by trichloroacetic acid (10% w/v)-precipitable radioactivity using equal nucleic acid concentrations. DNA radioactivity was determined from the acid-precipitable nucleic acids remaining after treatment with RNase A (Worthington, 200 units ml^{-1} at 25°C for 45 min). RNA radioactivity was determined similarly after treatment with DNase I (Worthington, 20 μg ml^{-1} at 25 °C for 15 min).

As purification of the viroid RNA involves partitioning into the 2 M LiCl-soluble fraction, the most appropriate internal control was the 5S ribosomal RNA. The synthesis of this low molecular weight (~36,000) species is significantly inhibited (Fig. 4) over the actinomycin D concentration range. The higher molecular weight ribosomal RNAs purified in the 2 M LiCl precipitate were similarly inhibited by actinomycin D. These results agree with the classical mode of action of actinomycin D as an inhibitor of DNA-directed RNA synthesis.

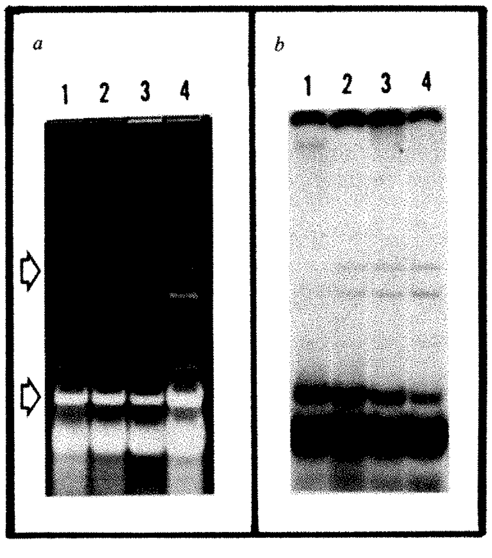

Fig. 2 Polyacrylamide slab gel (5%) electrophoretic patterns of 2 M LiCl-soluble nucleic acids obtained after ^{32}P incorporation into *Gynura* leaf tissue as described in the text. *a*, Nucleic acid patterns after staining with ethidium bromide (0.1 μg ml^{-1}) in healthy tissue (1), and CEV-infected tissue without addition of actinomycin D (2), with 10 μg ml^{-1} actinomycin D (3), or with 20 μg ml^{-1} actinomycin D (4). *b*, Autoradiograph of the same gel after exposing Kodak XR-5 film for 7 days. All nucleic acids were treated with DNase I (Worthington, 2 μg ml^{-1} for 5 min at 25°C) just before loading on to the gel. The arrows indicate positions of CEV RNA (top) and 5S ribosomal RNA (bottom).

0028-0836/80/040399—02$01.00

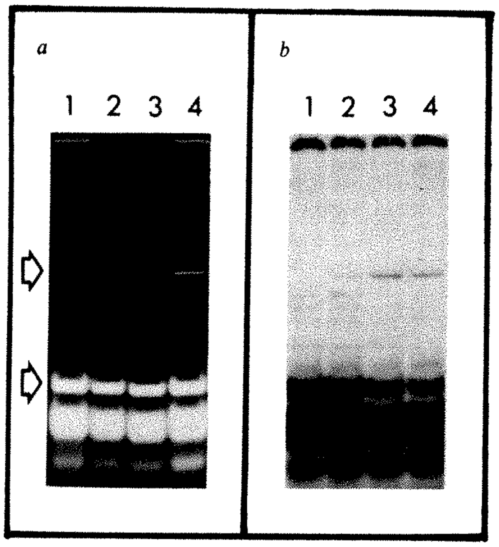

Fig. 3 Polyacrylamide slab gel (5%) electrophoretic patterns of 2 M LiCl-soluble nucleic acids obtained after ^{32}P incorporation into potato sprouts as described in the text. *a*, Nucleic acid patterns after staining with ethidium bromide in healthy potato sprouts (1), PSTV-infected potato sprouts without addition of actinomycin D (2), with 10 μg ml^{-1} actinomycin D (3), or with 20 μg ml^{-1} actinomycin D (4). *b*, Autoradiograph of the same gel. The nucleic acids were treated with DNase I as described in Fig. 2 legend. The arrows indicate positions of PSTV RNA (top) and 5S ribosomal RNA (bottom).

In contrast to the inhibition of host RNA synthesis, the synthesis of CEV in *Gynura aurantiaca* and potato spindle tuber viroid in potato (Figs 2, 3) was not as affected by actinomycin D. Therefore, it is not possible to confirm the previously reported actinomycin D inhibition of PSTV[5,6] and cucumber pale fruit viroid[7] in tomato. Because, in these systems, relatively high concentrations of actinomycin D were used to reduce total RNA synthesis by 80–90%, the interpreted inhibition may have resulted from a general toxic effect on cell metabolism and not the specific action of actinomycin D. Furthermore, the autoradiography procedure used here for analysing the synthetic rate of RNA species is more sensitive than slicing of cylindrical gels.

The absence of any significant inhibition of viroid synthesis is consistent with the primary role of the CEV complementary RNA sequences as intermediates in viroid replication[3]. Any inhibition of viroid replication by actinomycin D would seem to be mediated through a host-genome specified function and not through a viroid complementary DNA sequence. This inhibition by actinomycin D may be analogous to the sensitivity of viral RNA-directed RNA synthesis during early phases of infection[14]. Complementary RNA sequences in the PSTV system have been detected, whereas confirmation for the existence of complementary DNA sequences could not be accomplished (M. Zaitlin, unpublished). These data are consistent with the present finding that viroid synthesis is not specifically inhibited by actinomycin D. Data suggesting the absence of inhibition by actinomycin D have been confirmed by T. J. Morris (unpublished) using a different technical approach with the PSTV system.

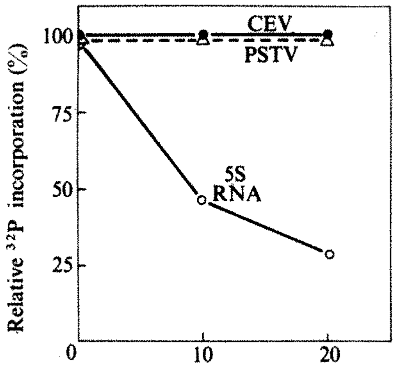

Fig. 4 Incorporation of ^{32}P into viroid RNA (CEV, PSTV) and 5S ribosomal RNA as influenced by actinomycin D concentration. The intensity of the radioactive RNA bands observed in the autoradiograph of the 5% polyacrylamide gel were quantitated by scanning the film at 600 nm and determining the area of each peak. The concentration of the radioactive viroid RNAs were set at 100% and the radioactive 5S RNA concentration determined accordingly.

PSTV was provided by T. J. Morris. These studies were supported by NSF Grant 13622.

Immune and virus-induced interferons may activate cells by different derepressional mechanisms

F. Dianzani, M. Zucca, A. Scupham & J. A. Georgiades

Department of Microbiology, The University of Texas Medical Branch, Galveston, Texas 77550

Virus-induced interferon (VIF), and immune interferon (IIF) produced by lymphocytes following activation by various mitogens (phytohaemagglutinin, concanavalin A, staphylococcal enterotoxin A) or by specific antigenic stimulation (tuberculin, bacterial toxoids, and viral antigens) show important functional differences. These include different antitumour[1] and immunoregulatory activities[2] and differential inhibition of activity by mercaptoethanol[3]. Another important difference has recently been shown: cells treated with IIF acquire the antiviral state much more slowly than those treated with VIF[4]. This may be due to (1) difference in cellular receptors, (2) presence of an inhibitor of antiviral activity in the IIF preparations, or (3) a different mechanism of activation of the antiviral state by the two types of interferon. The first two hypotheses seem unlikely, since (1) no difference between cell association by the two types of interferon has been detected[4], and (2) the presence of the slow acting IIF preparation did not inhibit the rapid activation by VIF[4]. The present study shows that the different kinetics of induction of the antiviral state result from a major difference in the mechanism by which IIF and VIF activate cells.

It has generally been accepted that interferon itself is not the direct inhibitor of viral replication[5]. Instead, interferon acts by inducing the cells to produce one or more secondary protein(s), the so called antiviral or effector protein(s), which are needed for ultimate antiviral activity by cells. In support of this model one laboratory has reported that at least one newly formed protein correlates with the antiviral activity of VIF-treated cells[6]. It has also been shown, by using metabolic inhibitors, that VIF directly induces the production of the antiviral protein(s) without first

Mouse virus-induced interferon was obtained from mouse C-243 cell cultures induced with Newcastle disease virus as previously described[9]. Human virus-induced interferon was obtained by the Antiviral Substances Program, NIAID and was produced as described previously[10]. Mouse and human immune IFs were obtained by stimulation of lymphoid cell cultures with staphylococcal enterotoxin A and were characterised as immune-type IFs as described previously[11].

* Interferon used at 100 reference units ml^{-1}.

† GD-7 virus haemagglutinin yield was used for measurement of resistance in mouse cells, and Sindbis virus haemagglutinin yield was used for human cells.

inducing intermediary proteins[7]. Specifically, mammalian cells treated with VIF in the presence of cycloheximide developed the antiviral state immediately after reversal of the drug action. This finding indicates that an mRNA leading to the production of the antiviral protein was transcribed in the presence of VIF and cycloheximide and was translated only after reversal of cycloheximide action[7]. The addition of actinomycin D before removal of cycloheximide did not block the development of viral resistance. This suggests that VIF directly induces the antiviral protein without the need of intermediary proteins.

The same experimental plan was used to study the mechanism of activation of the antiviral state by IIF. In a first set of experiments, cultures of murine or human cells were treated with cycloheximide and then exposed to 100 reference units of homologous VIF or IIF, as previously described[8]. In our assay the titres reported as reference units correspond exactly to the actual titres observed in the experiments after 24 h incubation of interferon with the cells. The cultures were washed free of interferon and cycloheximide 4–5 h later, and challenged with GD-7 virus (mouse cells) or Sindbis virus (human cells). The virus yield was measured after 18 h incubation. The results are shown in Table 1.

As has been shown previously, cycloheximide did not prevent development of the antiviral state in mouse or human cells treated with VIF, suggesting that the mRNA for the effector protein(s) was induced by VIF during inhibition of protein synthesis and was rapidly translated after removal of cycloheximide. In contrast, cells treated with human or mouse IIF in the presence of cycloheximide failed to develop a significant level of antiviral activity. This finding might indicate that cells treated with IIF in the presence of cycloheximide either did not produce mRNA for the effector protein(s) or else they did produce this mRNA for the antiviral protein(s) but it was not translated quickly enough to prevent replication of the challenge viruses. To test these hypotheses, two-stage experiments were designed. During the first stage, production of mRNAs was permitted to occur by treating cells with VIF or IIF during inhibition of protein synthesis by cycloheximide, while in the second stage these mRNAs were allowed to be translated after addition of actinomycin D to block further RNA transcription. Specifically, cell cultures were pretreated with cycloheximide for 15 min and then treated with VIF of IIF in the continued presence of cycloheximide. After 3 or 5 h actinomycin D was added to some of the cultures to inhibit any further transcription of mRNA and 30 min later the cultures were washed three times (to remove interferon and reverse the inhibition of protein synthesis by cycloheximide but not the inhibition of transcription of RNA by actinomycin D). Some of the cultures were then challenged immediately, while others were challenged 1 and 3 h later. The results of a representative experiment are shown in Fig. 1.

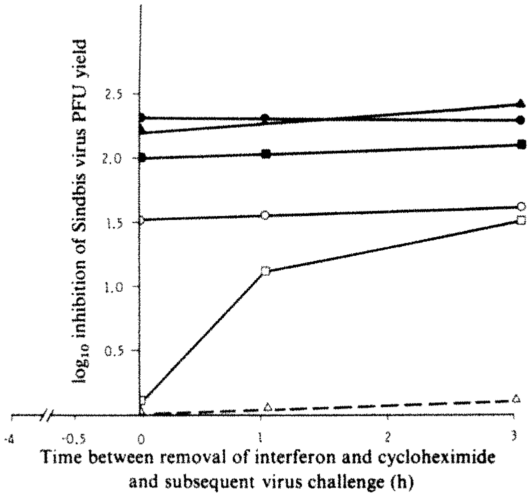

Fig. 1 Development of the antiviral state in human foreskin fibroblast cultures challenged at various times after exposure to human leukocyte interferon (VIF) or immune interferon (IIF) in the presence or absence of metabolic inhibition of protein or RNA synthesis. Four sets of cultures (six tubes per set) were pretreated with cycloheximide, 20 $\mu\text{g ml}^{-1}$, and 15 min later, 100 reference units of VIF (■) or IIF (□) were added to each tube. At the same time VIF (●) or IIF (○) was added to other cultures not treated with cycloheximide. After 3.5 h of incubation at 37 °C, actinomycin D, 5 $\mu\text{g ml}^{-1}$, was added to two of the sets of cultures treated with cycloheximide and IF (▲ and △). After 30 min, IF and the inhibitors were removed by multiple washing and the cultures were challenged thereafter at the indicated times with Sindbis virus. The level of the antiviral state was measured by determining the inhibition of virus yield in a single growth cycle as described previously[9]. Control cultures treated with the metabolic inhibitors as indicated above showed that protein synthesis (as measured by incorporation of ^{14}C-leucine) was inhibited by 95% but RNA synthesis (as measured by incorporation of ^{3}H-uridine) was unaffected during treatment with cycloheximide. After removal of cycloheximide, protein synthesis resumed fully within 0.5 h, indicating the reversibility of the inhibitor. In comparison, transcription was irreversably blocked (92%) by the added actinomycin D. Additional control experiments showed that: (1) cell cultures treated with metabolic inhibitors for the times indicated above gave full yield of virus after removal of the drugs, and (2) treatment of the cells with 5 $\mu\text{g ml}^{-1}$ of actinomycin D for 30 min before addition of IF was completely able to prevent the development of the antiviral state. During the experiments the incubation temperature was carefully maintained at 37 °C as described previously[8].

It may be seen that, as previously observed[7], cultures treated with VIF developed maximal resistance when challenged immediately after removal of interferon, regardless of the presence of cycloheximide and the subsequent addition of actinomycin D. This result confirms the direct induction of the effector protein(s) by VIF. In contrast, cultures treated with IIF in the presence of cycloheximide alone failed to show detectable resistance when challenged with virus immediately after removal of the inhibitor, but gradually acquired the antiviral state when challenged 1 and 3 h later. The somewhat lower level of antiviral activity which appears to be induced by IIF as compared to VIF in Fig. 1 is due to the slower kinetics of cell activation by IIF (ref. 4) since the same activity was induced by both IFs at 24 h. However, again in contrast to the results with VIF, if actinomycin D was added before removal of cycloheximide, no detectable resistance appeared. The same results were obtained in mouse L cells treated with mouse VIF or IIF or when 30 μg per ml of cordycepin or 1-β-ribofuranosylbenzimidazole (DRB) were used as inhibitors of mRNA synthesis instead of actinomycin D, or when larger amounts of interferon (500 units instead of 100) were used. These findings rule out the delayed translation hypothesis and suggest that in the presence of cycloheximide IIF does not directly induce the formation of mRNA for the effector protein(s).

To further exclude the possibility that the IIF-induced mRNA for the antiviral protein(s) is translated more slowly than that induced by VIF, mRNA was induced in cells treated with IIF alone. Its rate of translation was then determined by blocking further mRNA synthesis with actinomycin D and thereafter measuring the level of viral resistance every hour. The data showed that cells stimulated with IIF, treated with actinomycin D after 3.5 h, and then challenged immediately or every hour thereafter for 4 h developed 1.5 $\log_{10}$ of viral inhibition prior to the addition of actinomycin D; however the level of resistance did not rise thereafter, indicating that, similar to VIF, there is no delayed translation of the mRNA for the effector protein(s).

Another, though unlikely, possibility is that IIF simply induces a less stable mRNA for the antiviral protein. If this were the case, then the development of resistance in cells which would have produced the putative unstable mRNA after treatment with IIF and cycloheximide would begin at the same time as in cells containing stable, VIF-induced, mRNA but the maximum level of resistance would be lower. Instead, the first development of resistance is late and the maximum resistance is the same (Fig. 1). There are other more complex possible explanations, considering the multiple variables, but it is clear that IIF represents a novel mechanism, requiring a more complex cell-activating process than does VIF.

Taken together, the findings imply that there are multiple genetic derepressional events in the mechanism by which IIF activates the antiviral state. This interpretation is necessarily indirect due to the use of metabolic inhibitors as probes; however the conclusion is relatively strongly supported since the specificity of action of actinomycin D, cordycepin and DRB has been reasonably well established. Therefore the most probable interpretations are that VIF directly induces a mRNA for the antiviral or effector protein(s)[7], but IIF does not directly induce functional mRNA for the effector protein(s). Studies are in progress to identify the product(s) of the gene(s) activated by IIF.

Thymic nurse cells—Ia-bearing epithelium involved in T-lymphocyte differentiation?

Hartmut Wekerle & Uwe-Peter Ketelsen

Max-Planck-Institut für Immunbiologie, Freiburg, FRG

The vertebrate thymus has a crucial role in the development and organisation of the immune system. Physiologically, maturation of primitive incompetent precursor cells to immunocompetent T lymphocytes takes place in the thymus[1]. Recently, evidence has been presented suggesting that the capacity to recognise determinants of the self major histocompatibility complex (MHC), which underlies MHC restriction of T-lymphocyte recognition, is also acquired within the thymus[2]. Pathologically, T-cell lymphomas are known to arise within the thymus[3]. In all three cases, it is probable that at least some developmental events require close spatial interactions, if not direct contact, between migrating lymphoid cells and sessile stromal thymus elements. We describe here a state of maximal contact between both thymic cell partners, which might represent certain contact-dependent stages of T-cell development. We found that in all normal mouse and rat strains tested so far, the thymuses contain a sizeable number of huge cells of epithelial origin, which engulf and release up to 50 thymic lymphocytes. As the epithelial cells do not degrade the invading lymphocytes, but may rather provide microenvironmental requirements necessary for lymphocyte proliferation and differentiation, we call them 'thymic nurse cells' (TNCs). These TNCs express all the MHC determinants required by a cell involved in the establishment of T-lymphocyte MHC restriction. They express high doses of K/D antigens of the H–2 complex, and equally high doses of I–A region determinants. However, TNCs lack surface immunoglobulin and T-lymphocyte-specific Thy-1 antigen.

We have already developed a method that allows culture of rodent thymus stromal cells as pure monolayers[4]. This method is based on tryptic dissociation of minced thymic tissue by a stepwise digestion procedure. After repeated, exhaustive trypsinisation of thymic material, we recently found that unusually large, intact round cells (diameters up to 50 μm) can be recovered from all preparations. These round cells, TNCs, contain high numbers of small to medium-sized lymphoid thymocytes. Due to the enormous size of these cells, it is possible to isolate them from other, smaller lymphoid or stromal elements by simple repeated sedimentation through fetal calf serum layers. We recover routinely about 15×10^3 TNCs from one young adult mouse thymus and up to 10×10^4 TNCs from corresponding rat organs.

A number of observations suggest that TNCs are epithelial cells rather than macrophages, and that the engulfed lymphocytes have actively entered the TNCs rather than being phagocytosed. The crucial morphological features of TNCs revealing their epithelial nature are demonstrated in Fig. 1. This ultra-thin section shows a typical TNC incorporating at least seven thymocytes. The well organised tonofilament bundles in the TNC cytoplasm, and the typical vacuolisations make them indistinguishable from the cortical epithelial cells described *in situ*[5]. TNCs also functionally behave like epithelial cells. They are released from the thymic stroma only after extensive trypsinisation. They thus must be firmly anchored within the stromal network. This is in contrast to macrophages, which can be released by mere mechanical dissociation. When taken into culture, TNCs do not promptly adhere to plastic surfaces, as macrophages do, but rather tend to form cell aggregates. Finally, long-term cultures of purified TNC fractions display classical epithelial morphology lacking both mesenchymal and macrophage components, which may predominate in infractionated thymus cultures.

0028–0836/80/040402—03$01.00

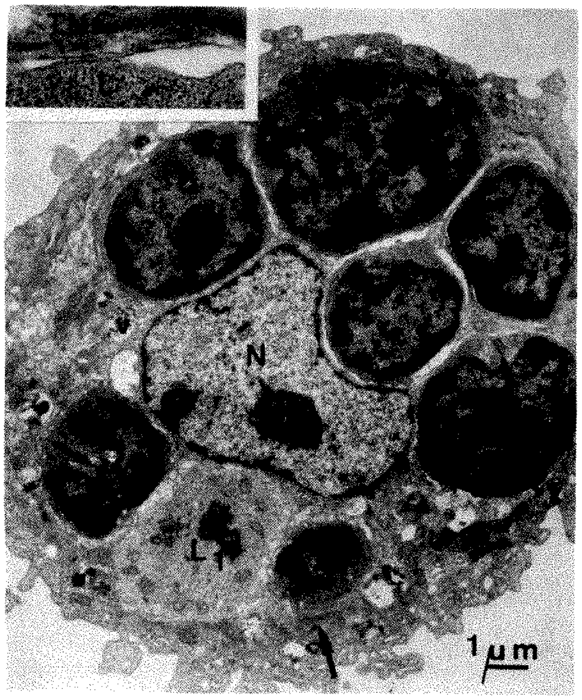

Fig. 1 Thymic nurse cell containing intact, proliferating thymocytes. Mitotic thymocyte (L_1), and centrioles in thymocyte cytoplasms (arrows). TNC nucleus (N) with typical prominent, reticular nucleolus. Prominent features of the TNC cytoplasm: vacuoles filled with coarse, granular material (v), and tonofilament streams in the periphery (double arrow). Inset: higher magnification of contact area between thymic lymphocyte (L) and TNC-containing tonofilaments. Thymuses from 40 young adult female C3H/f mice were washed in cold phosphate-buffered saline (PBS), minced with scissors, and subjected to differential trypsinisation[4]. The minced tissue was transferred into a trypsinisation bottle, and agitated in cold PBS for 5 min to remove most of the loose thymocytes and macrophages. The remaining tissue fragments were softened by further agitation in warm trypsin/DNase solution (50 ml 0.25% trypsin, plus 0.02 mg ml^{-1} DNase in Ca^{2+}- and Mg^{2+}-free PBS) for 10 min. After discarding the supernatants, the main trypsinisation rounds were carried out in warm trypsin/DNase solution for 20 min per round. Single cell supernatants containing appreciable numbers of TNCs were pooled and resuspended in 3 ml HEPES-buffered Eagle's medium (EM-H). This suspension was layered on top of 10 ml undiluted, heat-inactivated fetal calf serum (FCS) in a conical 40-ml glass centrifuge tube. After sedimentation at unit gravity for 15 min, the top fraction containing the majority of all small cells was discarded, whereas the serum fraction and the sediment containing the large TNCs were collected. The cells were resuspended in 0.5 ml EM-H, layered over 2 ml FCS in a 10-ml Falcon plastic tube, to purify further the TNC populations. Practically pure TNC fractions were obtained after 4 or 5 sedimentation rounds. For electron microscopy TNC fractions were fixed in 3% glutaraldehyde, postfixed in 1% OsO_4, embedded in Epon before ultra-thin sections

The majority of the thymocytes engulfed in TNCs appear to be fully intact, as judged by morphological criteria. Many of these thymocytes seem to be involved in proliferation, as suggested by the unusually high incidence of mitotic figures and centrioles (Fig. 1). The thymocytes are completely enclosed by a TNC membrane, but we never observed signs of fusion between both cell partners. That the surrounding caveolar cleft does not communicate with the extracellular space is indicated by the finding that antibodies binding to thymocytes, for example anti-Thy-1 antibodies, do not reach the engulfed thymocytes. Our observation that initially pure TNC fractions cultured overnight contain high numbers of viable free thymocytes suggests that at least a major proportion of the internalised thymocytes can migrate out of the TNCs.

The phenomenon that migratory cells can invade larger, sessile cells without being digested, has been termed 'emperipolesis'[6], and was mainly described in tissue culture conditions. Note, however, that *in situ* emperipolesis of thymocytes in thymic stroma cells has been observed in normal rat thymuses[7], as well as in thymuses from mice undergoing graft-versus-host disease[8]. It seems reasonable to assume that migration of thymocytes into autochthonous stromal cells is initiated by recognition of stromal determinants by the migrating thymocytes. Indeed it has been shown[9] that normal thymocyte populations contain considerable numbers of clones capable of recognising self determinants expressed on autochthonous stroma cells.

It is tempting to speculate that the TNC phenomenon has some role in intrathymic T-lymphocyte differentiation, and, in particular, in the T-cell education/selection process, as recently proposed by Zinkernagel[10] and Bevan[11]. These authors found that the capacity of the T-cell compartment to acquire self-MHC-restricted reactivity against foreign determinants, which may coincide with generation of T-cell diversity[12], is developed within the thymus. T-lymphocyte reactivity is known to be restricted by self determinants coded for both by K/D as well as I regions of the murine MHC. If selection processes within the thymus would involve TNCs, both K/D and I region determinants should be expressed on TNC membranes.

We determined the H–2 antigen formula of TNC membranes using indirect immunofluorescence and monoclonal antibodies, which are directed against determinants of various H–2 subregions (Table 1). TNCs which do not bind anti-Ig and anti-Thy-1.2 antibodies express high doses of classical K/D region histocompatibility antigens on their surface, and equally high concentrations of I–A region determinants. The latter finding is particularly remarkable, as I region antigens are known to be restricted to relatively few cell types, such as (B) lymphocytes, macrophages and sperms[13].

Some recent reports have demonstrated the presence of I-region antigens on thymic components. However, it has proved difficult to classify exactly the antigen-positive cell type using light microscopical screening of thymus sections[14,15]. This holds true in particular for distinction between thymus epithelium and thymus macrophages, which may be abundant constituents of the organ[16]. We applied a fluorescence double labelling method, which allowed functional classification of macrophages, and, at the same time determination of the surface antigen phenotype. Cellular phagocytosis was determined using TRITC-labelled zymosan, whereas the membrane antigens were assayed by indirect immunofluorescence using monoclonal antibodies and FITC-RAMIG, as described in Table 1. Figure 2 shows a mixed T-cell population composed of TNCs, macrophages and a few thymocytes, which were first exposed to

Table 1 Antigens expressed on TNC membranes

Antisera (batch code)*	C3H/f (H–2^k) TNC†	C3H/f (H–2^k) Thymocytes	C57BL/6 (H–2^b) TNC	C57BL/6 (H–2^b) Thymocytes
FITCS–RAMIG alone	–	–	–	–
+ anti-Thy-1.2 (F7D5)	–	+ +	–	+ +
+ anti-K^k (H100-27R9)	+ +	±	±	–
+ anti-I–A^k (H118-49)	+ +	–	±	–
+ anti-I–A^b (B17-123.R4)	±	–	+ +	–
+ anti-H–2D^b (B22-277.R1)	–	–	+ +	±

* Monoclonal hybridoma antibodies were derived from hybridoma-induced ascitic fluid[17]. Anti-Thy-1.2 (F7D5) was from Olac. FITC–RAMIG was a fluorescein-labelled rabbit anti-mouse immunoglobulin antibody preparation from Miles–Yeda.

† Cell preparation and labelling procedures as in Fig. 1 legend. The mice were 4–6-week-old females. Fluorescence was scored: + + bright, distinct ring-shaped fluorescence; + definite, though less intensive ring shaped; ± vague fluorescence, without ring formation, and – no fluorescence at all.

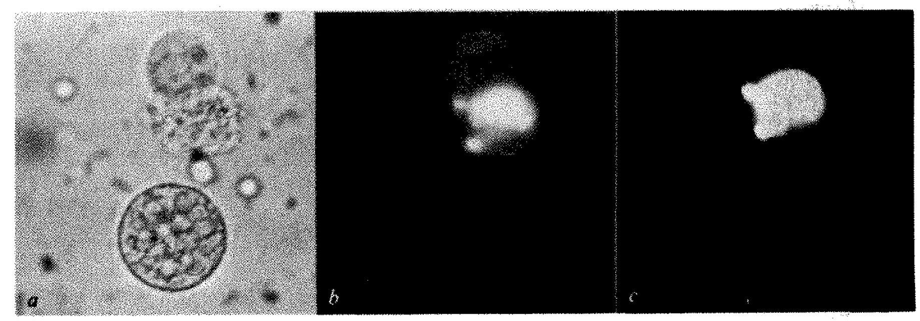

Fig. 2 Expression of Ia antigens on TNCs and thymic macrophages. *a*, Light microscopy of a semi-purified TNC fraction prepared from C3H/f thymuses following the methods described in Fig. 1. TNC (lower cell), thymic macrophage (centre), and unclassified thymic stromal cell (top), along with three thymocytes. *c*, TRITC-labelled zymosan ingested by a thymic macrophage, viewed under red-pass filter. Zymosan (20 mg, lot no. DZ-3185, Schwarz/Mann) was suspended in 30 ml boiling 0.5 M sodium bicarbonate solution (*p*H 9.5). Total de-aggregation of the particles was achieved by additional short ultrasonication. After cooling the suspension, we added 1.6 mg tetramethyl-rhodamine-isothiocyanate, isomer R (TRITC, Nordic Laboratories). The mixture was stirred overnight at 4 °C. The stained zymosan particles were centrifuged (2,000*g*, 10 min, 4 °C) and washed five times in each 30 ml ice cold acetone water (3 parts distilled water, 1 part acetone), before being resuspended in 1 ml 0.5 sodium bicarbonate solution. This stock solution was stored in the dark at 4 °C. For the phagocytosis assay, TNC populations were resuspended in 1 ml EM-H, supplemented with 10% FCS (1×10^6 cells ml^{-1}). We added 20 μl TRITC–zymosan stock solution. After 30 min incubation at 37 °C in normal atmosphere, the cells were centrifuged and resuspended in 0.5 ml EM-H, and underlayered with 2 ml FCS. Within 15 min, most of the living thymus cells sedimented to the bottom, whereas the small free zymosan particles were left in the upper layer. *b*, Membrane fluorescence of the same cells under green-pass filter. For immunofluorescence demonstration of Ia antigens, TNC populations were resuspended in Eppendorf conical plastic tubes, in 100 μl PBS (plus 0.2% NaN_3). We added 10 μl undiluted monoclonal antibody containing ascites fluid H-118-49 (reacting against Ia.2, I–A^k, ref. 17). After 30 min incubation on ice, the cells were washed twice in each 1 ml PBS, resuspended in 200 μl PBS. After addition of 20 μl fluorescein-labelled rabbit anti-mouse immunoglobulin antibody solution (diluted 1:6 in PBS, Miles–Yeda), cells were incubated on ice for a further 30 min, washed twice, and screened under a Zeiss fluorescence microscope. Photomicrographs were taken on Kodak Tri-X pan film (400 ASA), with an exposure of 60 min. The macrophage ingested zymosan shows some residual fluorescence in these conditions.

TRITC-Zy and subsequently to anti-I-A antibody and FITC-RAMIG. Both macrophages and TNCs, but no free thymocytes, express I-A region determinants, as indicated by the fluorescence under a green-pass filter (Fig. 2*b*). Our investigations showed, moreover, that TRITC–zymosan was never ingested by TNCs, and also that TRITC–zymosan ingesting cells, macrophages, never contained more than one morphologically intact lymphocyte (Fig. 2*c*). This provides further support for our previous ultrastructural evidence that TNCs and macrophages are distinct cell types.

Thus, TNCs indeed possess all antigenic requirements needed by a thymic stromal cell involved in a selection process of self-restricted T-lymphocyte clones. We are attracted by the possibility that immature T-cell progenitors with receptors for self antigens recognise self-MHC determinants on TNC membranes as a first step of selection. The recognising cells could be caused to invade the TNC, and, within the peculiar intracellular environment, could be induced to differentiate to immunocompetent T cells. The unusually high rate of proliferative activity of the engulfed thymocytes seems to support such a hypothesis.

Our data at this stage are merely descriptive and do not relate to actual functions of TNCs in T-cell maturation. Our techniques to isolate practically pure TNC populations from normal thymuses might, however, form a good basis for future experiments.

We thank Ms Maria Luchmann and Cornelia Flamm for technical assistance and Dr Günther J. Hämmerling for the monoclonal anti-H-2 alloantibodies. This work was supported by a grant from the Deutsche Forschungsgemeinschaft.

Production of alloreactive T-cell lymphomas

C. G. Fathman* & I. L. Weissman†

* Department of Immunology, Mayo Clinic, Rochester, Minnesota 55901
† Laboratory of Experimental Oncology, Stanford University Medical School, Stanford, California 94305

Experiments predicting[1,2] or demonstrating lymphomagenesis in mice undergoing graft-versus-host (G-v-H) or chronic immunological reactions have been reported[3–5]. In such cases, lymphomagenesis seemed to operate through the agency of activated murine leukaemia viruses (MuLV) and occurred only after very long latent periods, and most (but not all) lymphomas were of host origin[4]. No attempts were made in these studies to assess the relative role of T-cell subpopulations in lymphomagenesis. We have proposed elsewhere that certain MuLV-induced T lymphomas might be the progeny of that subset of normal thymocytes bearing antigen specific T-cell receptors for MuLV envelope antigens[6–10]. Further, the MuLV binding to these cells provides both a portal of infection and a mitogenic signal[6,9,10]. These cells and their thymic progeny would be subject to continuous restimulation by the endogenously produced MuLV envelope glycoproteins, and thus the apparent and 'uncontrolled' proliferation of the cells would be due to their inability to resolve the viral infection and escape the resultant antigenic microenvironment. This receptor-mediated leukaemogenesis hypothesis predicts that any T-cell clone that cannot escape its stimulating antigens would appear to be lymphomagenic in that environment. Recent experiments in our laboratory have demonstrated that unique clones of strain A alloreactive T cells exist which can recognise hybrid mixed lymphocyte reaction (MLR)-stimulating determinants present on (C57B16×A/J)F$_1$ (B6A) stimulator spleen cells[11–15]. A variety of such clones have been isolated and characterised[13–15]. We reasoned that, using these clones, it might be possible to generate alloreactive T-cell lymphomas by *in vivo* injection of these cells into hybrid B6A mice. We report our successful results here.

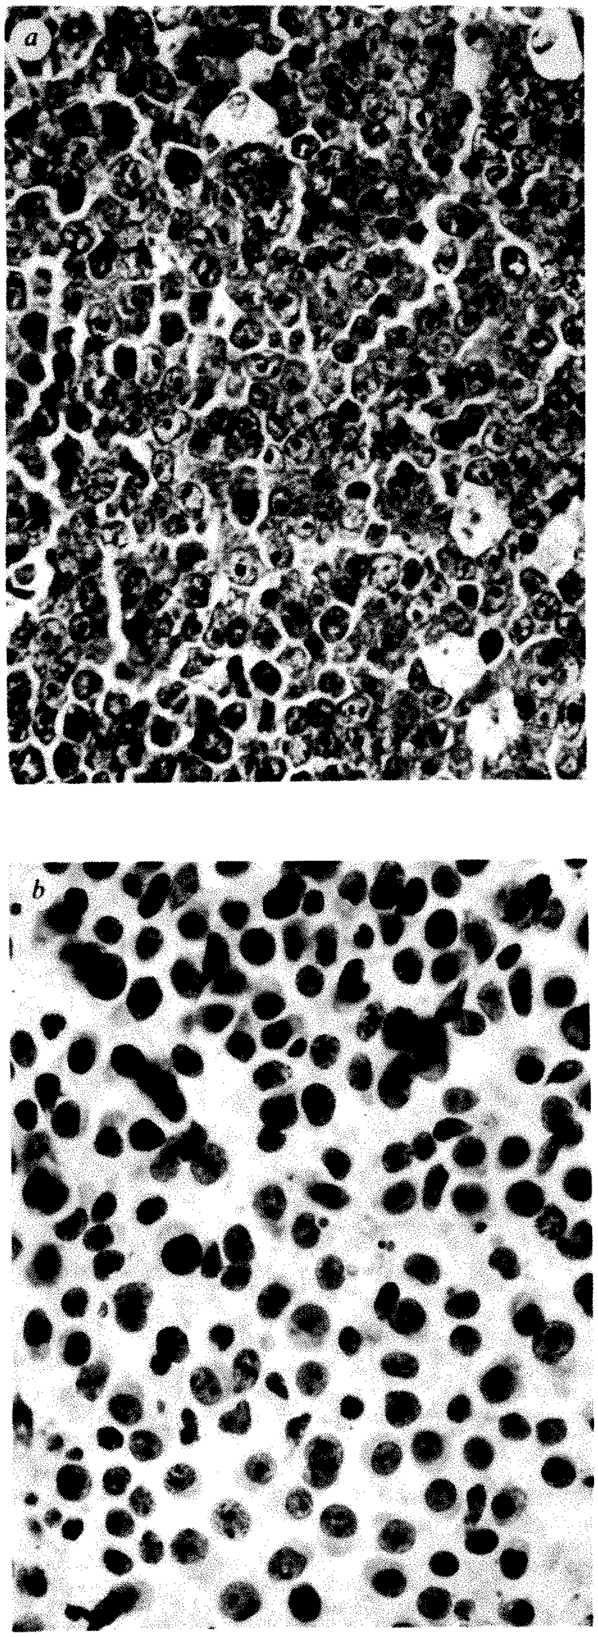

Fig. 1 *a*, Light microscopic appearance of immunoblastic lymphoma involving pancreatic lymph node (initial tumour). *b*, Cellular imprint preparation from pancreatic lymph node demonstrating immunoblastic morphological features of tumour cells: large central nucleoli, thick nuclear membranes and strongly staining expanse of cytoplasm (alcohol fixation, haematoxylin–eosin stain, ×640).

Table 1 Proliferative responses of clone A(B6A)1-1

Stimulator cells				
A	B6	B6A	DBA/2	SJL
2,105 ±198	2,865 ±111	55,531 ±851	3,104 ±144	1,832 ±87

The response (±s.d.) of triplicate cultures of 25×10^3 A(B6A) 1-1 cells measured as c.p.m. of an overnight pulse with 2 μCi of ^{3}H-thymidine following 48 h co-culture with 1×10^6 irradiated (3,300 R) spleen cells (stimulator cells) of strains A/J(A), C57B16 (B6), (B6A)F_1, DBA/2 and SJL/J.

Studies by Cole and Nowell[5] suggested that repeated and prolonged proliferative activity would increase the probability of transformation in stimulated parental strain lymphocytes in a parent-into-F_1 G-v-H system. The use of alloreactive T-cell clones as the source of donor lymphocytes generates a unique situation in which the host is incapable of rejecting the donor cells, and the donor cells are in a situation of continuous stimulation and proliferation. As this clone apparently contains only Ly-1$^+$ 'helper' T cells (see below), induction of regulatory or cytotoxic T cells of donor origin would be unlikely and the donor cell proliferation would therefore be unregulated in B6A hosts.

The alloreactive T-cell clone A(B6A)1-1 selected for *in vivo* injection has been described previously[13]. Table 1 shows the reactivity pattern of clone A(B6A)1-1 on a small panel of stimulator cells. This clone has been carried for over 18 months *in vitro* without undergoing transformation and needs serial restimulation for propagation. At time 0, six separate mice, two each of strains A, B6 and B6A were injected intraperitoneally (i.p.) with 5×10^6 alloreactive T cells of this clone. One mouse from each of the three groups received sublethal (200 R) total body X-ray irradiation. Approximately 1 month after i.p. injection of clone A(B6A)1-1 cells, both hybrid B6A animals had large abdominal masses whereas neither the A nor the B6 animals showed any signs of tumour growth. Both B6A animals were killed and tumours, which seemed to be confined to the mesenteric lymph nodes, were excised and characterised as described below. The *in vivo* injected mice of strain A and B6 were killed 2 months after i.p. injection and none of the four mice showed evidence of tumour growth macroscopically, histologically or by attempted *in vitro* passage of lymphoid cells from their thymus, spleen or lymph nodes.

The lymphomas which arose in the two B6A mice were uniform in appearance. There was extensive replacement of lymph node elements by immunoblastic cellularity in mesenteric and pancreatic nodal tissues, and the spleen and pancreas were massively infiltrated by similar lymphoid cellularity (Fig. 1*a*, *b*). The immunohistological appearance of these lymphomas at the light and electron microscopic level will be reported elsewhere. The involved tissue was excised and the cells were passaged both *in vivo* and *in vitro*. Serological characterisation of the lymphomas for selected cell-surface determinants was carried out in the laboratories of Chella David at Mayo Clinic and Bonnie Matheson at NIH, by conventional techniques of complement-mediated cytoxicity, indirect immunofluoresence and absorption. The lymphomas derived from both mice were serologically identical and all were of cell-surface phenotype H-2K^k, 1a^a, Ly-1.2 and Thy-1.2 positive. They were surface immunoglobulin, H-2K^b, H-2D^b, 1a^b and Ly-2 negative. Preliminary studies on the virological status of these lymphomas using indirect immunofluorescence have shown that they are surface gp70 positive and p30 negative.

Despite continuous growth *in vitro*, on three separate serial *in vivo* passages the lymphomas derived from the original i.p. injection of B6A mice with clone A(B6A)1-1 would only grow in B6A mice (with or without X-ray irradiation). Repeated efforts to passage these lines in animals of strain A and/or B6 (with or without irradiation) failed to yield any tumour growth. Surprisingly, the tumour passed and cloned *in vitro* grew as a continuously replicating cell line. Thus, we have a perplexing situation which may be explained by two possibilities: either antigen drive is requisite for *in vivo* growth but not necessary for *in vitro* proliferation, or growth in B6A mice and the failure of these lymphomas to grow in strain A or B6 mice could be attributed to host regulation rather than lack of appropriate antigenic signal. This system supports the concept of lymphomagenesis occurring in a situation of antigen-driven lymphoproliferation. The model lends itself to extensive exploration as to the origin of the transforming event and the search for alloantigen receptors and/or cloned products on such alloreactive T cells, and has perhaps provided us with a useful tool for future hybridisation studies of immunocompetent T cells.

Common pathways of interferon and hormonal action

J. Edwin Blalock & James D. Stanton

Department of Microbiology, The University of Texas Medical Branch, Galveston, Texas 77550

The action of interferon[1] as well as polypeptide hormones[2] has been shown to be transmissible between cells, possibly through gap-junctional transfer of secondary messenger molecules. This and other similarities between interferon and polypeptide hormones[3] have led us to propose that there is a common cellular pathway of interferon and hormonal action. If correct, this hypothesis would predict that interferon should cause a species-specific hormonal response and a hormone should induce tissue-specific antiviral activity. If these two responses are mediated by similar secondary messengers, they should be transmissible and cross-activate cells. Here, we show that interferon caused a species-specific hormonal response (noradrenaline-like stimulation of the beat frequency of cultured mouse myocardial cells). Noradrenaline induced an interferon-like antiviral state in mouse myocardial cells but not human amnion (WISH) cells. In conditions which demonstrate interferon-induced transfer of viral resistance, exposure of co-cultures of mouse myocardial cells and WISH cells to either human interferon or noradrenaline caused an increased beat frequency in the myocardial cells and development of antiviral activity in WISH cells, respectively. These studies strongly suggest common pathways of interferon and hormonal stimulation that are transmissible between cells.

Figure 1*a* shows the dose response of the spontaneous beat frequency of cultured mouse myocardial cells to noradrenaline and is in agreement with previously published results[2,4,5]. Increases in beat frequency also resulted from treatment of the cultures with mouse but not human interferon (Fig. 1*a*). The interferon concentrations required to cause a change in beat frequency are equivalent to those which induce antiviral activity and are well within the concentrations produced *in vivo*. The similarity of the slopes of the noradrenaline and interferon dose responses suggests that they increase the beat frequency by a similar mechanism. These results show that interferon can elicit a hormonal response in a species-specific manner.

Figure 1*b* shows that overnight treatment with noradrenaline caused a dose-dependent development of antiviral activity in myocardial cells. Interestingly, the maximal antiviral activity was observed at the same concentration (10^{-6} M) of noradrenaline as the maximal stimulation of beat frequency. This finding suggests a relationship between noradrenaline-induced increases in beat frequency and the development of antiviral activity. The noradrenaline-induced antiviral state was not as strong as that induced by interferon (0.7 to 1.0 $\log_{10}$ reduction in virus yield compared with 2.0 $\log_{10}$ reduction). As will be shown below, in identical conditions, noradrenaline did not cause antiviral activity in human amnion (WISH) cells, thereby demonstrating its tissue specificity. These findings demonstrate that in addition to its classical effect on beat frequency, noradrenaline treatment of its target (myocardial) cells causes the development of an antiviral state.

Table 1 shows that purified fibroblast interferon ($10^{8.5}$ units per mg protein) caused an increase in beat frequency. Additionally, the stimulatory effect of a crude interferon preparation was neutralised by specific anti-interferon antisera. In other studies, interferon preparations of varying purity increased the

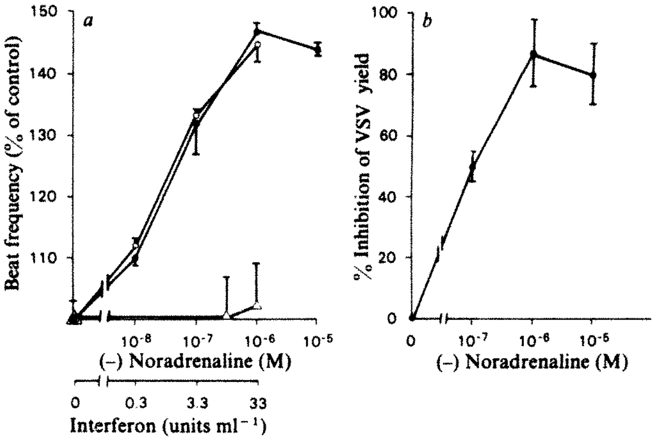

Fig. 1 Effect of (−)noradrenaline and interferon on the beat frequency (*a*) and virus replication (*b*) in cultured mouse myocardial cells. Except for the omission of filtering through nylon mesh, cells were prepared as previously described[16]. For the frequency experiments about 2.5×10^5 cells were plated into each well of Falcon multiwell tissue culture plates in 1 ml of Eagle's minimal essential medium (MEM) supplemented with 10% fetal calf serum, penicillin (100 U $\mathrm{ml^{-1}}$) and streptomycin (100 μg $\mathrm{ml^{-1}}$). After 24 h cultures were placed at room temperature for 1 h to equilibrate and experiments were carried out at this temperature. During the experiments the medium remained near *p*H 7.4. Each value is the mean ± s.d. ($n = 4$ cells in parallel culture). Beat frequency was determined visually with the aid of a microscope (×100) and stopwatch (Scientific Products). Each cell served as its own control. Control basal counts were 60–80 beats per min. Beat frequencies were determined 5 min after the addition of 0.1 ml of the indicated concentrations of each compound at room temperature. For virus replication studies 2.5×10^4 cells were plated into each well of Falcon microtitre tissue culture plates in 0.1 ml of culture medium. After 24 h medium was replaced with the indicated concentrations of noradrenaline in 0.1 ml volume in duplicate cultures and incubated overnight at 37°C in 4% CO_2 atmosphere. Supernatant fluids were removed and cultures were infected with vesicular stomatitis virus (300 plaque forming units (PFU) per culture). Virus yields were determined 24 h later by a previously described microplaque assay[1]. Control virus yields were about 1×10^6 PFU $\mathrm{ml^{-1}}$. Each point represents the mean % inhibition of the control virus yield ± s.d. ($n = 4$). ●, (−)Noradrenaline; ○, mouse interferon; △, human interferon.

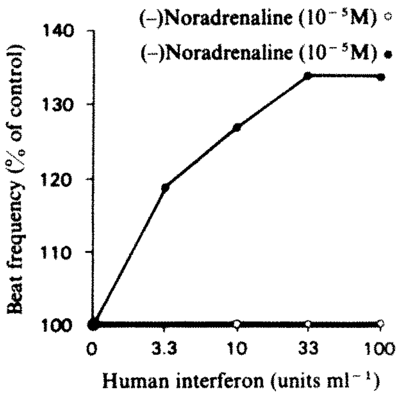

Fig. 2 Effect of human interferon on the beat frequency of mouse myocardial cells co-cultured with human amnion (WISH) cells. Mouse myocardial cells (2.5×10^5 per well) were plated into adjacent wells of a Falcon multiwell plate. Half of the wells then received 2.5×10^5 WISH cells. After overnight incubation, cultures were equilibrated to room temperature, human fibroblast interferon (1.8×10^6 units per mg protein) was added to achieve the indicated concentrations and the beat frequency ($n = 3$) determined as described in Fig. 1 legend. After beat frequencies had been determined, (–)noradrenaline (10^{-5} M) was added to cultures which had been previously treated with human interferon (100 units ml^{-1}) and the beats were again counted. ●, Myocardial cells + WISH cells; ○, myocardial cells.

beat frequency in direct proportion to their antiviral titre (data not shown). We also found (Table 1) that once myocardial cells were maximally stimulated with mouse interferon, addition of noradrenaline (10^{-5} M) caused no further significant increase. Also, interferon and noradrenaline increased the beat frequency with similar kinetics. Maximal stimulation with noradrenaline required about 1 min whereas interferon required 2 min (Table 1). This represents the most rapid reported final action of interferon. Taken together, these results strongly suggest that the effects of noradrenaline and interferon on the beat frequency of mouse myocardial cells occur through a common mechanism.

When the antiviral activity of noradrenaline was characterised, we found that the continued presence of noradrenaline and interferon was not required, as the antiviral state remained after overnight treatment and washing the cells to remove these substances. This shows that both interferon and noradrenaline act on the cell rather than on the virus. The interferon-induced antiviral state is inhibited by actinomycin D (refs 6, 7). Similarly, the induction of antiviral activity by noradrenaline was blocked by actinomycin D (Table 1). Like interferon, noradrenaline did not show virus-specific antiviral activity (see below and Fig. 3). In conditions of high multiplicity of infection, vaccinia virus is not sensitive to interferon[1] and was not inhibited by noradrenaline (data not shown).

The indication that interferon and noradrenaline share common pathways that may involve similar secondary messenger molecules implies that the hormonal activity of interferon and the antiviral activity of noradrenaline should be transmissible between cells. This hypothesis was tested with co-cultures of mouse myocardial cells and human amnion WISH cells. Human interferon did not increase the beat frequency of mouse myocardial cells (Figs 1*a*, 2). However, when human interferon was added to co-cultures of mouse myocardial cells and human WISH cells (which are sensitive to human interferon), there was a dose-dependent increase in the beat frequency of the myocardial cells. This effect was only observed when the myocardial cells were in contact with human cells. When noradrenaline (10^{-5} M) was added to co-cultures which had been maximally stimulated with human interferon there was no further increase in beat frequency, whereas noradrenaline addition to mouse myocardial cells treated with human interferon increased their beat frequency to that of the co-cultures (Fig. 2). The dose dependence of this response resembled that observed with mouse interferon on mouse myocardial cells (compare Figs 1*a* and 2). Both cell types in the co-cultures in the presence of human interferon also developed antiviral resistance whereas human interferon-treated mouse myocardial cells alone did not. Ten units of human interferon caused a 90% reduction in vesicular stomatitis virus (VSV) yield from mouse myocardial cells co-cultured with human WISH cells. Kinetic studies showed that the increased beat frequency due to mouse interferon treatment of mouse myocardial cells precedes by 1–2 min that observed in co-cultures treated with human interferon (data not shown). The observed sequence is consistent with the initiation of events in the human cell by human interferon, and their subsequent transfer to the myocardial cell. These data show that in conditions which can lead to transfer of interferon-induced viral resistance, transfer of the hormonal activity of interferon occurs.

The possible transmissible nature of the antiviral activity of noradrenaline was explored by infection of co-cultures with poliovirus, which only infects human cells[8]. Figure 3 shows that noradrenaline did not induce antiviral activity in human WISH cells alone. However, it produced a dose-dependent decrease in poliovirus yield from the WISH cells in the co-cultures. Poliovirus did not replicate in mouse myocardial cells in the presence or absence of noradrenaline, and co-culturing myocardial cells and WISH cells did not affect the yield of poliovirus from the WISH cells. Similarly, mouse interferon (50 units ml^{-1}) treatment of co-cultures (1 : 1 ratio) of mouse myocardial cells and WISH cells resulted in a 85% reduction in poliovirus yield from the WISH cells (data not shown). When VSV was substituted for poliovirus, the yield of virus from either cell type alone or in combination was similar. Noradrenaline caused a dose-dependent decrease in VSV yield from myocardial cells alone (Fig. 1*b*), but had no effect on the virus yield from WISH cells alone (Fig. 3). As the cells were mixed in a 1 : 1 ratio, if there had been no development of viral resistance in the co-cultured WISH cells one would have expected about 50% of the yield of a co-culture without noradrenaline. Figure 3 shows that noradrenaline caused a dose-dependent decrease in the expected VSV yield, indicating antiviral activity in the co-cultured WISH cells. Thus, noradrenaline causes the transfer of nonspecific virus resistance between its target cell and other cells.

Table 1 Characteristics of the hormonal activity of interferon and the antiviral activity of (–)noradrenaline on mouse myocardial cells

Addition to mouse myocardial cells	Beat frequency (% of control)*	Time required for maximum change in beat frequency (min)†	% Inhibition of VSV yield‡
Purified interferon§ (50 units ml^{-1})	142 ± 8	2	ND
Purified interferon (50 units ml^{-1}) + (–)noradrenaline (10^{-5}M)	161 ± 14	ND	ND
Crude interferon (50 units ml^{-1})	151 ± 3	2	99 ± 1
Crude interferon (50 units ml^{-1}) + anti-interferon antisera (1 : 20 dilutions)	88 ± 18	>10‖	ND
(–)Noradrenaline (10^{-5} M)	ND	1	75 ± 3
(–)Noradrenaline (10^{-5} M) + actinomycin D (2 μg ml^{-1})	ND	ND	0 ± 10

Procedures were as described in Fig. 1 legend. Crude interferon and anti-interferon antisera were mixed and incubated at room temperature for 30 min before addition to mouse myocardial cells. Beat frequency was counted. ND, not done.

* Values are means ± s.d.

† Times were derived from kinetics experiments as described in Fig. 3 legend.

‡ Procedures were as described in Fig. 1 legend. Noradrenaline and actinomycin D were added simultaneously. Values are means ± s.d.

§ $10^{8.5}$ Units per mg protein.

‖ There was no change in beat frequency after 10 min.

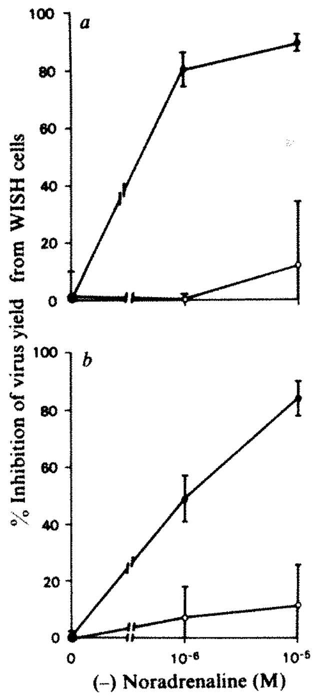

Fig. 3 Effect of (–)noradrenaline on virus replication in co-cultures of mouse myocardial cells and human amnion (WISH) cells. Mouse myocardial cells (3.0×10^4 per well) and human WISH cells (3.0×10^4 per well) were cultured alone or in combination (1:1 ratio) in Falcon microtitre tissue culture plates. After 24 h medium was replaced with the indicated concentrations of noradrenaline and incubated overnight. Supernatant fluids were removed and cultures were infected with 300 PFU of either VSV (*a*) or poliovirus (*b*). Virus yields were determined 24 h later by a microplaque assay[1]. Each point represents the mean % inhibition of the control virus yield ± s.d. ($n = 6$). VSV yield from myocardial cells alone was inhibited (Fig. 1*b*). Poliovirus did not replicate in mouse myocardial cells. ●, Myocardial cells + WISH cells; ○, WISH cells.

Thus, we have demonstrated that interferon can have hormonal activity and that hormonal stimulation can result in interferon-type antiviral activity. From these findings we conclude that interferon and hormonal action are probably mediated by common pathway(s). The transmission of the reciprocal actions of interferon and noradrenaline not only gives further credence to a common pathway of their actions but also suggests that common transferred molecule(s) are generated after interaction of either substance with the appropriate cell membrane. Superficially, cyclic AMP seems a candidate for the interferon-induced increase in beat frequency, because cyclic AMP can cause this response[2,9,10] and interferon in certain conditions can elevate cyclic AMP levels[11,12]. However, cyclic AMP alone cannot account for the antiviral effects as it is not antiviral[13] and interferon does not stimulate adenyl cyclase in all cells[11,12]. A more likely situation is that cyclic AMP and/or another small molecule(s) is responsible.

A question which results from these studies is, is interferon a hormone? The many similarities between interferon and polypeptide hormones indicate that interferon should be classified as such, and this is supported by our inability to distinguish interferon action from a hormonal response. As such, the natural role of interferon may be regulatory, with its effects on virus infections being secondary. The instances of low levels of interferon in normal individuals may not result from inapparent virus infections but may reflect this more general interferon regulatory mechanism. Additionally, this could be related to the side effects observed during clinical trials using high levels of interferon[14] as well as some aspects of viral pathogenesis. If interferon can cross-activate for other hormonal activities, this might explain the many diverse actions of interferon (for review see ref. 15). A shared mode of action of interferon and hormones would suggest that interferon action is not unique and makes questionable the view that the varied biochemical changes in interferon-treated cells are interferon specific.

A second question is, what are the limits of responses to hormones? The present findings suggest that hormones may, in addition to their known actions, protect tissues against viruses or maintain differentiation. If this could be documented *in vivo*, a new strategy of tissue-targeted antiviral and antitumour therapy might evolve.

We thank Drs J. Georgiades and S. Baron for helpful discussions. Purified mouse interferon and anti-mouse interferon antisera were supplied by Dr J. Georgiades and NIAID, respectively. This work was supported by US Army Medical Research and Development Command contract no. DAMD 17-78-C-8048.

Corrigendum

In the letter 'Gravitational magnetism' by S.-P. Sirag, *Nature* **278**, 535 (1978), in Table 1 the maximum magnetic moment, *P*, for Her X – 1 should be 35×10^{26} A m^2.

Errata

In the letter by C. D. B. Bridges and S.-L. Fong, *Nature* **282**, 513 (1979), the title should have read: 'Different distribution of receptors for peanut and ricin agglutinins between inner and outer segments of rod cells'.

In the letter 'Oxidant damage mediates variant red cell resistance to malaria' by M. J. Friedman, *Nature* **280**, 245 (1979), the second sentence of Fig. 2 legend should read: 'The interaction of H_2O_2 and Hb results . . .'.

In the letter 'Inhibition of mixed lymphocyte response by monoclonal antibody specific for a rat T lymphocyte subset' by M. Webb *et al.*, *Nature* **282**, 841 (1979), the symbols in Fig. 1 have been wrongly given. The correct designation is: -●- w3/25 IgG, -○- W3/25 F(ab')$_2$, -□- W3/13 IgG.

In the News and Views article 'Is anyone out there?' *Nature* **281**, 528 (1979), two lines were inadvertently omitted leading to the attribution of views to I. Shklovsky entirely opposite to those he actually stated. The correct sentence should read: "I. Shklovsky of the Sternberg Astronomical Institute suggested that the choice of a value for *N is a function of the age of the investigator. He attributed 'youthful optimism' to T. Kuiper of the Jet Propulsion Laboratory who suggested that N may be a very large number* ($\gtrsim 10^9$).

MATTERS ARISING

Reevaluation of mitosis in the red alga *Porphyridium purpureum*

BRONCHART AND DEMOULIN have reported that mitosis in the red alga *Porphyridium purpureum* is 'unusual', with no kinetochores or well defined spindle pole bodies (SPBs), and they described a unique association of microbodies (MBs) with the spindle poles[1]. Our studies, however, lead to different conclusions and we report here some of our results.

P. purpureum, isolate 637 of the University of Texas Culture Collection of Algae, was grown in von Stosch enriched seawater medium under a 14 h light/10 h dark photo regime in 60-mm Petri dishes. Light microscopy showed 30% of the cells dividing 11 h after the start of the light period. Cells were fixed *in situ* at that time in culture media-phosphate-buffered 1% glutaraldehyde, postfixed in osmium, stained *en bloc* with 2% uranyl acetate, dehydrated in acetone, embedded in Epon, sectioned and poststained with lead.

Electron microscopy of serial sections showed that most dividing cells were in prophase. Each cell contained a large, stellate chloroplast and an eccentric nucleus. In early prophase a pair of SPBs was associated with the nuclear envelope (NE) in a region destined to become one of the division poles. Each SPB (Fig. 1*a*, *b*) had a relatively broad, elliptical portion proximal to the NE. In some micrographs it appeared attached to the NE by fine struts. The smaller, layered, cylindrical distal portion appeared connected to the proximal portion by an amorphous substance. Several MBs and a small zone of exclusion surrounded each SPB. Microtubules (MTs) appeared to originate near the zones of exclusion and increased in number between SPBs as one SPB migrated to establish the other division pole.

By metaphase the proximal portion of each SPB disappeared, while the distal SPB portion remained at the fenestrated poles and became closely associated with the intranuclear spindle MTs (Fig. 1*c*). Most MTs bypassed the chromatin, but several MTs were seen between the poles and chromatin, inserted on indistinct, but identifiable kinetochores (Fig. 1*d*).

During early anaphase the chromatin moved to the poles followed by a pronounced elongation of the interzonal spindle. The distal SPB portion and some extranuclear MTs were still present in early interphase.

It is understandable that kinetochores and SPBs were concluded to be absent in *Porphyridium*, although both appear to be evident in the published micrographs[1]. It was initially difficult to locate them even though we examined serial sections of many dividing cells. Kinetochores, because of their size and inconspicuous structure, were rarely encountered; and while SPBs were frequently observed in prophase, they were easily overlooked in subsequent mitotic stages when only the distal portion remained.

It is not possible to assign functional attributes to the MBs associated with the nuclear poles. This feature, considered to be unique to *Porphyridium*[1], has been observed in unicellular green algae where it is believed that the MBs are simply taking advantage of the spindle to ensure equal allocation to each daughter cell (K. Stewart, personal communication). We support this idea concerning the polar distribution of MBs because they are not known to be implicated with spindle formation or function and because there are other spindle-associated organelles which are now thought to be nonfunctional in nuclear division and are instead taking advantage of a 'free ride'[2,3].

Based on our observations, we conclude that the word 'unusual' is inappropriate and misleading to describe mitosis in *Porphyridium*, and should be used in

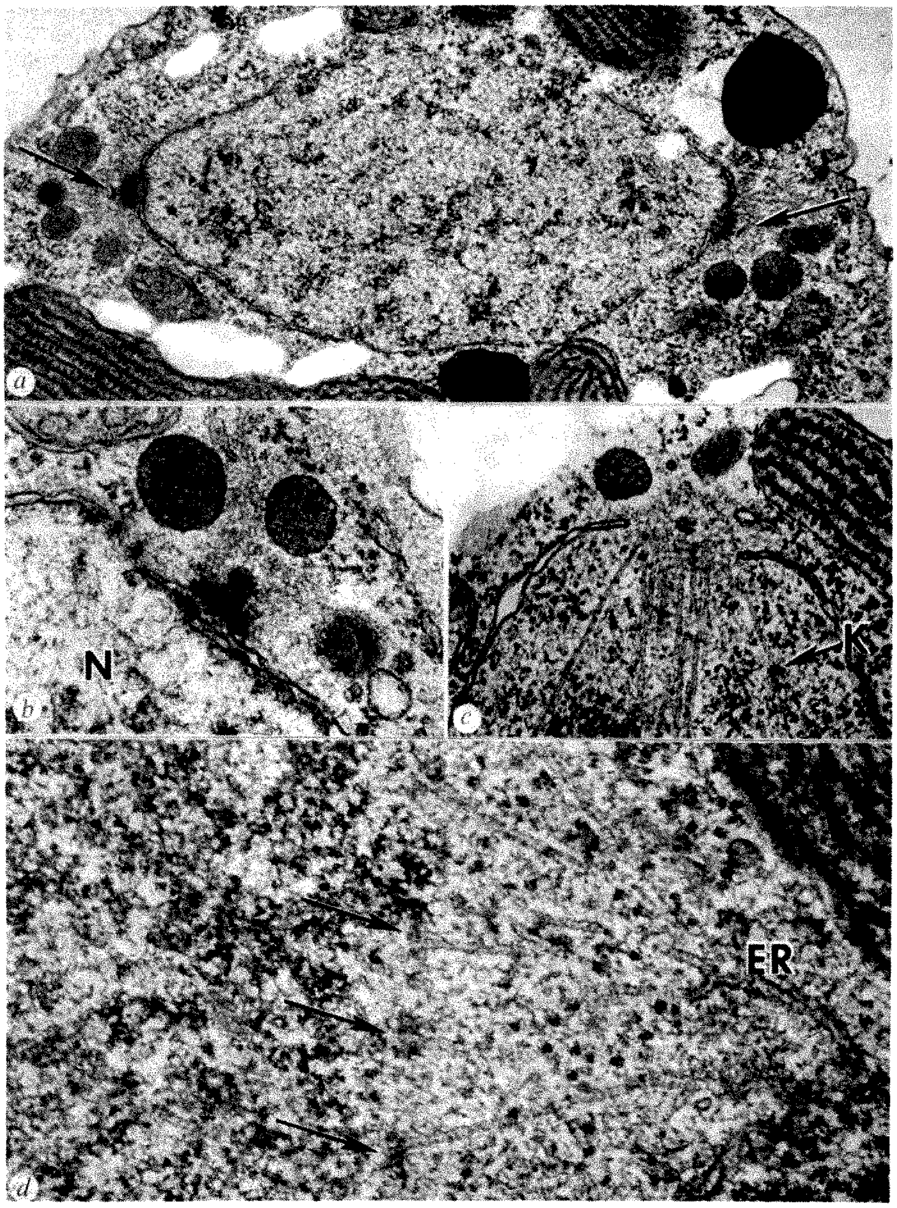

Fig. 1 *a*, Longitudinal view of late prophase nucleus showing established division poles. Each SPB (arrows) bridges a slight NE depression. The intranuclear spindle has not formed yet. The NE of this cell was apparently disrupted during specimen preparation, for it is well preserved in most cells (×33,750). *b*, Early prophase SPB. Note its association with the NE and MBs. Few MTs are present near the small zone of exclusion at this time. N, nucleus (×67,500). *c*, Distal portion of SPB at metaphase. K, kinetochore (×42,000). *d*, Tangential polar view of a metaphase nucleus showing kinetochores (arrows) with attached MTs. Endoplasmic reticulum (ER) is often seen at the poles (×90,000).

characterising organisms whose mitotic mechanisms resemble those currently found only in primitive forms such as the hypermastigote flagellates, dinoflagellates and certain other protozoa[4]. Also, while there are minor modifications, the fundamental characteristics of mitosis in Bangiophycean and Florideophycean red algae appear to be the same (ref. 5 and our work in preparation with C. Bosco and J. Thomas). Furthermore, it has been suggested that an interrelationship exists between red algae and certain fungi[6,7]. The presence of morphologically similar, NE-associated SPBs in both groups, along with other common ultrastructural cell division features[4,8] may serve to strengthen this idea.

BRONCHART AND DEMOULIN REPLY—Schornstein and Scott have added some interesting observations to our data on mitosis in *Porphyridium*, and their interpretation of spindle pole body behaviour is especially welcome. Their main criticism of our paper seems to concern the use of the word 'unusual', a very subjective point. Our use of that word is due to the association of microbodies with the spindle poles, a fact confirmed by Schornstein and Scott. Neither unpublished reports of such a situation in some other algae nor speculation about its meaning change our opinion that our use of that adjective was legitimate. Our use of the word unusual did not result from a belief that either kinetochores or spindle pole bodies were absent.

Kubai[1] gives a lengthy table (Table 6) of organisms displaying microtubules terminating in chromatin without differentiation of kinetochores. We are aware that improved fixation and staining, or better luck in obtaining the right section, may eventually have revealed in those organisms, structures that might be described as kinetochores. Thus we did not stress the fact that we had not seen them in *Porphyridium*.

There is nothing unusual in the absence of a spindle pole body which is the rule among higher plants, but, as we said in our report, we observed and photographed (Fig. 2) such an organelle in *Porphyridium*. We spoke, however, of a microtubule-organising centre, for we were sure only of its presence in prophase and were not certain of its existence at the spindle poles in metaphase. We did not feel the small dark masses present at the poles in metaphase (our Fig. 1 and Fig. 1*c* of Schornstein and Scott) could qualify as a 'well defined pole body'. It is to the merit of Schornstein and Scott to have shown their constancy and relation to part of the prophase organelles. Those observations however do not make mitosis in *Porphyridium* closer to that in *Membranoptera*[2], because except for a qualification of the kinetochore situation (kinetochores are well defined in *Membranoptera* and inconspicuous in *Porphyridium*) every difference we noted remains true (presence of microbodies; lack of polar ring, well condensed chromatin and nuclear envelope doubling by endoplasmic reticulum). As to the relationship to fungi, there is certainly some similarity to the situation in Basidiomycetes. We already had that feeling in 1977 but did not stress it for fear of being accused of stretching the evidence in favour of a red algal ancestry for higher fungi, to which one of us is devoted.

Cancers and the immune system

EXCEPTIONALLY high levels of antibodies against the Epstein–Barr virus have been found in the blood of children who later developed African lymphomas[1], and this finding is widely regarded as evidence of a viral origin for these unusual tumours[2]. However, the tumours are little more than exceptionally localised (and easily cured) lymphatic neoplasms, and they are all but confined to areas of holoendemic malaria where the diffuse disease (lymphatic leukaemia) is conspicuous by its absence. In these same regions, over 50% of childhood cases of myeloid leukaemia have localised collections of myeloid cells (chloromas[3]) as the presenting symptom. Therefore, we could be witnessing the effects of general constraints on cancers of lymphatic and haematopoetic tissues in regions where a combination of high infection risks and low standards of nutrition makes the acquisition of exceptionally high levels of immunological competence during infancy a condition of further survival.

This hypothesis assumes that although the immune system may have more difficulty in recognising quasi-foreign cells (for example, mutants) than wholly foreign cells (microorganisms), nevertheless, it is playing essentially the same role in infective and neoplastic diseases. Therefore, an appropriate test would be one which compared the illnesses and immune reactions of European or American children with lymphatic leukaemia and more localised lymphatic neoplasms such as lymphosarcoma and Hodgkin's disease.

DE THÉ AND GESER REPLY—The comments of Stewart and Kneale on the contrast between the preponderance of localised lymphomas in tropical climates versus diffuse lymphoid malignancies in temperate climates are interesting. The prospective study carried out from 1972 to 1978 in Uganda showed that up to 4 years before Burkitt's tumour development, the future cases were marked by high antibody titres against Epstein–Barr virus (EBV)-specified viral capsid antigens, when compared with the general child population of the same age, sex and locality. The study further showed that other herpes virus antibody levels were not elevated in the Burkitt's lymphoma (BL) candidates and we consider that this specific stimulation of EBV antibody production contradicts the view implied by Stewart and Kneale that BL is caused by an exceptionally high level of immunological competence during infancy, rather than by a specific EBV-related event. As discussed elsewhere[1], Burkitt's lymphoma develops, as do most cancers, as the result of a multi-stage process, each step having specific causes. That high levels of immunological stress could promote the development of localised lymphatic neoplasms (BL) rather than leukaemias as seen in temperate climates, is an old and conceivable hypothesis, which does not contradict the involvement of a specific initiating viral event, as proposed for BL.

We agree with Stewart and Kneale that a comparative epidemiological, clinical and immunological study of lymphatic leukaemias versus localised lymphosarcomas, in temperate and tropical regions, would answer the question of whether children with localised lymphomas are more immunologically competent than those with diffuse lymphoid malignancies.

REVIEWS

Impact of microelectronics

Andrew Holmes-Siedle

The Future with Microelectronics. By Iann Barron and Ray Curnow. Pp. 243. (Frances Pinter: London, 1979.) £7.95.

THE subtitle of this book, *Forecasting the Effects of Information Technology,* though less eye-catching than the main title, gives a better impression of its content. Here, in fairly raw form, is a report to Her Majesty's Government's Department of Industry. It contains the "intelligent extrapolations" of the two authors concerning probable impact of microelectronics over the next fifteen years. The Department certainly got what it needed. The authors have grasped the nettle firmly and given some serious criticisms combined with some quite radical recommendations for change in policy. To put their criticisms in a nutshell, the authors say that, so far, there has been talk only about the impact of microelectronics and that any practical moves made by the Government have all been small and poorly directed. As a result Britain, which has the capability of being in the top three is, in fact, seventh amongst the countries of the world in terms of progress in the use of microelectronics. The report provides a substantial number of the tools necessary to guide the Government in correcting this state of affairs.

In the 'Information Revolution' mankind has been granted a boon that it does not yet quite recognise. Swamped with information, man can now handle it at a low cost and with such ease that his life may greatly increase in quality. Unfortunately many see silicon microprocessors and memories as a threat rather than a boon. The revolution will impinge on business, on the factory floor, and on the home. Large sections of certain industries (for example, those making meters and electromechanical devices) may become redundant and this, if handled wrongly, could obviously be traumatic. Later on, even paper could be largely replaced by silicon. The benefits will lie in increased prosperity; a reduction of the anxiety felt today as we are presented with more information than we can handle; a greater opportunity for people to use their intelligence rather than their brawn; and better use of increasingly scarce material resources. The book under review does not spend time delineating these benefits. Its object is to describe how to reap them. Not only does it provide the forecasts demanded but, even more usefully, it details how Britain can improve its position in the field, using well reasoned argument.

One example of a tight technical argument is that provided on a strategy of production of silicon devices. The authors suggest that, within a short time, a generally adequate level of performance in integrated circuits will have been reached. When that point has been reached, British manufacturers should not continue trying to surpass their competitors in device performance but should instead attempt to extend their markets by a reduction in the price of the same devices. The authors note that this can best be done by reducing the number of rejects and devising a less labour-intensive way of encapsulating the silicon chips. By these means, a British firm could prosper against foreign competition. Such ideas might seem to represent nothing but conventional manufacturing commonsense but, for an industry so wedded to development of the silicon part of their product, the ideas have a revolutionary ring. Such arguments make it clear that at least one of the authors has considerable experience in the business of making microelectronic devices. Civil servants will be advised to listen well to such people before deciding policy. Makers of policy will also be helped by the effort, comprehensively made here, to carry their technical arguments logically into the sphere of industrial aid policy. Perhaps one of the most important items in the report is a recommendation that the government shift their financial support away from research and towards assisting the actual sales of devices; moreover, the authors recommend that support be shifted away from Government research establishments and towards industry laboratories. I would imagine that the aim of this recommendation is not primarily to put an axe into research but rather to increase substantially the whole level of Government funding of microelectronics, keeping the research level constant but helping to promote specific ranges of the equipment which has been improved by the use of microelectronics. Such a direction could, the authors hold, much more surely increase Britain's share of the market in several highly profitable fields, such as office equipment (the authors see clerical work as one of the fields most prone to be changed by microelectronics in the near term). Again, the idea might seem obvious did not the authors note that many Government committees find it more congenial to fund research than to support the manufacture of end-products. Though stated kindly and factually, the implication of the authors is clear: some of our civil servants have, in this field, tended to steer clear of hard decisions which involve the fate of a business. I would welcome a longer book which includes some discussion as to why this should be so, and how British practice compares with that in, say, France and the USA. Is it a lack of technical appreciation of the microelectronics industry, aggravated, perhaps, by the great speed with which it is developing? Or is it a fundamental characteristic of civil servants to avoid the more critical gambles? If so, will a report, like this, however convincing, conquer that tendency?

For the general reader, the main problem with this book will come with the style, which is that of a technical report. In the interests of bringing the report quickly to a wider public, it would seem that little time was spared for making it more intelligible to that public. The one superficial addition, a glossary of technical terms, is a particularly weak effort. In fact, many definitions miss the point and some of the more obscure terms in the text are not covered. Moreover, the authors sometimes favour Americanisms (what is an "implementation house"?) and adjectival phrases ("handling, machining, forming and labour intensive"). It is a pity that an important statement of the future, as I believe this is, may only further baffle the general public.

Does the book give a well-rounded picture of the next fifteen years or more? Here, it may be said that the authors' immersion in one technology may work against them. They are clearly "silicon men" and claim that silicon devices of one class, n-channel MOS devices fabricated from single-crystal silicon, can answer all of our needs in microelectronics, at least in the medium term. They therefore give virtually no time to considering the potential technical advances in other branches of semiconductor technology, such as that of gallium arsenide and certain thin-film structures. Even in the medium term, such devices could possibly both outperform *and* underprice silicon devices. I would most certainly agree that there is ample room for the expansion of the use of silicon devices in low-speed microelectronics (for example, a silicon diary could inform one of tomorrow's appointment and still operate at a very low data rate); but other growing fields, such as mass data-processing, demand such high switching speeds that the designers of fast computers already claim that silicon is "running out of capabilities". This, however, is one of the few points which is insufficiently argued in a book which, without doubt, is an important contribution to the debate on Britain's role in the Information Revolution. The highly condensed statement whcih they give leaves room for several further books which expand on the issues so succinctly raised and it is to be hoped that this statement will be a first step in a wider, more sophisticated, debate on the impact of microelectronics on our future lives. □

Andrew Holmes-Siedle is Consultant to the Physics Department of the Fullmer Research Institute in the fields of solid-state physics and radiation physics.

Ageing research

I. Davies

The Biology of Senescence. Third edition. By A. Comfort. Pp.414. (Elsevier: New York, 1979.) $19.95.

THE study of ageing is now taking place on a large scale throughout the world. There is a rapid proliferation of new books with "overviews" of the subject to date. The second edition of Dr Comfort's book was produced in 1964 and at that time was one of the few texts analysing senescence in a variety of animal species, and also presenting a critical survey of current theory in the field of ageing research. One rather expected that the latest edition of this book would attempt to carry out the same task, but with an updated review of the current literature. However, the end product is rather a strange hybrid, a very thorough analysis of early research in the ageing field, followed by a somewhat scanty examination of the later literature.

Much of the text is easily recognised as being from the earlier edition and contains an interesting description of the historical and philosophical background of the study of the ageing process. There is a mass of data on the maximum life-spans achieved by animals from most of the major phyla, together with discussions of the various measurements (morphological, biochemical, physiological, and so on) made on such ageing populations. The influence of genetic constitution and growth on senescence is also described. Much of this information is valuable and informative, but the majority of the references cited are pre-1964 with hardly any reference to the wealth of recent data.

Various other defects are also apparent — such as non-matching of references in the text with those in the extensive bibliography, and also examples of changes in symbols between diagram and legend — but presumably these can be blamed on the publishers.

The remainder of the book examines the proposed mechanisms of senescence, a discussion of the position of ageing studies, and a call for the direct measurement of human ageing. This is the most recent section of the text and contains a very brief review of current concepts in the field of gerontology. The discussion is too short and is not critical enough. In addition, there is some rather blatant grafting into the previous edition with a close juxtaposition of statements such as "antibodies are now thought to be produced by lymphocytes" and then more or less detailed descriptions of current research on immunological factors in the ageing process. The scantiness, and the choice, of the references used to question (for example) the blind acceptance of senile neurone loss, is also doubtful. Similar criticism could be levelled at other topics.

Overall, I found this book very disappointing. There is a good deal of useful information which would be of use in establishing background for graduate course work in a study of senescence. However, because of the less than satisfactory updating of the book it would be of limited use for a review of current research into the ageing process. □

Basic physics of X-ray spectroscopy

D.S. Urch

X-Ray Spectroscopy: An Introduction. By B.K. Agarwal. Pp.418. (Springer: Berlin, Heidelberg and New York, 1979.) DM74; $40.70.

X-RAY SPECTROSCOPY is enjoying a renaissance with the development of techniques such as extended fine structure (EXAFS), with the availability of high-resolution spectrometers and with the construction of powerful sources of synchrotron radiation. It is therefore a pleasure to welcome Professor Agarwal's new introduction to the subject. Of necessity much of the book is concerned with the basic physics of X-rays and this involves the presentation of a considerable amount of historical material. This is done in a clear and logical way with full mathematical derivations. Indeed, if there is a general criticism of this book, it is that there is possibly an over-emphasis on mathematical rigour at the expense of descriptive explanation.

The first three chapters are devoted to a description of X-electromagnetic radiation, to characteristic X-rays and to the interaction of X-rays with matter. This latter subject then leads on to specific topics of current interest. The value of the book is greatly enhanced at this stage by a consideration of the photoelectric and Auger effects, and the consequences which these processes have for X-ray spectroscopy. Peak widths and the origin of the non-diagram (satellite) lines are dealt with in detail. As high resolution X-ray spectroscopy in both emission and absorption can shed considerable light on the electronic structure of metals, alloys and other solid materials as well as molecules, this 'chemical' application is described in some depth. The various types of chemical bond are described and there is a brief introduction to molecular orbital theory so that chemical shifts of X-ray emission peaks can be rationalised. The fine structure near X-ray absorption edges is discussed in the same way and a basic account is given of the EXAFS technique and of the information that can be derived from it. Even so, it is unfortunate that in this chapter (as in others) very few recent references are to be found (less than 10% of the references are post-1970). This lack is particularly felt in the chapter on the fast growing area of soft X-ray spectroscopy where fundamental advances are either omitted (for example, Henke X-ray tube) or barely mentioned (for example, grazing incidence spectrometer).

General experimental methods in X-ray spectroscopy are dealt with quite briefly, only the basic physical principles being explained in detail. The emphasis in this book is theroretical, rather than experimental, but it has merit as an introduction to the basic physics of X-ray spectroscopy and to its applications. It should therefore form a valuable addition to the libraries of X-ray laboratories and could be used in postgraduate courses in X-ray physics. □

Soluble cell products in the immune response

Anne S. Hamblin

Biology of the Lymphokines. Edited by S. Cohen, E. Pick and J.J. Oppenheim. p.626. (Academic: New York, San Francisco and London, 1979.) $42.50; £27.60.

THE word lymphokine was originally invented to denote those cell-free soluble factors, other than immunoglobulins, generated *in vitro* during the interaction of sensitised lymphocytes with specific antigen, and with biological activities consistant with them functioning as regulators of immune responses *in vivo.* Subsequent work has shown that the same, or similar, activities may be produced from other cells of both lymphoid and non-lymphoid origin under a variety of circumstances. The editors have therefore taken the view (with which there might be some disagreement) that their terms of reference for topics discussed in this book should be wide, and include "soluble cell products of all categories to which a function in the central or peripheral regulation of the immune response has been attributed, with the exception of classical antibodies". Within the potentially enormous list of substances which could be discussed in this context, the editors have made a clearly stated selection of those which will receive attention and those which will not. This book is therefore about the activities of some soluble cell products, mostly derived and demonstrable *in vitro,* which are at present considered relevant to the regulation of immune responses *in vivo.* However, it is not simply a list of factors, but more interestingly an attempt to focus on some aspects of current lymphokine research, and in particular mechanisms of action.

The book consists of twenty chapters by different authors, most of whom have considerable experience of experimental work with lymphokines. The first, by the editors, entitled "The lymphokine concept", clearly explains the problems surrounding the definition, origin and relevance of lymphokines, and sets the stage for the ensuing chapters. The second entitled "Lymphokines as inflammatory mediators", includes a useful discussion of all the available, compelling, although inconclusive, evidence that these substances, the activities of which are based on *in vitro* assays, do have a role *in vivo,* and provides a basis for argument with those who regard lymphokines as test-tube artificats. Thereafter follow sixteen chapters, some of which review 'classical' lymphokine activities (migration inhibitory, cytotoxic and mitogenic factors) and some of which describe more recent fashionable additions to the lymphokine repertoire (factors affecting T cell - B cell cooperation, antigen-specific regulatory factors, and specific and non-specific suppressor T cell factors). In addition, there is an interesting chapter by L. Epstein comparing the properties of classical and immune interferons, a chapter on the important and difficult problems of purification and characterisation of lymphokines, and several chapters on lymphokine activities derived from a variety of cell sources of both lymphoid and non-lymphoid origin. The book concludes with two general reviews; the first a stimulating article on the role of intracellular mediators in the immune response by C. Parker, which although it makes little reference to lymphokines, was presumably included on the basis that the editors feel that future research on their biology may focus on such mechanisms; and the second an overview of the biology of lymphokines by B. Waksman.

The topics selected for inclusion in this book reflect current aspects of the study of lymphokines which the editors view as important. Within our present state of limited knowledge about soluble cell products involved in immune regulation, and in particular their biochemical purification and characterisation, the relative importance of the subjects discussed remains a matter of speculation. Nonetheless, the book brings together information and concepts which can form the basis of useful discussion amongst those actively involved in lymphokine research, as well as those more generally interested in biological control mechanisms. □

Simple qualitative molecular orbital theory

Anthony Stone

Molecular Structure and Bonding: The Qualitative Molecular Orbital Approach. By B. M. Gimarc. Pp. 224. (Academic: New York, San Francisco and London, 1979.) £11.70.

THIS book endeavours to explain how a knowledge of simple qualitative molecular orbital theory can give a detailed understanding of the shapes of molecules. It is rather limited in scope, covering only H_3, H_4, AH_2 to AH_4, AB_2 to AB_6, HAB and H_2AB, A_2H_2, A_2H_4 and A_2H_6, and dimers of AB, AB_2 and AB_3 (where A and B are first or second row elements; there is no mention of transition-metal compounds) but these molecules are discussed in considerable detail, with many references to experimental and *ab initio* data. The book is aimed at senior undergraduates or first-year graduates, though it is not entirely consistent in level: for example, it is not thought necessary to explain what is meant by the Hartree-Fock method with configuration interaction, but the simple molecular-orbital picture of H_2 is discussed in some detail. Similarly the reader is not expected to know or learn any group theory beyond "a knowledge of symmetry classifications", but the molecular orbitals of the various species are given, in qualitative form, without any hint of the group-theoretical procedures used in their derivation. Such theoretical explanation as is given (for example, of the change in the form of the orbitals on bending on AH_2 molecule) is woolly and unconvincing. Students who had not met Walsh diagrams before would have difficulty with the treatment of AH_2, let alone the more complicated examples.

However, the main limitation of this book is its single-minded commitment to one approach. Changes of energy on passing from one structure to another are to be viewed wholly in terms of changes in overlap. There is no mention, in the main text, of Walsh, whose classic series of papers dealt with most of these molecules 25 years ago, or of the Jahn-Teller effect or the pseudo-Jahn-Teller effect. The only concession to other methods of tackling these problems is a couple of pages at the end of the book, in which other approaches are briefly mentioned, almost as if to counter the accusation that the author has never heard of them, but there is no attempt whatever to integrate these ideas into the book as a whole. In the discussion of H_4 for example, three possible structures are considered, namely tetrahedral, square-planar and linear. The overlap criterion is used to rank these in order of energy, and it is concluded, not very convincingly, that the linear structure lies lowest. But application of the Jahn-Teller theorem shows conclusively that the ground state *cannot* be tetrahedral or square-planar, because either of these structures would, according to the theorem, distort spontaneously. The reader should be told about this far more rigorous approach.

In summary, the book contains a good deal of useful information on a rather restricted subject, but it is discussed from a very narrow point of view. A disappointing book. □

Blood-brain barrier

Stanley I. Rapoport

The Concept of a Blood-Brain Barrier. By Michael Bradbury. Pp.465. (Wiley: Chichester, UK, and New York, 1979.) £22.

THIS book by Michael Bradbury, of King's College, London, is a scholarly, comprehensive and readable analysis of past and recent studies on the blood-brain barrier (BBB) by a researcher who has made major contributions to the field. It extends the important review by Davson (*Physiology of the Cerebrospinal Fluid*, Churchill, Livingstone: Edinburgh, 1967) and complements, with only slight overlap, my own book (*Blood-Brain Barrier in Physiology and Medicine*, Raven: New York, 1976). It contains more than 1,000 references, and should be of value to researchers as well as to neuropharmacologists, neurochemists, neurosurgeons, neurologists and transport physiologists.

The BBB separates the brain and cerebrospinal fluid (CSF), on the one hand, from blood on the other, and is a regulatory system consisting of three tissue sites — the cerebrovasculature, the choroid plexus and the arachnoid membrane. Each site contains at least one cell layer that is connected by tight junctions (which restrict intercellular diffusion of water-soluble drugs and proteins) and that has specific transport mechanisms that help to regulate the ionic and water contents of the brain, and to facilitate delivery to the brain of critical substrates for metabolism and synthetic processes.

Chapter 1 introduces the anatomical and functional relationships between barrier tissue sites and brain cells. Chapter 2 summarises early studies on the barrier to intravascular dyes and colloids, and presents methods of compartmental analysis that can be used to estimate cerebrovascular permeability. The vasculature is selectively permeable to lipid-soluble as compared to water-soluble agents. Chapter 3 reviews historical controversies about BBB sites, and shows that the BBB at the cerebral vasculature arises at the continuous layer of endothelial cells that have little pinocytosis and are connected by tight junctions. The chapter also analyses methods of measuring cerebrovascular permeability *in vivo*, and discusses capillary hydraulic and water permeability. Bradbury concludes that functional pores exist at the vascular endothelium for non-electrolyte diffusion, although I believe that evidence suggests that they do not. The sink action of CSF, in washing material from the brain extracellular space, is discussed.

Chapter 5 indicates that apparent regional differences in blood-brain exchange reflect differences in capillary surface area between white and grey matter. It considers the special, high permeability regions in the brain in detail (that is, median eminence, posterior pituitary), which have vessels with porous, fenestrated endothelia and have neuroendocrine and chemoreceptor functions. Blood vessels in the retina, optic nerve and peripheral nerve also have a continuous endothelial lining.

Chapter 6 elaborates the properties of saturable, stereospecific mechanisms at cerebral capillaries for facilitated diffusion of sugars, amino acids, ketone bodies and monocarboxylic acids. Bradbury suggests that amino acids are transported actively from brain to CSF, although the evidence for this is weak. Chapter 7 critically evaluates experiments designed to prove active transport at the cerebral capillary, and finds most of them wanting. The best one is that by Davson and Hollingsworth with ^{131}I.

Chapters 8 and 9 summarise much of Bradbury's original studies on homeostatic regulation of ions within the nervous system. The apparent selectivity of the cerebral capillary to K^+ as compared to Na^+ could be due to active K^+ transport or to exchange diffusion of K^+. Transport at the choroid plexus maintains CSF concentrations of Ca^{2+}, Mg^{2+}, Na^+ and K^+ within strict limits, despite marked changes in plasma concentrations. A sigmoid relationship between CSF K^+ and K^+ efflux at the plexus, and a K^+-independent influx, could stabilise CSF K^+. Brain and CSF *p*H are also stabilised through modification of choroidal secretions and brain organic ion content (especially in alkalosis). Control of brain ionic content helps to maintain a constant brain volume during a chronic change in plasma osmolality.

BBB phylogeny is discussed in Chapter 10. BBB structures are in place but are less tight in the immature than in the mature brain. Regulatory mechanisms for specific ions mature at different rates, but are completely developed during the final spurt of brain growth.

Chapter 11 discusses the BBB to drugs, neurotransmitters and metabolites. Most current methods are not sufficiently sensitive to measure capillary permeability of slowly permeating agents, such as peptides. Clinical depression and schizophrenia are related to CSF concentrations of specific neurotransmitters or their metabolites. CSF concentrations of folic acid, vitamin C, peptides and morphine are regulated by choroidal transport.

Chapter 12 summarises effects of different insults on BBB permeability — hypercapnia, seizure, hypertension, toxic agents, hypertonic solutions. Bradbury concludes that the possible mechanisms that might increase cerebrovascular permeability — tight junctional widening, increased vesicular transport, transendothelial channel formation — remain to be evaluated critically. The resistance of the BBB to hypoxia and ischaemia is emphasised, as are principles underlying cerebral oedema. Chapter 13 summarises overall BBB function. A final proof reading of the book would have avoided a few trivial errors. □

Birdwatching postscript

C.M. Perrins

The Mitchell-Beazley Birdwatchers' Pocket Guide. By Peter Hayman. Pp. 192. (Mitchell-Beazley/RSPB: London, 1979.) £3.95.

THIS is a slender, wallet-sized book which can be conveniently carried with one into the field. It is crammed full of coloured sketches, most of which are very small (less than an inch across), but they usefully portray the birds in a variety of plumages and poses (perched and in flight) and from different angles. Juvenile plumages are also often shown, though I would have preferred more of these to have been included.

The text is very sparing but includes the most important features of each species, their calls, their habitats, and range. Some of this information is given in the form of symbols, thereby saving space. There is also usually a small silhouette of each species against that of either a sparrow or a pigeon in order to give a quick idea of size. This is not a total success; when the bird in question is very large compared with scale model (for example, pheasant with sparrow or eagle with pigeon) the model may be less than 2 mm in size. In such cases, the poor reader is left to determine which of these two models this tiny spot of ink is supposed to represent!

The book covers some 350 species and hence includes almost all the birds of Western Europe. More detail is given for those which are commonest in Britain than for the rarer birds; the latter are sometimes grouped together on a page and so are not located with their closest relatives. The order used is not an accepted taxonomic one, but one designed to help the beginner locate the species concerned. On the whole this is a well produced, highly portable little book which many will find very useful. □

C.M. Perrins is Director of the Edward Grey Institute of Field Ornithology, University of Oxford, UK.

31 January 1980

Scientific exchanges must serve science, not the Soviet government

THE exile of Dr Andrei Sakharov, coming so soon after the Soviet invasion of Afghanistan, raises once again the problem of a scientist's duty to take a stance on world affairs. Ironically it comes this time in defence of a man whose actions, over the past twelve years, have made it inevitable that scientists should be expected, by the public at large, to have such a stance. Just earlier this week, he issued a statement from internal exile in Gor'kii, via his wife, calling for a fair and democratic society and the defence of human rights. At the same time he accused the Soviet government of repression.

It would be simplistic, and far from correct, to attribute to Sakharov's influence the current concern of scientists with the social consequences of their research. Nevertheless, the appearance in *samizdat* in 1968, and subsequent publication in the West, of Sakharov's "Thoughts on Progress, Coexistence and Intellectual Freedom" have added a new dimension to the public image of the research scientist. Instead of what Isaac Asimov had called the "Frankenstein syndrome", the public were presented with a nuclear physicist, "father of the Russian H-bomb" (a title which Sakharov himself has always denied) who had turned over all his earnings from the weapons programme to cancer research, and begun a lone campaign for increased intellectual freedom and international exchange as a means of overcoming international tensions and confrontation.

In later years, Sakharov was to criticise this essay as immature. Certainly, as he became more closely identified with the growing wave of intellectual unrest in the Soviet Union, his approach to the problems of *détente* became more profound and, perhaps, less trusting of official statements of intent. The appearance of his essay in 1968, the "year of Czechoslovakia", however, threw a fundamentally new light on the Soviet scientific establishment. Hitherto, dissent had largely been confined to literary and student milieux, and Soviet scientists had been seen, at any rate from abroad, as enjoying an elitist position, with all the many privileges that the "classless" Soviet society gives to those it wishes to cherish.

For a Soviet scientist to risk his job, position and freedom, for the sake of an ideal has led, inevitably, to a new focus on the problem of the scientist's personal responsibility for the use to which his or her research is put — and, more generally, his or her obligations to fellow scientists and to humanity at large.

Dismissal from employment compatible with Sakharov's background and abilities came swiftly, providing the Soviet media with the chance of presenting him as a "drop-out" who has done no real science for the past 12 years. Even if this were true — and the circumstances of his arrest last week, on the way to a physics seminar, suggest otherwise — Sakharov's former scientific achievements and his continuing membership of the Academy surely constitute at least as much a claim for support from the scientific community as they would in the case of an aged and long retired professor emeritus. The storm of protest telegrams from scientific bodies and individual scientists indicate that this obligation has been felt and answered.

What form, apart from verbal protests, should this concern over Sakharov take? Already the US government has cut back on technology transfer to the Soviet Union — and this at a time when the new Five Year Plans are being completed — plans which would have originally assumed the availability of US knowhow and/or hardware. Although the Soviet government will admit only Olympic visitors this summer, there are a number of international conferences scheduled to take place in the Soviet Union, before and after the Olympic shut-down, as well as an impressive programme of exchange visits and joint projects. Most significant, next month, the Hamburg Scientific Forum meets to discuss the implementation, as regards science, of the Helsinki Accords.

Since the first plans were made for Hamburg, the irony of the case of Yurii Orlov, has been observed on a number of occasions. Orlov, a physicist and founder of the Moscow "Helsinki Monitoring Group" is in a Soviet labour camp precisely for attempting to report on breaches of these accords. A number of western human rights activists, notably Valentin Turchin, advocate boycott of Hamburg until such time that Orlov is free to attend. Sakharov's exile, they claim, makes the case for boycott even stronger. At the other extreme lies the "soft diplomacy" approach: keep the contacts going, and try to do what one can behind the scenes. A doctrine which can all too easily become an apologia for inaction.

It would be ironic if, in defence of Sakharov, the world scientific community denies itself vis-a-vis the Soviet Union, all forms of international exchange which Sakharov himself advocated. On the other hand, it would be idle to pretend that the reprisals against him make no difference.

If scientific exchanges are to continue, then they must be seen to serve science and scientists — not the propaganda interests of the Soviet government. This, surely, is the time to implement a policy of "accept no substitutes"; to turn away from conferences those uninvited participants who turn up, armed with an irrelevant and insignificant paper, in place of the invited speaker whose passport somehow failed to materialise; and to protest against the terms of the form, signed by every Soviet scientist leaving the country, which limits his discussions to materials already published or passed for publication in the "open journals", thus cutting out the discussion of work in progress which is one of the most valuable features of any scientific meeting. And, when attending conferences in the Soviet Union, to make every effort to contact one's opposite numbers who may have been excluded from the conference — even if taking place in their own speciality and in their own home town — as happened a few years ago to the Goldshtein brothers.

Finally, when the occasion arises in the course of such conferences and contacts, scientists should relentlessly press for the implementation of those human rights agreements for which Sakharov has become, *par excellence*, the symbol of the concerned scientist. Indeed, perhaps the greatest tribute to his work is that the Soviet authorities now expect scientists who go abroad for conferences or exchanges to be challenged on such matters. In signing the pledge form referred to above, the Soviet scientist officially commits himself to answering all such enquiries according to the principles laid down in the official Party press. ☐

1981 budget reverses shift from physical sciences to life sciences

Defence research increases set the pace for a 13% growth in the R&D budget which President Carter is asking from Congress in 1981. **David Dickson** reports from Washington

THE Carter administration is seeking to use the 1981 budget to reverse what it sees as a "disturbing trend" in science policy over the past decade and a half, namely a relative decline in funding for research in mathematics and the physical sciences compared to the growth in medical research and life sciences.

Official calculators, for example, show that support for physics dropped by 13.5% in real terms between 1967 and 1980, and for mathematics by 16.7% over this period. In contrast funding for the life sciences increased by 19%, and the environmental sciences experienced a real growth of 33.7%.

Moves to correct this imbalance — for example within the budget of the National Science Foundation, which plans to give particular emphasis to increasing support for fields such as computer science — figure prominently in a budget request also characterised by a growth in research projects jointly sponsored by the federal government and private industry, and dominated by significant increases in Defense Department expenditure on research.

Overall President Carter, who singled out basic research in his budget message to Congress last Monday, as one of the few areas meriting increased support, is asking Congress for a 13% growth in support for research and development, including a 12% increase in funds for basic research.

Given an officially-estimated increase in cost of 9% (a figure some claim to be overly-optimistic) this will mean real growth in 1981 of 4% and 3% respectively in the total R&D and basic research expenditures.

Much of this is directly due to increases in the military research budget. Military sponsored R&D is planned to grow by 20.2% — including funds for research in very high speed integrated circuits and for full scale development of the MX intercontinental ballistic missile — and military support for basic research will be up by 21.4%.

The growth in the budget of the National Aeronautics and Space Administration will be comparatively smaller, at 9.8% for overall R&D (taking into account an extra $300 million being requested for 1980), and 11.5% for space science.

However Dr Robert Frosch, Administrator of NASA, calls it a "good start" to the decade, with growth in all areas of the budget, at least compared to last year when the extra costs of the space shuttle meant no new space science programme starts.

Included in NASA's request for 1981 are funds for a gamma ray observatory, and an operational National Oceanic Satellite System (NOSS), which will build on the success of last year's SEASAT mission, and will be jointly funded with the Department of Defense and the National

Energy department announces 'slip' in laser fusion

THE Department of Energy has decided to allow "slippage" in construction work on the NOVA neodymium glass laser and irradiation facility at the University of California's Lawrence Livermore Laboratory in order to ensure a "more balanced" programme of advanced driver studies for inertial confinement fusion technology.

Construction work on NOVA started last year, and over $80 million will have been spent on the project by the end of the current fiscal year. However in its budget request for 1981, the department has included no extra construction money — although it says that construction work will continue. Final costs are estimated at $136 million.

In contrast to inertial confinement, the budget for magnetic fusion research has been increased by 13.5%, to a total of $403.6 million. This figure includes a 40% increase for development and technology, and a 36% increase for applied plasma physics.

NSF to fund laboratory renovations

THE National Science Foundation is planning to introduce a new programme to help universities renovate out-dated research facilities. Federal funding for the first year of the programme will be $14.3 million, and the money will be awarded on a matching-grant basis, with academic institutions matching federal support with funds from non-federal sources.

According to NSF director Dr Richard Atkinson, the money will not be available to buy new instrumentation or equipment, or to restock libraries, but is intended to be spent on the improvement of existing facilities, on the basis that outdated facilities "bring less than optimal return on the investment of federal dollars for support of research". A statement from the Office of Science and Technology Policy says that the cost-sharing programme will focus on "the nation's most productive research universities".

Defense Department increases university research support

THE Department of Defense plans to increase by about 25% in 1981 its support of both research and development in general, and basic research in particular, carried out by US universities.

Figures released by the Office of Management and Budget indicate that DOD support for university research is expected to increase only 10.5%, from $401 million to $443 million, part of an overall 9.5% increase in federally-funded university research predicted to reach a total of $4.6 billion.

However Dr Frank Press told a press briefing that according to Dr William Perry, Defense Under-Secretary for Research and Technology, new programmes planned by the DOD will mean that the actual increase is more than twice this rate. Overall support for basic research by the Defense Department is proposed to increase by 21% in 1981.

Energy research: less for nuclear, more for coal

PRESIDENT Carter is recommending to Congress that the Department of Energy's support for nuclear fission research be reduced by 22% — largely by abandoning work on the Clinch River liquid metal fast breeder reactor — but that there be a 34% increase for research into the uses of coal.

Despite a continued failure to persuade Congress to accept his arguments for killing the Clinch River project, the President is recommending that support for LMFBR research be cut from $615 million to $300 million. In addition, he is also suggesting that research be terminated on the gas cooled fast breeder concept, currently supported at a level of $26 million a year and on the thermal reactor fuel cycle.

Reflecting a growing political interest in coal as a source of energy, the budget recommends coal research be increased from $779 million to $1047 million.

0028-0836/80/05416-02$01.00

Oceanic and Atmospheric Administration.

Funds for basic biomedical research at the National Institutes of Health are scheduled to be raised by 6.2% to $1.7 billion. Congress is likely to add a little to this figure, but it will be nowhere near as substantial as in the last decade.

Of the various biomedical research institutes, the National Institute of Environmental Health Sciences is slated for the biggest increase — 15% — and the Institute of General Medical Sciences 6%, while the two largest institutes, the National Cancer Institute and the National Heart Lung and Blood Institute, are planned to grow 0.7% and 3.8%.

In the National Science Foundation, which is planned to increase its basic research budget by 18.8%, special emphasis will be given to supporting research in the physical sciences and engineering. For example, the budget request allows for a 16% increase for physics research, 28% for computer research, and 28% for electrical, computer and systems engineering research.

In contrast, support for biological, behavioural and social sciences is scheduled to grow by only 9.3% — scarcely above the expected level of cost inflation.

Prominent in the NSF's budget request is increased funding for research projects jointly sponsored with industry, a move prefigured in the President's innovation message to Congress last November. For example, support for small business innovation and industrial technology will grow from $7.4 million to $18.2 million, and for industry/university cooperative research from $7 million to $20 million.

The most dramatic manifestation of this new linkage is agreement between the NSF and several major oil companies to jointly sponsor a 10-year, $700 million ocean margin drilling programme (*Nature* 24 January page 321) using the ship Glomar Explorer as a drilling base.

But the Foundation will also be developing a comparable programme of automotive research, which will receive initial federal funding of $20 million in 1981. The estimated costs of $1 billion over ten years will be shared between government and the automotive industry. ☐

1. Obigations is the amount of money committed to a programme
2. Takes into account extra $300 million requested for 1980
3. Excludes cost of spacecraft
4. Excludes energy research money expected from energy security

---

Part of these funds will go to three large demonstration projects for coal liquefaction and gasifaction processes, carried out on a cost-sharing basis with private industry.

$15 million allocated for new UN science fund

THE Carter administration proposes in its budget request to contribute $15 million in 1981 to an interim fund to support scientific activities in the Third World agreed at the UN Conference on Science and Technology for Development (UNCSTD) in Vienna last year. The size of the contribution is less than had initially been hoped for, and some feel this may reflect US unhappiness about the reorganisation of science policy machinery within the UN.

High energy physics keeps its head just above water

DESPITE previous agreement that funding for high energy physics would do no more than keep pace with the general rise in costs, the administration has responded to recent complaints by the physics community and agreed to a 10.5% increase in the budget for 1981, officially representing a 1.5% growth above the predicted 9% inflation rate.

This increase will bring the HEP budget to a total outlay of $350 million in 1981, a sum which includes the final year of funding for Fermilab's energy saver/doubler project, and the initiation of the tevatron colliding beam facility at the same site.

A 9.5% increase is being requested for nuclear physics. In addition to supporting the continued construction of the National Superconducting Cyclotron Laboratory at Michigan State University, this money will also allow construction work to begin on a tandem accelerator system at the Argonne National Laboratory.

Gamma ray observatory preferred to comet mission

PLANS for a gamma ray observatory were given funding preference by the National Aeronautics and Space Administration over a proposal to initiate work on a joint flight to the comets Halley and Tempel 2 because it offers "a more fundamental mission", according to NASA Administrator Dr Robert Frosch.

The administration is asking Congress for $19.9 million to begin work on the observatory in 1981, a project actively canvassed for by space scientists for several years as a successor to earlier gamma ray satellites. The observatory is now scheduled to be launched from the space shuttle in 1985.

Dr Frosch told a press briefing that there was a "reasonably good chance that the much-delayed space shuttle, still officially scheduled for launch this summer, would have its first flight by the end of the year, although there was a likelihood that it would have to be postponed until the first quarter of 1981. In addition to a 1981 budget request $800 million more than originally planned for the shuttle, NASA is also asking Congress for an extra $300 million for the current year to cover unexpected costs, largely the result of problems with fixing insulating tiles to the shuttle's surface.

NIH to reduce training grants

THE National Institutes of Health is to reduce the number of training grants for postdoctoral students in 1981 by 7% from the 1980 level of 10,175. The most significant reduction will be in individual grants, which will drop 33% from 1626 to 1080. Institutional grants will be reduced by 2% to 8390. At the same time the value of stipends will be increased by about 5%, and this comes on top of a 30% increase agreed for 1980. In 1981 stipends will range from $14,040 to $17,892 a year, compared to $10,000 to $13,000 in 1979.

The total value of training grants issued by NIH will be reduced by 7.4%, from $176 million to $163 million. At the same time the administration has agreed to keep the number of new competitive research grants at about 5000.

United States

PCP dioxins found to pose health risks

Following wide debate on the hazards of TCDD, US scientists are now expressing concern about the possible health hazards of low-level exposure to other dioxins, particularly those in the widely-used wood preservative pentachlorophenol (PCP). **David Dickson** reports

SEVEN years ago, Dale Feucht, a dairy farmer in Canton, Ohio, decided to build a new barn for his herd of several hundred cattle. Two months after the animals had moved into their new home, they began to suffer various ailments, from general ill health to a rapid drop in the calf survival rate.

Veterinarians were at a loss to explain or treat a variety of apparently unrelated symptoms, affecting both existing stock and the animals bought to replace those that died. Within a few years, the herd had been decimated, and the last cattle died last summer.

Having eliminated changes in the water or feed supply as the source of the problem, suspicion focused on the one new factor in the environment, the barn. In particular high levels of pentachlorophenol (PCP), used to treat the wood as a preservative, was found in blood samples from the dead animals — assumed to result from the cattle chewing or rubbing the wood.

Mr Feucht is now suing the barn manufacturers, Morton Company. The case, to be heard in Ohio within the next few weeks, is being watched by many large chemical companies.

For PCP is currently one of the most widespread chemicals in domestic use, particularly in demand for its highly effective anti-fungal and anti-bacterial properties. Over 50 million pounds are produced annually by over 250 companies, and world-wide production is more than 100 million pounds.

Recent events, however, have started to fuel public controversy over the long-term, low level effects of dioxins that have so far been largely overshadowed by the more obvious effects of the most toxic dioxin, tetrachlorobenzo-p-dioxin (TCDD), both a contaminant of the herbicide 2, 4, 5-T, and the chemical released in the Séveso accident in 1976.

The toxic properties of PCP itself have been known for some time. Ironically it was the development of oedema in chicks that first warned scientists of the possible dangers of dioxins. Little is known of the physical, chemical and toxicological properties of other dioxins, particular the hexa-, hepta-, and most prevalently in PCP, the octachlorodibenzo-p-dioxin.

So far, no firm action has been taken against PCPs, which remain on the shelves of hardware stores throughout the country merely with warnings about the need for careful use. Timber companies, for example, do not issue warnings with wood that has been treated with PCP.

Two years ago, the Environmental Protection Agency, following evidence of the teratogenicity and feto-toxicity of PCP during animal laboratory tests, announced that it was studying whether tougher regulations were needed. These are now expected to be published later in the year.

In the meantime, the lack of strict regulations meant that the Dow Chemical Company, having introduced a new preservative, Dowicide EC7, in which dioxin levels had been reduced two orders of magnitude by using more expensive production techniques, found the product uncompetitive against rival, non-decontaminated brands. Dowicide EC7 has now virtually disappeared from the market place.

But the political momentum previously lacking may now have arrived. Last year residents near the Lexington Blue Grass army depot in Kentucky started to claim that a high local incidence of leukaemia, as well as various other medical disorders, was the result of exposure to PCP used to preserve ammunition boxes at the depot.

Not only had workers in the depot been exposed to the chemical, but wood from the boxes had been sold off for as little a one dollar a car load. This was used primarily for firewood, but investigators subsequently found a range of other uses, including the construction of porches, barns, chicken coops and pigpens.

Following information collected by a local physician, a preliminary study carried out for the EPA by research workers from the University of Miami confirmed that there appeared to be an abnormally high incidence of leukaemia in the area.

Further data are now being collected by researchers from the National Institute of Occupational Safety and Health. They face a double detective task: first to discover whether the leukaemia incidence is substantiated by epidemiological data: secondly to determine whether, given the other substances at the base heavily used duirng the Vietnam War to store chemical warfare agents, the blame can be placed on the PCP.

But in the wake of the Agent Orange and Séveso incidents, suspicion has been focused on the wood preservative and the contaminants that it contains. And in addition to results of laboratory animal studies, this suspicion is also supported by recent research carried out at the National Institute of Environmental Health Sciences and North Carolina State University into the effects of PCP in cattle feed.

Research workers at the two institutions conducted a study under which five groups of heifer were compared over a 160-day period. One group was given a feed containing analytical PCP prepared in the laboratory, a second fed with technical PCP containing the dibenzodioxin and dibensofuran contaminants found in commercial preparations. Two groups were given a mixture of the two. The fifth group was used for control.

The results of the research, which are soon to be published, indicate a number of dose-related effects in the heifers exposed to the contaminated PCP, compared to the controls or those exposed to the analytical PCP. These included a decrease in body weight and feed efficiency, as well as progressive anaemia, and at the end of the test the researchers found a number of unexpected lesions in cattle using the contaminated feed, in particular in the mucosa of the urinary bladder through which the PCP would have been secreted.

"The results of our study show clearly that the toxicity of PCP in cattle is primarily attributable to its contamination with toxic impurities, either the dibenzodioxins or the dibenzofurans," says Dr Eugene McConnell, head of the Comparative Pathology Section of NIEHS and principal investigator of the study.

Which of the two is the culprit has not been demonstrated, but the North Carolina results are broadly compatible with evidence from low level exposure of monkeys to dioxins currently being carried out by Dr James Allen at the University of Wisconsin. Despite its lack of conclusiveness, such scientific evidence is likely to play an important role in forthcoming court cases.

William Brown, the attorney representing Mr Feucht, said last week that he was already dealing with two other PCP-related claims, one from a family that had built a house from PCP-treated timber supplied by a do-it-yourself construction company, the other from a farmer claiming disability after handling PCP-treated posts.

Mr Brown added that he had been contacted by others with similar complaints. A number of other court cases are pending in Michigan. "Everyone is watching this case very closely," says Mr Brown, pointing to the widespread use of PCP-treated timber, not only in homes and farm buildings, but also for railway sleepers and telegraph poles. "I really think it is the tip of the iceberg." □

Soviet Union

Sakharov arrest threatens East-West scientific exchange

Vera Rich reports on the reactions of the scientific community in the West to the arrest of Dr Andrei Sakharov (right) in Moscow last week and his subsequent internal exile

BANISHING Dr Andrei Sakharov, physicist and leader of the human rights movement in the Soviet Union, to Gor'kii is not the way to promote international scientific exchange. This is the clear consensus of the western scientific community.

Referring to Sakharov's "internal exile" as "a shocking" and "a blatantly punitive" act, Dr Philip Handler, President of the US National Academy of Sciences, noted that "in recent years the scientists of both nations have carefully built structures of communication and good will", and that the move against Sakharov "can only be regarded as a challenge to further cooperation and an act of deliberate ill will. . . . I find it difficult to imagine scientific exchange continuing in the spirit we had created heretofore."

"The exile of Professor Sakharov", said Kenneth Boulding, Chairman of the Board of Directors of the American Association for the Advancement of Science, and Frederick Mosteller, President of the AAAS, "deprives the people of the Soviet Union and the world of a brilliant voice in support of mutual understanding and the defense of human freedom". His banishment, according to 25 US Nobel laureates, who sent their own personal telegram to Brezhev "will silence an eloquent voice of wisdom desperately needed in our troubled world".

For the US Committee of Concerned Scientists, Drs Max Gottesman and Mark Kac, expressed their concern that the move against Sakharov coming "as the aftermath of Afghanistan" might "portend a change which threatens the continuance of cultural and scientific relations between our two countries." Telegrams from the French Academie des Sciences and Société des Physiciens expressed similar shock and concern.

In London, the "President and Officers" of the Institute of Physics, expressed "shock and dismay" fearing that "this action . . . will damage both Soviet physics and the relations between Soviet and British physicists". The Royal Society, with its usual diplomacy, expressed the view that "voices sound louder through doors that are open than through those that are locked".

This is not the first time that western colleagues have felt obliged to leap to Sakharov's defence. In September, 1973, an ominous *Pravda* article, entitled "To be a Russian scientist means to be a patriot" was widely seen as a first move towards expelling Sakharov from the Academy of Sciences. No expulsion in fact took place, perhaps due to the storm of foreign protests the article provoked, but also to the reluctance of the Soviet Academy to permit undue government and Party meddling in its internal affairs. (The Academy is the last remaining Soviet body to have elections by secret ballot with a plurality of candidates). A short while later, when a similar attempt was made to deprive Veniamin Levich, the Jewish "refusnik" of his "Corresponding" (i.e. Associate) membership of the Academy, the attempt failed, his son Aleksandr told *Nature*, "because even some members who were quite anti-Semitic had decided to vote against the motion, feeling that their own position was threatened by any attack on the Academy".

Perhaps as a pre-emptive measure against such academic solidarity, Soviet "explanations" of the Sakharov affair have stressed how much he is out of step with the ideal of a Soviet scientist. The initial allegation (in *Izvestiya*) was that he had abandoned science for "the political walk of life" following a crisis in his own creativity. (No mention was made of his sudden dismissal from his government job — following the *samizdat* publication in 1968 of his "thoughts on Progress, Coexistence and Intellectual Freedom").

This approach, however, was negated when the western media stressed that Sakharov had been arrested on his way to a physics seminar at the Academy of Sciences — and by confirmation from close friends that he was still, in spite of the demands on his time made by his human rights activities, keeping up his theoretical work on physics, though with little hope of publication. Indeed, the *Izvestiya* accusation, that Sakharov was being "used as a channel for passing on important Soviet secrets to the . . . imperialist powers" was incongruous with their allegation that he had abandoned science.

The next stage came with an attack on Sakharov by individual members of the Academy. Academician Evgenii Fedorov spoke of the committment of Soviet scientists to "social work, the struggle for peace, cooperation with our colleagues abroad in science and technology" (almost echoing the title of Sakharov's first essay!). A "large community" of Soviet scientists, he said, are "fed up with Sakharov's remarks and his general attitute . . . contrary to everything for which Soviet people, including representatives of Soviet science, have fought". Academician Mark Mitin spoke of the "humanitarian" action of the Soviet government, which in spite of Sakharov's slanders of the Soviet way of life had simply deprived him of his state honours and sent him out of the capital. Nevertheless, Mitin observed unctuously, "as a member of the same Academy of Sciences I cannot but feel sorry about the downfall of this man."

Some, it would seem, felt more than mere sorrow. The resignation of Vladimir Kirillin from his posts as Deputy Prime Minister and head of the State Committee for Science and Technology was almost certainly connected with the Sakharov affair — though speculations vary as to whether Kirillin resigned voluntarily in protest or was manoeuvred into a situation where resignation became inevitable. Of recent years he has been a well known visitor to Britain to negotiate extensions to exchange agreements in technology and trade. (The next round of talks, due in London in May, will almost certainly now be at least postponed).

During the past few months, there have been a number of indications of conflict between the State committee (which comes directly under the government) and the Academy, which still shows a remarkable independence of spirit, paticularly where its own autonomy is concerned.

Although the move against Sakharov must be seen against a whole wave of repressions against a wide spectrum of human rights activists over the past few months, the fact that the authorities felt able to renew their challenge to the Academy may suggest that the strength of the Academy has somewhat waned in comparison with 1973. Certainly, it is Dzherman Gvishiani, a representative of the State Committee who will lead the Soviet delegation to next month's Hamburg Forum — an event which, incidentally is still going ahead, although as one of the organisers told *Nature* "current political tensions will naturally be reflected there in some way". □

Soviet Union

Fire threatened fast reactor cooling system, says unofficial report

"WE have no accidents which would give rise to anxiety among people and set them aginst the development of nuclear power engineering," Andronik Petrosyants, chairman of the State Committee for the Utilisation of Atomic Energy, told the press recently.

This, however, is not the opinion of the townspeople of Sverdlovsk, in the Urals. A clandestine report which has just reached the West gives a vivid description of the alarm caused by a fire at the Beloyarsk nuclear power station some 60 km away.

The author, who identifies himself only as "N.N" appears to have inside knowledge of the workings of the power station. He alleges that during New Year's Eve celebrations in 1978/79, a fire started in the "machine hall". Several firefighters lost their lives in combatting the blaze. It was not brought under control until "everything that could possibly burn was completely burned up."

"N.N" admits that there was no immediate risk of the reactor exploding; however, the reactor cooling system was, he says, threatened. The Beloyarsk station has a fast-reactor, and the primary circuit of the heat-exchanger contains highly radioactive molten sodium at 500°. A rupture in the primary circuit would cause an explosion scattering radioactive material in a cloud like that produced by the 1957 Kyshtym disaster.

"N.N" says that the threat of a similar cloud from Beloyarsk was sufficiently real for the authorities to provide special trains and buses, standing by to evacuate, if necessary, the settlement of Zarechnyi close to the plant.

Following the fire, says "N.N", a KGB team from Moscow, led by a General, came down to investigate. Their findings remain, he says, unknown, but the local population feel that a significant part was played by the fact that "the shift was drunk, like almost everyone else in the Soviet Union that night." No official allusion has been made so far to any fire at Beloyarsk.

Like the 1973 fire at the Shevchenko fast breeder, which was due to a rupture in the sodium circuit, the Beloyarsk fire was not technically a "nuclear" disaster. According to Academician Anatolii Aleksandrov, President of the Soviet Academy of Sciences and himself an experienced nuclear engineer, fully half the funding of nuclear power stations is spent on safety.

This however, N.N's report suggests, is insufficient; the human factor also must be taken into account. **Vera Rich**

High energy physics

End of the physics phoney war

Competition for the prize of the intermediate vector boson is leading to doubts about the future of CERN, the European centre for subnuclear physics. But the real competition may be trans-Atlantic. **Robert Walgate** reports

IN a few weeks' time, the European Committee for Future Accelerators will be holding an extraordinary meeting to discuss what amounts to a perceived competition between West Germany and CERN. ECFA, which has no constitutional power but which represents the views of an influential body of European physicists, is thus cautiously falling in line with Italy, which first shed doubt on Germany's intentions.

The Chairman of ECFA, French physicist Professor Marcel Vivargent, was recently quoted in an Italian newspaper as saying that Italian efforts to clarify CERN's future programme "merits the best attention" and is supported by many European physicists. (In late December, the Italian delegation to CERN walked out of a meeting of CERN Council in a protest at "lack of sufficient discussion" of CERN's future, and allusion to potential German competition.)

Vivargent told *Nature* that he understood the Italian position, as a relatively small nation relying on CERN: "they want CERN to remian the top lab in Europe". He also said that he understood the German desire to find a future for its lab, DESY. The problem, which had been neglected by CERN Council, was to mesh the two objectives together.

Strictly ECFA will be discussing 'complementarity' between two accelerator proposals; HERA for the German laboratory DESY near Hamburg, and LEP for CERN. HERA is designed ultimately to collide 30 GeV electrons with 820 GeV protons and shed light on interquark forces, and perhaps the structure of the quark. (It is equivalent to a 52 TeV electron linac firing at a stationary target, giving a 'spatial' resolution of some 100,000th part of the proton radius.)

But the first part of HERA, according to its coordinator Bjorn Wiik, will collide 35 GeV electrons with equal energy positrons. It will operate in this mode for four years before the proton ring is complete. "Our proton ring will be by far the biggest superconducting effort in Europe" explains Wiik "so we have allowed a long lead time to build it". According to present targets, the electron phase of HERA will be ready in 1985, and the protons in 1989.

LEP, on the other hand, is dedicated to the collision of electrons and positrons at beam energies between 22 and 130 GeV. Protons do not come into the proposal, although the proximity of the CERN complex of proton machines, up to the 400 GeV SPS, make the use of protons a possibility.

The gem in this energy range is the Z^0, which at 90 GeV would be the heaviest particle yet and a key element in the unified theory of the weak and electromagnetic interactions. In the theory, due to Abdus Salam and Steven Weinberg, the Z^0 plays the role of the photon in the weak interaction (which causes nuclear decay and limits the output of the stars).

The Z^0 (or neutral intermediate vector boson) is mesmerising physicists like Moby Dick mesmerised Captain Ahab. LEP would create it (if it exists) with 45 GeV colliding beams. So would HERA, if it could be stretched up to that energy; and since approval for LEP is unlikely to come before mid-1981, and construction (at a constant CERN budget) is predicted to take seven years, there is a possibility — it is argued — that HERA would have snatched the Z^0 four years before LEP.

The question is actually more complicated, because CERN is likely to find the particle in 1981 — but not with LEP. CERN is building a proton-antiproton collider which will produce 270 GeV on 270 GeV collisions towards the end of 1981, with a view to creating a few Z^0s. But it will not produce many — opinions

Machines which might compete for the Z^0

Device	Projected cost	Circumference	Earliest likely physics	Beam energy	Luminosity* +
LEP	$640m	30.6 km	1989+ + +	22-130 GeV**	10^{32}cm^{-2}s^{-1}
HERA	$167m + +	6.5 km	1985 (electrons)	35 GeV	10^{32}
SPC	$60m	1.8 km*	1984	50 GeV	10^{30}
antiprotons	(budgeted)	6.8 km +	1981	270 GeV	10^{30}* + *

* in two loops

+ in the SPS ring

** main option 86 GeV

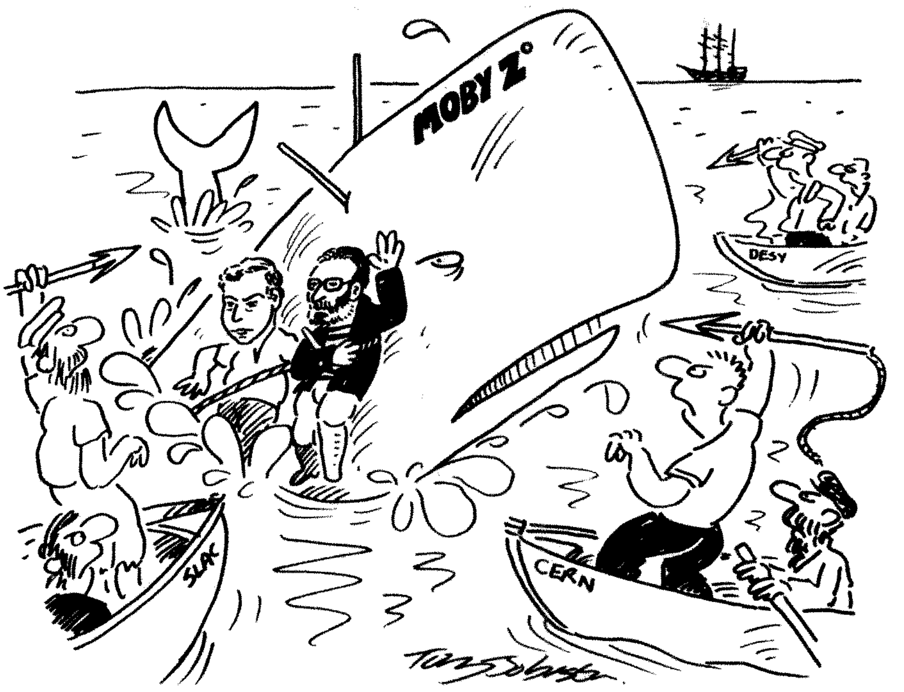
+ + electrons only; with protons double this

* + event rate per unit collision cross-section at peak energy

* + * fraction of events producing Z^0 some 30 to 50 times lower

+ + + could be earlier if large fraction of present research programme cut

0028-0836/80/05420-02$01.00



differ, but perhaps some four orders of magnitude fewer than LEP — and those will come among a great deal of unwanted matter (from the spare quarks in the proton and antiproton).

The goal is to produce a lot of clean Z^{0}s, so that they can be studied in detail. If HERA stole LEP's thunder, questions would be asked about the value of LEP. And since CERN has argued that it can run down a number of its facilities, such as the intersecting storage rings, to leave room in its present budget to build LEP, it may find that member states are asking it to run down — without LEP.

But Wiik, HERA's builder, quashes the speculation. "At 45 GeV, the synchrotron radiation [X- and gamma-rays emitted as the electrons turn corners] in HERA might be completely prohibitive" he told *Nature*. "And we'd need a large investment in extra cavities — something we haven't budgeted for".

The principle limitation on the energy of electron machines is the amount of radiofrequency power that can be pumped in to keep the electrons in their orbits, to compensate for synchrotron emission. The field of the bending magnets is usually low, and not a limitation (contrasting with proton machines).

"Furthermore" says Wiik "the geometry of the machine is not optimised for 45 GeV". DESY has designed in long straight sections (which increases corner curvature and hence synchrotron radiation) to allow polarisation of the electrons for electron–proton studies. Wiik could not give a figure for the power consumption that HERA would demand at 45 GeV (although it increases from 8 to 13 MW from 30 to 35 GeV) but added that "I don't know even if we would have room to put the extra cavities in". According to one observer, superconducting, cavities would be necessary, and these are not likely to be available by 1985.

The HERA design is almost complete; and later this year there will be an application to Bonn for the DESY budget to be increased by some DM60 million a year from its present DM150 million. Over 10 years, this would be expected to pay for both phases of the accelerator; there will not be a formal application to build HERA. The CERN subscription would not be affected either; "that money comes from a different pot" said a DESY spokesman.

Competition for LEP, however, may arise from an entirely different quarter: the United States.

Over on the West Coast, at the Stanford Linear Accelerator Center, Professor Burton Richter has a plan for a cheap "Z^0 factory". At an estimated $60 million ("plus or minus 25%" says Richter) the 'single pass collider' would undercut first phase HERA costs by a factor of three, and LEP (main 86 GeV version) by a factor of ten.

Richter's device gambles on the presence of the Z^0 (a fair bet) and makes use of the 90 GeV resonance to avoid the need for large and costly storage rings. Thus Richter turns the tables. His small storage ring SPEAR won him the Nobel prize and set the current fashion for storage ring physics (LEP is basically a scaled-up version of SPEAR).

Since the cross-section at the resonance will be very high, he reasoned, a single collision between one bunch of electrons and one of positrons should be enough to produce a reasonable number of events. So he constructed a plan around the SLAC one-mile electron linac that would do the job. It involves increasing the energy of the accelerator to 50 GeV; and accelerating an intense pulse of positrons down the linac followed, 20m behind, by one of electrons. At the end of the accelerator these pulses are wheeled around a radius of 300m one to the left and one to the right, and brought into collision.

Richter is very confident that the machine can be built, despite very close tolerances. SLAC is pursuing a design study and will make a request in March for full funding. If the application went smoothly, the SPC could begin building in October 1981, "but I give that no better than evens" said Richter. In the long term he considers political prospects for the collider to be "very good. Everyone is enthusiastic about it".

Since the project is small enough to avoid the need for an externally imposed managing architect (the choice of which delayed PEP, SLAC's medium energy electron ring, due to start in March, by nine months), the SPC could be built in two and a half to three years, thinks Richter.

The technical obstacles are: accelerator improvements, where SLAC is putting in its largest theoretical effort (it will be necessary to align the accelerator components to 0.3mm to stop the long pulses slewing around, tail to the side) increasing the brightness of the positron source by a factor of two (a design exists for a factor ten, but engineering R&D is necessary); "damping" the energy spread of the positrons from the source; synchrotron radiation in the 300 m bends; and a final focus of the beam spots to 2 μm.

This latter compares with the 100 μm × 1000 μm spot in SPEAR, or the 90m diameter spot emerging from the linac. But the exercise is one of geometrical optics, particularly getting rid of the 'chromatic' aberrations present in the beam transport system given a beam momentum spread of 0.5% and this is designed in principle.

Finally the question is the number of Z^0 that the SPC could produce. "A million a year" says Richter — quite enough to learn a lot of physics. LEP would have 100 times more, and eight experimental regions, but the SPC ought to be able to detect all but the rarest decay modes of the particle.

This leaves LEP with the rare decay modes, and its higher peak energy, which with its main (86 GeV on 86 GeV) version should produce the charged companions to the Z^0, the W$^+$ and W$^-$, which are produced most efficiently in pairs.

This is good physics, but there are some doubts about how efficiently a storage ring could work at this energy. Further the power consumption will be extremely high (some 250 MW at peak power). LEP will consume an average 750 GW hours per year for 3,000 hours of experiments at 85 GeV raising doubts about running costs against electricity costs in the late 1980s and 1990s.

Although physicists are in wide agreement that LEP is by far the best possible machine to explore the physics of the Z^0 and the Ws, and to search out what lies beyond Weinberg and Salam, the machine is strangely beginning to look like a Rolls Royce against competition of a Model-T Ford which, nevertheless, gets you where you want to be. □

NEWS IN BRIEF

Livermore earthquake raises safety concerns

A debate about the safety of nuclear research facilities at the University of California's Lawrence Livermore Laboratories has been rekindled by an earthquake which hit the laboratory last Thursday causing minor injuries to almost 30 employees, and leakage in a storage tank containing tritium contaminated water. According to the laboratory, no radioactive material was released into the atmosphere or the environment as a result of the accident and key research buildings containing plutonium and tritium sources were undamaged. However, the laboratory added that a 30,000 gallon tank containing 50 microcuries/cc of tritium had leaked about 50 gallons into an asphalt basin on the ground, although none had escaped from the containment building.

The earthquake is also reported to have caused $1 million worth of damage to the Shiva facility. The bolts, holding down the metal frame holding the 132 ft facility, sheared. Other damage at the laboratory included the displacement of filing cabinets and office trailers which were knocked off their stands. Last year, the earthquake hazards faced by the laboratory became a major source of controversy when local groups seeking to curtail nuclear weapons research at the laboratory claimed that earthquake damage could lead to a major leak of radioactivity. Last week's earthquake which measured 5.5 on the Richter scale and was centered 10 miles from Livermore was one of the severest to hit the San Francisco region since the major earthquake of 1906.

Plan to dump toxic wastes in Third World

A number of US waste disposal companies are drawing up plans to dispose of toxic wastes in Third World countries as a result of the imminent introduction of strict regulations covering the dumping of such substances by the Environmental Protection Agency.

One Colorado company was reported last week to have plans to open waste recycling plants in three foreign countries, thought to be Sierra Leone, Liberia and Chile. Officials from the company, Nedlog Technology Group Inc., said that the plants are planned to extract metals such as copper, cadmium and zinc from industrial wastes.

Under new regulations it might prove impossible to dispose of wastes from this process in the US. The company was therefore "looking overseas to find countries that need foreign exchange and jobs and have the plant sites," said company vice-president James R. Wolfe.

State Department officials, however, are worried that any such moves by US corporations could generate a backlash in the developing countries, which might decide jointly to "condemn the US for dumping its wastes in the black man's backyard".

Deutch to resign from Energy Department

THE US Department of Energy confirmed last week that Dr John Deutch, previously director of the Office of Energy Research, and currently Under-Secretary of Energy — the third ranking position in the department — had submitted his resignation to the White House.

During his nomination hearings before the US Senate in 1977, Deutch made it clear that he intended to remain in Washington only for a limited period of time before returning to his position as professor of chemistry at the Massachusetts Institute of Technology.

However, speculation about Dr Deutch's future plans have been raised by reports that he may join President Carter's re-election campaign as an energy adviser and that White House aides are said to be increasingly disappointed with the political performance of Energy Secretary Charles Duncan. In particular, they are critical of his failure to "politicise" the department, for example by not taking a strong public stand criticising Senator Edward Kennedy's opposition to the decontrol of oil prices.

Nobel Prize changes Pakistan's science

Science in Pakistan has received a major boost after the award of the 1979 Nobel Prize for phycics to Abdus Salam. Pakistan's President, General Muhammed Zia-ul-Haq has publicly promised to allocate 1% of the country's GNP for scientific and technological research in accordance with suggestions made by Salam. This would mean an expenditure of $100 million annually instead of only $20 million at present.

The President has also agreed to give serious consideration to another far reaching proposal made by Salam at the Special Convocation held at the University of Islamabad during his recent two week visit to Pakistan. That is to make science, like religion, a compulsory subject at all levels of education. Since Salam's visit, scientists have been made exempt from the general ban on travel abroad.

Azim Kidwai

French cracks cause new nuclear start up delay

THE French Ministry of Industry announced last week that it would postpone by "several weeks" the scheduled start up of the troubled nuclear reactors, Gravelines I and Tricastin I. Cracks in the tubular base plates of the heat exchangers in the primary cooling circuits have already caused delays because of strike action by the trade unions involved who have demanded additional safety measures. The new delay will permit further tests to be made on equipment that has been desgined to follow automatically the evolution of the cracks during the lifetime of the reactors. Preliminary tests of the monitoring equipment by the manufacturer, Framatome, have been inconclusive because they have been done on surplus plates, originally scheduled for export to Iran, that have no cracks.

In the meantime, a petition campaign launched last June by 22 organisations for "an alternative energy policy and for a democratic debate on energy" has received 500,000 signatures.

Ariane given to private industry

THE council of the European Space Agency made final last week the French proposal to transfer the Agency's launch capability to the private firm Ariane-Espace. Ariane-Espace will be responsible for production and launching of all future ESA satellites. It will charge the Agency the following prices for various kinds of launches: 175mFFr for a launch requiring full Ariane power, 150mFFr for a satellite launch requiring only part power, and 95mFFr for a satellite that can be launched along with another in a double payload. The director-general of ESA will engage in discussions with the directors of Ariane-Espace to elaborate the details of the arrangement.

The ESA council also voted approval of the delayed 1980 budget and made the Earthnet programme of earth and meteorological satellite observations part of the official ESA budget. Earthnet had been previously funded on a voluntary basis by member states. The council also voted the funds for the Spacelab programme. In a related development, Switzerland, which is not an ESA member state, voted a sum of 7mFFr to participate in future improvements of the Ariane launcher.

Correction

In *Nature* 17 January, page 237, the statement by the Scientific and Medical Committee for Soviet Jewry should read: "not only should the Hamburg meeting include on its agenda the question of the freedom of movement of scientists, also any scientific body that may arise from the meeting must ensure that a clause dealing with this problem is written into its constitution".

0028-0836/80/05422-01$01.00

China: where the new and the historical materialism interact

Although scientists in China are being forced into a new role by rapid changes in Chinese life and closer contacts with the West, they are still guided by Marxist philosophy and the principle of social relevance. In the first of three articles on developments in Chinese science policy over the past year, **Tong B. Tang**, describes the organisation of research. In future articles, he will discuss higher education and the popularisation of science.

SCIENCE in China is growing increasingly quickly. It is based on ancient scientific heritage, the tradition developed under Marxism over the past 30-60 years, and the critical adoption of western methods and ideas. The importance of the last factor, however, has yet to be assessed. Although China stresses that its science will take a different path from that of western countries, its science and technology now seem poised to fill the economic and military roles which they have long occupied in industrialised countries.

China needs to promote the national economy and to deter what it calls international and regional hegemonists with greater help from the modernisation of science. Hence, the direction and prospect of its science are bound to be of profound interest, not only to scientists and science historians, but for the world.

Most scientific research is carried out at the 112 institutes of the Academia Sinica and at the 600 or more universities. The Academia, which celebrated its 30th anniversary in November 1979, is the designated "comprehensive centre of research into the natural sciences".

The entire pure and applied science budget is administered by the State Scientific and Technological Commission with Vice-Premier Fang Yi in charge. The Commission's preferences for different disciplines basically follow the National Plan for the Development of Science and Technology, a document of many volumes which was collectively agreed at the All-Nation Science Conference in March 1978 (*Nature*, 6 April 1978, page 482). Briefly the orientation is towards agronomy and applied physics. The Plan was slightly modified when the three years of 1979-81 were recognised as an adjustment period for the national economy, and a conference was convened by the Commission in November 1979 to discuss the implementation of these modifications, particularly in the area of science and technology transfer.

The Commission allocates research responsibilities and funds to the Academia or the Education Ministry, and then successively to institutes or universities, sections or faculties, each represented by 'academic committees', and finally research groups. The Academia, nominally led also by Fang Yi, has Li Chang as its First Vice-President, and the Minister of Education is now Jiang Nanxiang. Key installations may be operated directly by the Academia or the Ministry or both. In addition, other ministries may support researchers whose work is of direct relevance to agriculture, forestry or industry. Some of them run their own chains of research institutes and training colleges. However, the infrastructure that couples the (long-term) activities of institutes and universities to research carried out at scientific farms and research and development at factories appears weak; one indicator is the relatively long delay that sometimes occurs between completion of a project and the application of its result in production.

Giant propaganda poster stresses the political context of modernisation

Vice Premier Fang Yi, in charge of China's science budget and head of the Academia Sinica, meets students in Beijing

Most research projects are assigned from above, but occasionally a research group submits a proposal to the academic committee of its section or department, whose complete programme will be reviewed by the institute or university. But it is unusual for a research group to branch out in its own research areas. This contrasts with western universities but probably resembles more the situation in government and most industrial laboratories. Last November, however, the Academia passed a resolution to give institutes the freedom of securing external funding by taking on contract work. The research unit will be able, after making sure that its state-assigned projects will be

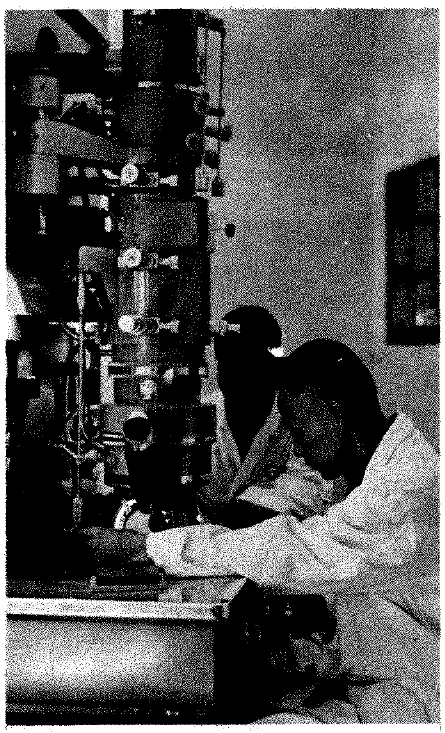
0028-0836/80/05423-02$01.00

completed on time, work on problems offered by a factory. Its time and expenses will be repaid by the factory either in one lump sum or as a percentage on the sale profit of the product concerned. It does not have to hand back to the state any net income that may result, but this procedure is said to be temporary only.

That the applied sciences continue to dominate in China is a reflection of the conviction that science receives its impetus from social needs: "from the very beginning the origin and development of the sciences have been determined by production". However the "socialist newborn-thing" of "inviting in" workers and peasants with practical experience to participate in experiments, and to a lesser extent that of scientists "going out" to work with the masses have largely gone. Now more 'pure' research is being encouraged. For example, two groups, one in Beijing, the other in Guangzhou, have started work on the detection of gravitational waves, and an observatory is planned near Kuming to carry out a comprehensive survey of the southern sky. More well known, perhaps, is the construction of a 50 GeV proton synchrotron at Beijing (the 'BPS').

Opinion is divided on the social relevance of going in for high energy physics in a big way, especially among guest advisors such as the Nobel prize winners Chen-Ning Yang and Tsung-Dao Lee. But Li Chang explained at the All-Nation Science Conference that particle physics, being a frontier subject, would play a leading role by stimulating advances in instrument technology and other fields. (The other two 'frontier sciences' which have been identified in a National Conference on Basic Sciences Planning held in October 1977 are astrophysics and cosmology, and the origin of life.) Fang Yi recently reiterated: "We consider basic research fundamental to all scientific progress".

Unfortunately, at present there is probably much duplication of applied research effort, on, for example, metal oxide semiconductor interfaces, stacking faults on oxidised silicon and other topics related to integrated circuit technology, rare earth metals as catalysts in petroleum refining, and lasers. All of these are among the priorities specified in the 1978-85 development plan. However, the nationwide coordination of research and resources and the exchange of results are hampered by bureaucratic barriers between ministries and administrative bodies, although the bureaucracy is no worse than in the West.



Worker-technicians Tsao Mu-Chuan and Chang Shih, working with China's first electron microscope

The Chinese are also discussing the relationship between central planning and local initiative. There is a trend for political authorities at the provincial or municipal level to take a greater part in the administration of science. Provided that democratic centralism is not eroded, and that the relationship of local autonomy to central control follows the changing situation, a limited devolution should make science more responsive to local needs without hindering the fulfilment of a unified state plan. Less tangible, though, are certain ideas on a 'mixed' system for research management, namely that science grows most quickly when it is also partly based on 'market economy' principles.

Many measures are still of a tentative nature. With some problems a variety of different solutions are currently being explored; a common solution will be nationally implemented only after an appraisal or reappraisal of all relevant experience. Up to the winter of 1978-79, policy statements were inclined to be contentiously forthright, for example, those concerning material incentives, learning from the West, and the professionalisation of education. Some of them were more "liberal" than in the years immediately before the Cultural Revolution, even than in the mid-1950s. Since spring of last year this tendency has been reversed. For instance, there has been more propaganda in the media and on public displays emphasising political work, revolutionary heroism, self-reliance and the danger of examination worship.

Western scientists in general and those of the social disciplines in particular are enthusiastic about the bourgeoning academic exchanges with China; about these more will be said in the next article. The Chinese welcome these developments but have firmly concluded that there is no question of importing wholesale modernisation or science and technology. The current slogan concerning foreign technology is, "use, learn, then modify, and finally invent". In April last year a meeting of academics in Beijing urged that Chinese science should retain its origina character. At the First Nationa Symposium on the Science of Science in August 1979, Li Chang reaffirmed that China will nurture a modern science, different from western science, by integrating the latter with the "dialectics of nature". Some Chinese have claimed that the dominant methodology endorsed by western science, while materialistic, is "metaphysical". This means that it contradicts the dialectical laws of thought, with its implicit assumptions of irreducible isolates and unitary identities.

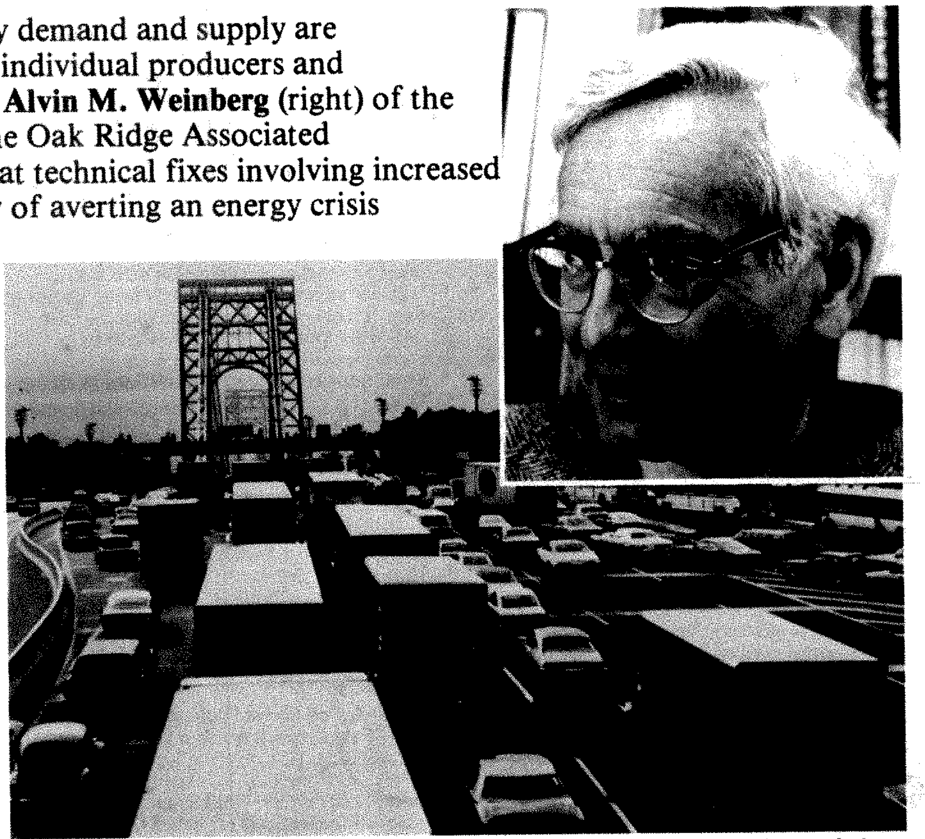
Many events confirm that the prominent features of Chinese science in Mao's era have remained intact and are being further enriched. The Chinese understanding of science (and arts) as orientated towards man's struggle in economic production comes from Marxist historical materialism. Efforts to combine the modern and the traditional, initiated as part of Mao's policy of "walking on two legs", continue. For instance, the Peking College of Traditional Medicine is among the five key medical schools named by the Education Ministry, and traditional medicine is on the (essentially standardised) curricula of all fourth-year students training for western clinical practice or research. Philosophical arguments based on Marxism retain a respected guiding position in scientific controversies. For example in particle physics the quark model is overwhelmingly preferred to the bootstrap hypothesis of hadrons, and the high-sounding applications of catastrophe theory to human phenomena are generally ridiculed.

Further, guided by Mao's conceptions of "one divides into two" and the transformation of opposites, the Chinese want science to "change wastes into wealth and turn harmful into beneficial" in all agricultural and industrial processes. Lastly, to achieve modernisation and a healthy socialisation of science, the Party pledges to mobilise the whole people, in accordance with the dictum that "the mass movement is necessary in all work. Things won't go without the mass movement".

Nevertheless, in its quest for rapid modernisation, the Party has broadened the political base of decision-making and given more scope to the initiative of experts. Senior scientists now join forces with state officials to administer science and education. The press has devoted considerable space to polemics on democracy in academic discussions, or "academic freedom", meaning that the minority can sometimes be right and should always have the right to disagree. Indeed, the frustration of scientists may be understandable especially if it arises from the indifference or the dogmatism of bureaucrats. Still, the leadership will not want greater freedom to result in wasteful competition, an erosion of planned research or the ascent of deviationists and technocrats. ☐

Energy: the need for technical fixes

Model-based predictions of energy demand and supply are unreliable, since the behaviour of individual producers and consumers cannot be guaranteed. **Alvin M. Weinberg** (right) of the Institute for Energy Analysis at the Oak Ridge Associated Universities, Tennessee, argues that technical fixes involving increased supply offer the most reliable way of averting an energy crisis



Increased oil prices have not deterred US consumers, so Carter has chosen to develop synfuels

I first became acquainted with energy demand modelling when I worked for the Federal Energy Administration in 1974. President Nixon had announced Project Independece: the United States was to import no oil after 1980. The FEA's job was to figure out how to reach this goal, or at least some goal that was consistent in spirit if not in fact with the President's announcement. For this purpose, it set up the most elaborate model the budding art of energy modelling had yet seen. Many millions of dollars were chewed up on two CDC 7500s; their neatly printed graphs showed how energy would be used and how it would be supplied in the United States through the year 1985.

A prime question was the price level of imported oil at which one could expect domestic supply to be so enhanced, and demand so dampened, as to reach the goal of self-sufficiency. The computers gave a fairly clear answer. At $16 per barrel, $6 per barrel higher than the 1974 OPEC price (at 1979 values), oil imports could fall to zero by 1985, provided the government encouraged accelerated production of domestic oil. The model predicted that, even without government intervention, US imports in 1980 would be only about 6 million barrels per day, falling to about 5 million barrels per day in 1985. As things turned out, the US imported more than 8 million barrels per day in 1979 even with the price of imported oil a good bit higher than $16 per barrel.

Looking back, it is apparent that the FEA model had overestimated the demand elasticity for liquid fuel — the percentage decrease in demand for a given increase in price. The output of the entire model depended critically on the value of this elasticity. Demand elasticities are notoriously uncertain: those used in various models differ by a factor of ten!

Last October, I (along with 200 energy modellers) attended the Dublin meeting on Energy Systems Analysis sponsored by the European Economic Community. The EEC is sponsoring a "super" model that encompasses the entire community; with sub-models applied to each country. At the Dublin meeting the modellers could compare the results of application of the EEC methods to each country.

This effort is of extraordinary scope. Yet, as the modellers themselves conceded, one can hardly depend on its predictions. Unexpected things happen. The Shah is overthrown; people simply don't react the way the models assume they should.

The moral is clear: policymakers must treat models warily. This is hardly an original view. Yet it seems that the modellers in the United States have had remarkable success with the opinion-makers if not, as yet, with the policymakers.

Most of the more recent models tend to stress reduction in demand rather than increase in supply. This viewpoint is promulgated in the recent report of the Harvard Energy Project, *Energy Future*. The book has already sold more than 100,000 copies. It has been widely acclaimed in the American press as containing both the best appraisal of the energy problem, and the best strategy for its resolution.

To meet the US demand in the late 1980s, the Harvard study estimates that 8 million daily barrels of oil equivalent (mboe) can be saved by conservation, and 3 mboe by widespread use of solar energy. "Conventional" supply, meaning coal and nuclear, is increased by only 5 mboe. These numbers are to be compared with the 37 mboe equivalent total US demand in 1977. Conservation and solar energy, by the late 1980s, are supposed to take care of almost one-third as much energy as was supplied by all energy sources in 1977. Although the Harvard study properly warns that conservation and a transition to 'Solar America' depend on innumerable decisions made by countless people, all conserving energy or installing their own solar devices, it leaves the impression that here was a true, and ideologically acceptable, path to energy salvation.

By contrast, Jimmy Carter's response to the energy situation last June was, to a remarkable degree, supply-oriented: spend $80 thousand million for several million barrels per day of synfuel. The President chose to put most of his money on a technical fix: synfuels. How much of the President's proposal will survive in Congress will depend on how much political pressure is generated by those who believe conservation and solar energy come painlessly.

I doubt that the President and his advisers weighed the uncertainties in predictions of demand when they decided to go for increased supply. But I believe their instinct was right. Technical fixes, especially those involving increased supply, require decisions by relatively few people. They finesse the impossibility of knowing how and how quickly 220 million people will react to a change in price.

Obviously the proper course is to increase supply as well as to conserve. This piece of common wisdom seems to be ignored by some of our noisier conservationists. Despite opposition from this segment of the energy community, I hope the President's commitment to augmenting supply will receive the public support it needs to survive in Congress. ☐

CORRESPONDENCE

French nuclear cracks pose no danger

SIR, — The article entitled "France faces a cold winter" (29 November, page 436), states that: "Although these cracks are not dangerous at this stage, Framatome experiments show that they tend to enlarge under the temperature transients of normal operating conditions, leading to possible component failure within four to six years, a failure which clearly would have catastrophic consequences involving the total loss of primary coolant."

And further that: "The only other possibility is permanent shutdown after five years" and: "These were the facts made public by both government and unions."

We regret that *Nature* did not consult the manufacturer of the components on which the cracks were found. The time limit of four to six years mentioned in your article (the currently accepted figure is six to eight years) concerns the minimum time for the cracks to fully penetrate the 10 to 16 mm thick stainless steel cladding which separates the reactor coolant from the component perse, and *not* the minimum time for component failure. Moreover this minimum time results from calculations based on the most pessimistic assumptions derived from experimental evidence. Similarly pessimistic calculations show that, after the cladding has been fully penetrated, component penetration could only occur several decades later. Furthermore, such penetration would result in a slow leak of primary coolant and in no way lead to what your article describes as "catastrophic consequences involving the total loss of primary coolant".

As concerns the last paragraph of the article, we have never been informed of any statements which contradict our position.

Yours faithfully,

JACQUES GAUSSENS

Framatome, Paris, France

The technical experts must be heard

SIR, — In your issue of 3 January (page 1) you had a short editorial entitled "Nuclear power: the critics must be heard". This seemed to me entirely sound but it is only half the story. Surely it is at least as important that the technical experts should be heard, and indeed listened to?

It is of course possible that the experts are biased, but it is also possible that critics are biased and while senior engineers might be unwilling to disclose all the relevant facts, you do not become a senior engineer by either ignorance of or misrepresentation of the technical facts of your profession and it is likely that the facts presented by such people are correct and worth listening to even if it is fair and reasonable for the critics to be exploring for facts which have not been released.

It must be apparent to anyone who has been watching the field that the media, especially the broadcasting media, frequently present as facts some quite wild guesses by critics and not infrequently fail to present facts given by the other side at all. A particularly serious example of this was a BBC programme towards the end of last year in which Dr Alice Stewart was given a sensible amount of time to discuss the reasons why she believes that doses of radiation are some 20 times as likely to produce cancer as is expected by the International Commission for Radiological Protection.

In a long taped interview Dr Reissland of the National Radiological Protection Board gave a number of detailed reasons for believing that Dr Stewart's statistical analysis of cancer rates at Hanford, which supported her thesis, was unsound and that the experimental data were inadequate to contradict the much larger amount of evidence taken into account by the ICRP. These criticisms have not been effectively refuted, but they were not even presented. The only statement by Dr Reissland which appeared on the programme was his answer to a question by the compère at the end of his interview asking him what would be the effect on radioactive regulations if Dr Stewart's findings were correct, to which Dr Reissland's answer was, when pressed, that *if* they *had* been correct it would involve a tightening up of regulations by a factor of 20. Without giving his previous explanation of the reasons showing that her conclusions were not supportable, this gave a complete misrepresentation for which no apology has ever been made.

Yours faithfully,

J. H. FREMLIN

Department of Physics, University of Birmingham, UK

Civil liberties and the nuclear critics

SIR, — Robin Grove White (20-27 December, page 774) has written a thoughtful and stimulating article on the alleged threat to civil liberties presented by an extended nuclear power programme. Unlike many (even most) critics of nuclear power, he is fair-minded enough to state that it is "conceivable" that alternative strategies would be worse. To his further credit, he takes seriously the possibility of "spying and infiltration of campaigning groups", even if he appears unsympathetic to the counter-measures available to the democracies.

However, I feel that it is unfair to intimate that there is anything peculiar to nuclear power about this latter aspect. The problem of uninvited involvement in our affairs seems to be with us anyway, as is indicated by such cases as those of Alger Hiss (according to a recent book), Philip Agee (according to a former CIA director) and Antony Blunt (according to himself). It is something which, in my opinion, the organisers of campaigns and demonstrations ought to face up to much more than they now do.

A problem to which Mr Grove White does not address himself at all is that of the tactics of some of the anti-nuclear people themselves. There have already been cases, in several countries, of vandalism and bombing. We can, I suppose, expect this behaviour to worsen if (as I expect and support) we choose to increase the contribution of nuclear power to the solution of our energy problems. At what point would these methods become an "impact . . . on civil liberties"? If kidnappings start? Or assassinations? This is by no means a rhetorical question. To put it another way, at what stage can we expect civilised and decent critics of nuclear power to abandon their position because of the activities of some of their associates?

Yours faithfully,

J.F. CRAWFORD

Klein Doettingen, Switzerland

Dioxin detection

SIR, — With regard to Dr Warren Crummett's comments (24 January, page 330) on my report of Dow Chemical's poor performance in detecting TCDD (dioxin) (8 March 1979, page 109), I should like to make the following points.

- Dr Crummett was asked to comment on his results at the EPA meeting and he told me that they were "poor" and "worse" than normal.
- Most of Dr Crummett's criticism of my report refers to the detection of TCDD samples below 9 parts per trillion. He is of course correct to say that the collaborators concluded that 9 ppt was the lowest acceptable detection limit and I made this point in my report.
- To my mind one of the most important issues is the reliability of measurements to detect TCDD in the 9-81 ppt range. Dow did not perform as well as the other laboratories in this study and the EPA report comparing all the results from the five laboratories bears testimony to this. Dr Crummett's comments to me at the EPA hearing only confirmed what was already in the EPA document.

Yours faithfully,

ALASTAIR HAY

University of Leeds, UK.

SIR, — My comments on Dr Hay's response are as follows:

I agree with Dr Hay that I used the words "poor" and "worse than normal", referring to the entire EPA Dioxin Implementation Plan study as "poor" and the Dow results in particular as "worse than normal".

The important issues in the reliability of the measurement of TCDD are, in order of importance: false positive results, false negative results, precision and accuracy of measurements, and confirmation by a second laboratory.

False positive results are most important because agencies in the United States, as explained by EPA's Tom Holloway at the Dioxin Implementation meeting, have a license to regulate whenever a toxic chemical is detected in environmental samples by state-of-the-art analytical methodology. Dr Hay is correct, however, in stating that the reliability of measurements in the 9-81 ppt range is scientifically important. In this range Dow and Wright State University produced comparable results on the same samples. No other laboratories examined identical extracts. So Dr Hay's comment that "Dow did not perform as well as the other laboratories" is his opinion.

I trust that this matter can now be put to rest without creating a continuous debate in your journal.

Yours faithfully,

WARREN B. CRUMMETT

Dow Chemical, Michigan, US

Suspicion of totalitarian ideologies

SIR, — Vera Rich in the article "Berufsverbote continues in spite of resolutions" (6 December, page 549) mentions the political disruption of academic life during the 1930s and remarks that it is strange that the anti-Berufsverbot campaign started so late.

But it is the 1930s that have made us suspicious of any totalitarian ideology. Left and right terror is no different, and we have already had more than enough disruption by Marxists in our universities. We should not help them to occupy influential positions in government service unless we want the suicide of democracy. There is a German proverb which says "Nur die allerdümmsten Kälber wählen ihre Schlächter selber" (only foolish calves choose their own slaughterer).

Yours faithfully,

ROLF SEIFERT

Universität Hamburg, West Germany

Was there a Maunder Minimum?

from Christopher Cullen

J.A. EDDY's claim (*Science* **192,** 1189; 1976) that solar activity was at an unusually low level during the years AD 1645–1715 (the 'Maunder Minimum') has so far seemed to be supported by the existence of a gap in East Asian naked-eye sunspot records covering this period. Two Chinese researchers at the Nanking Purple Mountain Observatory, Xu Zhentao and Jiang Yaotiao, have now drawn data from previously unused sources, and claim that on this basis solar activity can be seen to have continued unabated during the entire seventeenth century (*Nanjing Daxue Xuebao* (*Ziran Kexue Ban*) No 2, 31; 1976).

It is now acknowledged that the records of the Chinese State Astronomical Bureau form an invaluable body of data on celestial phenomena of all kinds, covering a period of two millennia. These data have come down to us in the form of digests given in the astronomical sections of the standard histories, *cheng shih*, of successive dynasties, which have in turn formed the basis of such works as Ho's catalogue of comets and novae (*Vistas in Astronomy* **5**, 127; 1962) and the special study of supernovae by Clark and Stephenson (*The Historical Supernovae*, Oxford, 1977). The first thorough listing of sunspot observations was that of Kanda (*Proc. Imp. Acad. Japan* **9**, 293; 1933), who also included Korean and Japanese data. Similar ground was covered in China recently by the Ancient Sunspot Records Research Group (*Tianwen Xuebao* **17**, 218; 1976), who in addition searched for short and long-term periodicities in solar activity over the past 2,000 years. Clark and Stephenson (*Q. Jl R. astr. Soc.* **19**, 387; 1978) have rechecked the sources used by these studies and find them to have located all relevant data. There is indeed not one sunspot recorded for the period AD 1645–1715.

Xu and Jiang point out, however, that such a gap in the records does not prove that no sunspots were observed by Chinese astronomers. In the first place, the lack of records can be partly explained by the fact that the *Ch'ing shih kao*, the draft history of the Ch'ing dynasty covering the period AD 1662–1911, simply omits to give a sunspot chronology similar to those in earlier histories. The Peking observatory was occupied by Allied troops in 1900 during the Boxer Rising, and some records may well have been destroyed. Further, apart from the standard histories compiled by central government there are a large number of local records, *fang chih*, published by local authorities or on the initiative of private persons. It is from the *fang chih* that Xu and Jiang have drawn new data. Nineteen different *fang chih* contribute 21 previously unknown naked-eye sunspot records from the seventeenth century, of which six fall into the period claimed by Eddy as the time of the Maunder Minimum. With those previously known, the total of seventeenth-century naked-eye sunspot records from East Asia now comes to 33 (see Table 1).

The six observations in the period AD 1645–1715 occur at a mean interval of 11½ years. In Kanda's catalogue the mean interval between records is 12½ years averaging over the period 28 BC–AD 1743, and Eddy himself expects to find 6 or 7 naked-eye sunspot observations in 70 years of normal solar activity as we know it today. Xu and Jiang thus conclude that solar activity in the latter half of the seventeenth century was essentially normal and claim that the Maunder Minimum is an artefact of insufficient data. After an analysis of all the seventeenth-century data they confirm that the period of variation in activity was then, as now, approximately 11 years, and propose revised dates for the maxima and minima given by Wolf and by Schove (*J. geophys. Res.* **60,** 127; 1955).

Table 1 Summary of all known seventeenth century naked eye sunspot records from Far Eastern sources.

No.	Year		No.	Year		No.	Year	
1	1603	K	12	1621	A	23	1638	K
2	1604	K	13	1624	K	24	1639	K

A, Taken from Ancient Sunspot Records Research Group list.
F, *fang chih* record from Xu and Jiang.
K, Kanda.
Full texts of original observations are given in Xu & Jiang.

Statistical analysis of the *fang chih* data on sunspots and other transient celestial phenomena must be approached with caution. In the case of the *cheng shih* standard histories we have a series of data covering successive periods of operation of the State Astronomical Bureau. We may begin with the assumption that the Bureau did its observational work with uniform efficiency and that the historians digested their data with equal thoroughness in each dynasty. The next step is to attempt to correct for the sampling error introduced by periods of political chaos or of simple incompetence in the running of the Bureau; the completeness of records of other types of phenomenon provides a useful cross-check here. The results of this process may still be open to doubt, but we can at least be sure that at any given time we are only dealing with one group of observers, and that their data are being transmitted to us through a single channel. In the case of the *fang chih*, however, the situation is much more complex. We have little or no idea who made the observations they contain or how the data came to be recorded; this is a source of randomness absent from the central government records. Further, it is quite unsafe to assume that the *fang chih* taken together present an unbiased sample of data. In comparing the frequency with which sunspots are recorded in different periods, we should remember that some periods will be more intensively covered by *fang chih* records than others. Before the required weighting can be applied to Xu and Jiang's data a considerable amount of

bibliographical research will be needed.

The dangers of sole reliance on the official records are now clear. For example, Clark and Stephenson have suggested that a phenomenon similar to the proposed Maunder Minimum may have occurred under the Ming dynasty between AD 1400 and 1600. They argue that since contemporary official records of other astronomical phenomena are relatively complete, the gap in the Ming standard history sunspot records for that period must be regarded as significant. However, as we have seen, an identical argument applied to the Ch'ing standard history would lead to the patently false conclusion that there were no sunspots at all between AD 1662 and 1911. Given the civil and military chaos at the end of the dynasty, a section of the Ming records may simply have gone missing in the same way as under the Ch'ing. The work of Xu and Jiang has shown that such points can only be decided after a search of the literature ranging outside the confines of the official sources. As well as the large number of local histories, such a search must attempt to cover the essays and common-place books, *pi chi*, of private scholars likely to have had astronomical interests; the yield from these will be considerably smaller, but still worth the effort. Until the results of such an arduous undertaking become available, judgment must be suspended. □

The 'blueprint hypothesis' of axon guidance

from David I. Gottlieb

DURING the development of the vertebrate central nervous system axons grow over long distances and bypass vast numbers of neurones to home in on a distinct target region where they form synapses with a characteristic subset of neurones. Although it has long been appreciated that axons have some means of recognising their final destination (see *News & Views* **282**, 672; 1979) it needs to be emphasised that axons also take a sterotyped route to their destination, they do not, for example, branch extensively and resorb the collaterals which fail to hit the target. How are these routes through the developing brain marked? Some recent anatomical investigations by M. Singer and his colleagues suggest that certain non-neuronal cells of the regenerating and developing central nervous system may have a crucial role.

Evidence for this view first emerged from anatomical studies of the regenerating lizard spinal cord. Egar *et al.* (*J. Morphol.* **131**, 131; 1970) showed that during the early stages of regeneration the cord consists of an epithelial tube formed predominantly of a single layer of cells called ependymal cells surrounding a central canal in continuity with the original spinal canal. An unexpected and exciting finding was that the distal portions of the ependymal cells (that is, the surface away from the lumen of the central canal) were arranged to form large extracellular channels which contained only an electron lucent amorphous material. During subsequent stages of regeneration these channels became choked with axons growing along the length of the cord and presumably originating from neurones located more rostrally. Similar ependymal channels were found in the regenerating cord of the newt (Egar & Singer *Expl Neurol.* **37**, 422; 1972).

Numerous anatomical investigations of the central nervous system during early development have revealed the presence of large, cell free spaces but these have usually been written off as fixation artefacts. However, in studies of the embryonic newt cord Singer *et al.* (*J. comp. Neurol.* **185**, 1; 1979) found large channels between ependymal cells that bore a striking similarity to those of the regenerating cord. As in the regenerating cord, the empty channels became filled with growing axons as development proceeded. In both regeneration and development the anatomical impression was clear: ependymal channels seemed to guide bundles of growing axons. Singer *et al.* proposed what they call the 'blueprint hypothesis', the central tenet of which is that ependymal channels provide the important cues which guide developing axons and result in the characteristic route taken by the major pathways of the brain. Along similar lines Katz and Lasek (*J. comp. Neurol.* **183**, 817; 1979) have performed experiments in which eyes were grafted onto the trunk of developing frog embryos; axons from these eyes enter the spinal cord and grow for long distances in a highly circumscribed tract near the lateral margin of the cord. Some substrate clues must channel these aberrant axons and ependymal channels seem like reasonable candidates. Evidence for cellular channels has also been found in the embryonic mouse retina (Silver & Sidman *J. comp. Neurol.* **189**, 101; 1980). In this case the channels appear transiently during development and seem to be situated in a way that would guide ganglion cell axons back into the optic stalk as they grow. Doubtless such cellular channels will be found in other regions of the embryonic central nervous system.

Do the channels actually guide growing axons in a way which can explain the characteristic paths of the major tracts in the central nervous system? One problem with this idea is that developing tracts in the embryo are relatively long (from several to tens of millimetres) while we don't really know how long the channels are. Serial reconstruction studies are needed to settle this point. Another is that a clean test of the idea such as altering the channels to see what happens to the tracts seems impracticable. Thus it may be a long time before we know whether ependymal cells carry some of the elusive molecular markers for specificity. Whatever the final outcome, ependymal cells and channels will be objects of lively experimental interest as neurobiologists try to understand how tracts find their way. □

How plants exploit animals

from Peter D. Moore

THE ecological position of most green plants, at the base of food chains, has placed them in what seems to be a rather vulnerable position. It is natural that many of their adaptations during the course of evolution have been defensive; both morphological and biochemical features have frequently been modified so that the grazer should regard them with more respect than relish. Notable exceptions exist, of course, such as the use of animals as vectors in the transport of seed and pollen. Here the plant is at pains to excite an animal's greed in order to exploit its freedom of movement, thus rendering more effective the dispersal of the species and the free exchange of genes. The ecological and evolutionary rewards of these processes have evidently justified the necessary energetic investment.

In view of the advantages gained by plants in these mutualistic associations with their mobile dependents, it would be surprising if their response to direct grazing were entirely passive. In a systems analytical approach to this question, Lee and Inman (*Ecology* **56**, 1455; 1975) concluded that although grazers consume only a very small proportion of primary production (see *News & Views* **282**, 443; 1979), they exert a dampening effect on the fluctuations in plant production which result from environmental oscillations. In this way they may contribute to the stability

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, King's College, London.

0028-0836/80/05428-03$01.00

of the ecosystem, which could be considered a benefit to all member organisms.

Owen and Wiegert (*Oikos* **27**, 488; 1976) sought for more tangible benefits to plants from the existence of a contingent of grazers in their midst. They asked the question in the forcible form "Do consumers maximize plant fitness?", and their guarded but affirmative reply was based on some detailed illustrations from nature. For example, they use the figures of Llewellyn (*J. appl. Ecol.* **9**, 261; 1972) to show that a population of a million aphids inhabiting a single lime (*Tilia*) tree, 14 m in height, could release sugar as honeydew at the rate of 407 g day^{-1}. Llewellyn's overall annual estimate of sugar rain was 1 kg m^{-2}. This will obviously have a profound influence on soil microbial activity and Owen and Wiegert single out for attention the free-living nitrogen-fixing microbial genus *Azotobacter*. The energetic stimulation of this component of the soil flora could result in higher rates of nitrogen input to the soil and consequently the ultimate encouragement of growth in the vegetation. This assumes, of course, that *Azotobacter* will be the sole or main beneficiary from the aphidic manna, which is not necessarily so, since the ecology of the competitive interactions among soil microbes is likely to be complex, but it is nevertheless reasonable to suppose that some increase in nitrogen fixation will occur. The important question is whether the nitrogen gain to the plant is worth the carbon loss.

A still more direct example of a stimulating consumer has been provided by Boscher (*Oikos* **33**, 451; 1979) in her studies of the cultivated leek, *Allium porrum*. This plant is frequently blighted by the leek moth *Acrolepiopsis assectella*, the larvae of which feed on leaves, scapes and pedicels, though not normally on the flowers, which Arnault (*C. hebd. Acad. Sci Paris* **280**, 2487; 1975) considered to be toxic to them. Boscher found that moderate defoliation of the leek had no adverse effect on fruit production, indeed some plants produced more fruit. Severe defoliation resulted in a considerable development of vegetative bulbils in the inflorescence. This is a reproductive strategy which allows rapid expansion of the population, since the bulbils produce plants which are sexually mature in their first year whereas plants grown from seed only flower in their second year. The switch to vegetative propagation is thus controlled by the consumer organism.

There are, of course, some plants which have themselves turned predator; some fungi trap and consume detritivorous arthropods, and there are the insectivorous pitcher-plants and sundews. But a more subtle system for the exploitation of animals as an energy resource has been developed by some tropical epiphytes which have formed associations with ants. These were first described back in the eighteenth century, but have recently been examined more closely by Janzen (*Biotropica* **6**, 237; 1974) and Huxley (*New Phytol.* **80**, 231; 1979). The stems of these plants are swollen and become hollow as a result of tissue death early in the life of the plant. The inner surfaces of these cavities are covered with warty protrusions. The hollow stems are invariably occupied by ants, and often by a variety of other organisms. The ants deposit quantities of detritus within these cavities and it was suggested during the last century that this could provide a source of inorganic elements for the plants if they were able to absorb them.

In laboratory and field experiments on two of these ant plant species, *Myrmecodia* and *Hydnophytum*, Huxley found that, in the presence of ants or of added inorganic nutrients, the plants grew more rapidly than without these. When ants were fed on honey water containing ^{32}P as phosphate and ^{35}S as sulphate and as methionine, subsequent autoradiography showed an accumulation of radioactivity around the surfaces of the warts and also in the plant vascular tissue. So the plant can absorb these elements, possibly by way of faecal material in the cavities. Rickson (*Amer. J. Bot.* **66**, 87; 1979) has conducted some similar experiments in which he provided the ant plant and its resident ants with a supply of fly larvae labelled with ^{14}C. Within 6 to 8 weeks radioactivity could be detected throughout the plants, demonstrating absorption and translocation of organic material either directly from the decaying fly larvae or indirectly through ant faeces.

Rickson proposes that the ants donate a proportion of their food to the host plant,

The parity of the pion

from John Edgington

TEXTBOOKS of nuclear physics are not noted for their flair and style. A rapidly developing subject, using difficult theoretical techniques to interpret and codify great quantities of experimental data, nuclear physics rarely affords us glimpses of the essential simplicity of nature, and the standard pedagogy tends to reflect this. However a result recently obtained by C. Wilkin (*J. Phys. G*, L5, 1980), though not new, is so refreshingly simple in its derivation that it should rapidly find its place in undergraduate courses. The topic is the intrinsic parity of the π-meson.

The original (and so far only) determination of the pion's parity was that made by Panofsky at Berkeley in 1951, confirmed in 1954 by Steinberger at Columbia. Drawing on an idea of Ferretti dating from 1946, the argument has been outlined in many textbooks since, notably in Bethe and the Hoffmann's semi-classic 'Mesons and Fields'. The reaction studied is $\pi^- + d \rightarrow 2n$; arguing from general conservation principles one shows that the very existence of this reaction requires the pion to have negative parity. The reasoning is unambiguous but requires knowledge of the initial quantum state of the π^-d system; the argument is that the pion cascades down through its electron-like orbits until the final strong interaction occurs in the lowest ($l = 0$) orbit. This assumption, though highly plausible, is not absolutely compelling. That the pion's parity is negative is not seriously in doubt, but it would be comforting to have a slightly more watertight experimental proof.

Wilkin has provided such a proof. He uses some results obtained at SIN, Switzerland, by a group led by R. Hess of Geneva University, and reported to the 8th ICOHEPANS* Conference at Vancouver last August. Hess *et al.* have been studying the reaction $p + p \rightarrow \pi^+ + d$, using a polarised beam and target; they have measured the dependence of the cross section on the relative spin orientations of target and projectile. Their motivation was to provide further data on the spin-dependence of the nucleon–nucleon interaction, and the present result is an amusing and unexpected bonus.

Wilkin points out that, in the forward direction, there is a simple relation between two coefficients, A_{LL} and A_{TT}, both of which measure the difference in reaction probability between states whose proton spins are aligned parallel, and anti-parallel, to one another. A_{LL} refers to the case where the spins are directed parallel (or anti-parallel) to the projectile's motion, while A_{TT} refers to the case where the spins are at right angles to this. Wilkin shows that

$$A_{LL} \pm 2A_{TT} = 1$$

the positive (negative) sign being taken if the pion has positive (negative) parity. By making a small extrapolation of the data of Hess *et al.* to the forward direction, he finds $A_{LL} = -0.3$, $A_{TT} = -0.6$; these values, with their rather small uncertainties, conform very comfortably with the notion that the parity of the pion is negative. Positive parity is unambiguously ruled out. Since A_{LL} may not exceed unity, positive parity would forbid A_{TT} from being negative, but it manifestly is so. This simple, yet pleasing demonstration of the pseudoscalar nature of the pion seems to have no controversial aspects.

John Edgington is a lecturer in the Department of Physics, Queen Mary College, London.

but this implies both that the ants carry in material in excess of the ant colony's needs and that the route of movement of ^{14}C is directly from the food material to the plant. From the data available at present, it is still possible that the ants are acting entirely out of self-interest and are consuming all food entering the cavity so that ^{14}C entering the plant is derived only from faeces. If this latter explanation is correct, then the ant loses nothing from the association since there is no undue energy investment on its part. In either event, the plant very obviously gains from the association in both its organic and inorganic uptake. The presence of the ants must therefore represent an energy resource for the plant which supplements its photosynthetic intake. It could be regarded as a symbiotically adapted facultative saprophyte.

The coevolution of plants and animals has led to such very obvious structures as flowers and thorns and to the evolution of a variety of chemical compounds from tannins to cardiac glycosides. It should not come as any surprise, therefore, to find that in taking advantage of the grazer the apparently passive plant is less green than it's cabbage-looking. ☐

New ways of applying pesticides

from Graham Richards

AT the biochemical level there is much in common between medical pharmaceutical research and the development of pesticides for agriculture. The great difference lies in overcoming the problem of application which is so much more difficult when dealing with plants. Researchers in this area have likened their problem to attempting to cure the common cold by dropping aspirins from an aircraft and hoping to catch a fair percentage of the population looking skywards with their mouths open. Small wonder then that the paper which caused the greatest interest at the 1979 British Crop Protection Conference held in Brighton* was the description by R.A. Coffee (ICI Plant Protection Division, Haslemere, Surrey) of an electrodynamic method suitable for the deposition of ultra-low volume droplets of insecticides, fungicides and herbicides.

In principle, the technique is akin to the famous Millikan oil drop experiment whereby the charge of the electron was first measured, and is similar in some respects to methods used in paint spraying. The sensational qualities are that Coffee's new design is free of any moving parts and can be run on torch batteries. Above all the droplets have curved trajectories so that when spraying the front of a plant the chemical is also delivered to the back.

The system which can be hand-held uses a gravity feed to supply liquid to a high-voltage nozzle. This voltage is achieved from the torch batteries using a solid-state converter. The emergent charged liquid drops are subjected to an intensely divergent electric field which is sufficient to carry the droplets to the target which is at earth potential. This field strength is about two orders of magnitudes greater than the gravitational pull, making for very much reduced drift and wind influence.

The almost magical quality of being able to deliver pesticides to the hidden surfaces of a plant when apparently spraying only one side arises from the curved flux lines of the electrically propelled droplets. As the Poisson equation demands, the lines of force are orthogonal to the equipotential contours so that the spray diverges from the high voltage nozzle only to converge on the earthed target and thus to penetrate to surfaces which are not visible on a direct line of sight from the sprayer.

A nozzle flow rate of about 0.1 ml s^{-1} corresponds to a spray volume of as low as half a litre per hectare; the droplets being of about 100 μm diameter (a power of 18 mW). This ultra-low volume application has many attractions. Most obviously it should lead to a significant reduction of environmental problems associated with crop spraying. The simplicity of the device should also mean that it can be used by peasant farmers in the less sophisticated parts of the world where the introduction of chemical aids can produce as much as a 10-fold increase in land cultivation.

Finally the device is an encouragement to chemists and researchers in crop protection since if the delivery of their compounds becomes more efficient then more expensive chemicals become economically viable and one constraint on their research is at least slackened. ☐

Graham Richards is a lecturer in the Physical Chemistry Laboratory, University of Oxford.

Inbreeding among zoo animals

from Robert M. May

IMPROBABLY located off Wiltshire Boulevard in Los Angeles is a small park containing the Rancho la Brea tar pits. Here the bones of creatures — dire wolves, sabretooth tigers, mammoths, ground sloths — from the romantically envisioned 'Rancho la Brean fauna' may be seen, both in existential clutters of bones in the original tar pits, and in analytic exhibits. These large mammals flourished in North America until comparatively recently, when 35 of 49 genera became extinct in the short period from roughly 11,000 to around 8,000 years ago; many people believe the extinctions were caused by the arrival in North America of the comparatively advanced Clovis and Folsom hunters at that time (Martin *Nature* **212**, 339; 1966).

The largest bird of those times was the now-extinct *Teratornis incredibilis,* whose wingspread of about 16 feet makes it the biggest soaring bird of prey yet to have lived. Its smaller congener, *T. merriami,* with a 12-foot wingspan and an estimated weight of 50 lbs, followed it into oblivion. The greatest bird of the Rancho la Brean fauna that survives is the California condor, with a wingspan of over 9 feet and a weight around 23 lbs; here I resolve the taxonomic pedantry of whether the Pleistocene *Gymnogyps amplus* and the present-day *G. californianus* are really two species, or the same species separated in time, by referring to both as the California condor. (Note that the three birds, which occurred together over part of their pristine ranges, form a nice Hutchinsonian sequence, with length ratios around 1.3 and weight ratios around 2; for an irreverent discussion of these ratios, see *Nature* **270**, 660; 1977.)

The California condor's chances of continued existence are, however, slim. Its Pleistocene range, west of the Rocky Mountains from British Columbia to Baja California and east of the Rockies in a great southern strip extending to Florida, has narrowed to two counties in southwestern California, in the dry, mountainous parts of the southern Coast range and the Sierra Nevada. The total population has fallen from an estimated 60 in the 1940s, to 42 in 1963, to 30 today. Some of the loss is demonstrably due to wanton shooting by idiots exercising their 'right to bear arms'. The breeding rate (typically one egg per year) is not calculated to rebound from such vicissitudes. Even this potential recruitment is not being realised, possibly because of the many disturbances associated with increasing human encroachment in the habitat, and possibly because pesticides in the food supply are weakening the birds' egg shells.

There is currently much controversy about what to do (see *NY Times*, 23 Dec. 1979, A17). Various Federal and California agencies, along with the National Audubon Society, have signed an

Robert M. May is Class of 1877 Professor of Zoology at Princeton University.

0028-0836/80/05430-02$01.00

agreement to commit resources to a "condor recovery plan". The proposal is to mark and fix radio transmitters to the surviving condors, hoping to gain more precise information about their autecology and about the causes of the continuing decline in population. The plan contemplates capturing 9 of the remaining 30 birds for captive breeding in zoos. Some conservation groups have attacked these proposals, on the grounds that (in the words of David Brower, founder of Friends of the Earth): "The condor deserves better than to be pushed toward extinction by enthusiasts of technological fixes. The proposed plan threatens to destroy the species in a misguided effort to save it". The observed trends suggest to me there is little hope for the California condor in the wild, no matter what is done.

If this gloomy view is correct, the condor will, at best, join an increasing band of creatures who live on only in zoos. There are many consequent problems. One class of difficulty has to do with getting the animals to breed in captivity; thus, although Andean condors have produced offspring in zoos, California condors have never yet done so. Another concern, which has received less discussion, has to do with the necessarily reduced genetic diversity associated with the small founding stocks of zoo populations. In particular, many zoo stocks will be inbred to a significant degree.

An important recent study of the effects of inbreeding in zoo populations is by Ralls, Brugger and Ballou (*Science* 206, 1101; 1979). They examine records bearing on the relation between inbreeding and juvenile mortality for 16 species of captive ungulates. The offspring were separated into two classes: "noninbred" for all young with unrelated parents; and "inbred" for all young whose parents were known to have an inbreeding coefficient greater than zero. The authors believe this coarse and somewhat unsatisfactory classification scheme is forced on them by the smallness of the sample size (the scheme includes the assumption that the founding individuals were not related, which is not always true). Of the inbred young for which explicit calculation of the inbreeding coefficient is possible, 75% had inbreeding coefficients in excess of 0.25. Within these two classes, young that survived 6 months or more were considered to have "lived", while the "died" category included all offspring surviving less than 6 months (including stillborn and those born prematurely).

The results are shown in the Table. The intuitive impression of a significantly higher juvenile mortality associated with inbreeding is confirmed at the 95% confidence level for 9 of the 16 species, and the sign of the effect is in the right direction for 15 of the 16 (kudu being the exception). In a different analysis, the authors showed that for "19 of 25 individual females, belonging to ten species, a larger percentage of young died when the female was mated to a related male than when she was mated to an unrelated male".

Juvenile mortality of inbred and noninbred young.

Species	Noninbred young		Inbred young	
	Lived	Died	Lived	Died
Indian elephant	11	2	2	4
Zebra	20	7	3	2
Pygmy hippopotamus	139	45	23	28
Muntjac	18	4	12	6
Eld's deer	13	4	0	7
Père David's deer	15	2	19	3
Reindeer	19	10	9	12
Giraffe	11	3	2	3
Kudu	10	4	8	3
Sitatunga	15	1	31	28
Sable	18	4	3	7
Scimitar-horned oryx	35	2	0	5
Wildebeest	6	1	29	12
Dik-dik	10	7	7	8
Dorcas gazelle	36	14	17	25
Japanese serow	52	21	27	35

This work is controversial. Although the deleterious effects of inbreeding are well known in animal husbandry, many conservationists and wildlife managers have argued that "Adverse comment about the ill-effects of inbreeding is . . . often exaggerated, and provided the area is well looked after and not overstocked, there should be no harmful effects" (Whitehead, in *Threatened Deer,* IUCN Publ., Switzerland, 1978). I think Ralls, Brugger and Ballou make it clear this is wishful thinking, and "that deleterious effects of inbreeding are widespread in captive populations of exotic animals and have remained unrecognized only because the majority of zoos have not maintained detailed records".

It must be emphasised that nobody is suggesting that the difficulties caused in inbreeding are a reason to give up attempting to breed animals and preserve species in zoos. It is simply that these difficulties are real, and that they need to be addressed constructively (by genetic management of small populations whenever practical), rather than ignored.

Nonlinear dynamics

from N. MacDonald

NONLINEAR dynamics is an explosively expanding subject, and a recent meeting* brought together more than 400 people from a great range of disciplines, from fluid dynamics to biomathematics, with a common interest in the recent advances in understanding nonlinear phenomena.

A major part of the meeting was devoted to studies, both experimental and theoretical, of the onset of turbulence. Turbulence is characterised by complex structures, on many different scales, in both space and time. However, the onset of turbulence, that is to say the first appearance of modes of motion more complex than laminar flow, is usually studied in the time domain, by analysis of the frequency spectrum of an appropriate experimental quantity. Traditionally, the transition from simple to complex frequency spectra characterising the onset of turbulence has been thought of as analogous to a series of bifurcations of the trajectories of a dynamical system (a system defined by a finite set of ordinary differential equations). The first transition is from a steady state to a closed curve with a definite frequency of transit; the second from that closed curve to motion on a torus (quasi-periodic motion with two incommensurable frequencies), and so on. More recently the possibility has been recognised that after one or two such bifurcations there may be a sudden jump to aperiodic motion. In the experimental data presented at this meeting (for example by G. Ahlers, Bell Laboratories, Murray Hill, and J. Gollub, Haverford College) the following features have been identified:

(1) Appearance of new incommensurable frequencies f_1, f_2 . .

(2) Entrainment of these frequencies so that (for example) f_1, f_2 approach values f_0, $2f_0$.

(3) Sudden appearance of aperiodic spectra.

(4) Appearance of subharmonics $f_1/2$, $f_1/4$, . . successively.

Certain of these features were also present in the data described by C. Vidal (CNRS, Talence) on the temporal behaviour of a stirred Belousov-Zhabotinsky chemical reaction, as the flow rate through the reaction vessel is increased.

Some reservations must be expressed with regard to this way of thinking about turbulence. As emphasised by P.C. Martin (Harvard University) essential aspects of the physics may be missed if one does not consider the spatial aspects of turbulence.

---

*A conference on 'Nonlinear dynamics' sponsored by the New York Academy of Sciences and organised by Dr. R.H.G. Helleman, Twente University of Technology, was held in New York on 17-21 December, 1979.

0028-0836/80/05431-02$01.00

Further, the appropriate theoretical framework for fluid dynamics, the Navier–Stokes equation, is defined on an infinite-dimensional phase space, that of the velocity vector field. D. Ruelle (IHES, Bures-sur-Yvette) reviewed the progress that has been made in understanding how far it is safe to apply the concepts of dynamical systems to solutions of the Navier–Stokes equations.

Within dynamical systems there are two important dichotomies; on the one hand that between dissipative systems — the category to which any presumed analogue of fluid dynamics must belong — and Hamiltonian systems, and on the other, within Hamiltonian systems, between the integrable and non-integrable cases. J. Moser (Courant Institute, New York) reviewed recent progress in understanding integrable systems. The most difficult of the long-established integrable cases, were solved by the method of separation of variables in the Hamiltonian-Jacobi equation. The recent zoo of curious integrable cases, such as the Toda lattice, has been studied in terms of the spectral theory of linear operators. It is now possible to trace a mathematical relationship between these two apparently diverse methods, and to give a systematic discussion of the connection between the various special cases.

The classical theory of integrable systems played a considerable part in the early development of quantum theory. As early as 1917, while the Bohr–Sommerfeld semi-classical method was being actively pursued, Einstein pointed out that this method could not hope to handle any non-integrable classical problem. The rise of quantum mechanics diverted attention from this, but in recent years the practical usefulness of semi-classical methods in atomic and molecular physics has led some authors to return to this problem. M.V. Berry (University of Bristol) reviewed the work which he and his associates have carried out on the quantisation of some well-known non-integrable systems, such as Arnold's cat and Sinai's billiards (see for example M.V. Berry *et al. Ann.Phys.* **122,** 26; 1979).

The trajectories of integrable Hamiltonian systems stay on energy surfaces of dimension lower than that of the phase space. Some or all of the trajectories of non-integrable systems fill up (in an imprecise sense) regions of the phase space (ergodic behaviour). There has been some controversy regarding the universal nature of a mechanism (Arnold diffusion) proposed for the transition from quasi-periodic to ergodic behaviour of the trajectories of a perturbed integrable Hamiltonian system. A numerical experiment bearing on this was reported by M.A. Lieberman (University of California, Berkeley and Imperial College, London). A particle is bounced between a plane wall and a parallel rippled wall. A transition can occur between trajectories confined to a single dimple and trajectories wandering over the plane.

Another aspect of the appearance of seemingly random features in a deterministic physical model was the subject of a talk by J. Ford (Georgia Institute of Technology, Atlanta). The model is a set of particles on a line, which are alternately free and harmonically bound. For low enough frequency of the bound particle oscillations, any blow on the end particle is transmitted as a wave pulse along the line, distance travelled being proportional to time elapsed. As the frequency is raised to a point at which there is a significant incidence of multiple collisions (a free particle striking its right-hand neighbour more than once before next striking its left-hand neighbour) the nature of the transmission of information changes. The wave pulse is damped out and the disturbance propagates like heat instead of sound, with the distance travelled proportionate to the square root of the time.

Just as the Navier–Stokes equation can be illuminated by cautious extrapolation of results from dynamical system theory, so the study of complex behaviour in dynamical systems received a considerable impulse from the striking properties of discrete mappings. The degree of complexity attained by the solutions of such apparently trivial recurrence relations as

$$\alpha_{m+1} = \alpha_m(1-\alpha_m)$$

is now familiar (see the review by May, *Nature* **261,** 459; 1976). Much attention was paid at the New York meeting (for example in the talks by O. Lanford, Berkeley, E.N. Lorenz, MIT and M.J. Feigenbaum, Los Alamos) to the remarkably precise scaling laws that apply to these solutions. In general, for the mapping

$$x_{m+1} = f(a, x_m)$$

where for fixed a the function f has a single maximum in x, there are, as a passes through values a_n, successive bifurcations from a periodic solution of order n to a periodic solution of order $n+1$. Feigenbaum has found that the limit for large n of the ratio

$$\frac{a_n - a_{n-1}}{a_{n+1} - a_n}$$

has the value 4.6642016 . . He conjectures (for details see *Phys. Lett.* **A74,** 375; 1979) that similar laws may hold for the subharmonic bifurcations observed in the experiments on the onset of turbulence.

This was undoubtedly a timely and stimulating meeting. The predominant impression was of a fruitful interplay between the construction of special models illustrating striking aspects of nonlinear dynamics, and the exploration of the underlying mathematical structures. □

N. MacDonald is in the Department of Natural Philosophy, University of Glasgow.

100 years ago

DIFFUSION OF COPPER IN THE ANIMAL KINGDOM

The fact of the normal presence of minute quantities of copper in various members of the animal kingdom has been noticed by several chemists within the past twenty-five years. Kingzett states that he has invariably found it to be a constituent of the human brain, while Odling and Dupré, and Bergeron and Hoté have determined analytically the average amount of copper present in the liver and kidneys of human beings and domestic animals. In the latter case the average percentage of copper found was about 35 millionths. Some two years since Cloez examined the blood of a deer, and found it to contain 6 millionths of copper. The most interesting instance of the occurrence of copper in the animal creation is, however, that communicated by Prof. Church to the Royal Society in 1869. At this time he was engaged in the investigation of a peculiar, soluble, red colouring matter present in the wings of the Turaco, a bird from the West Coast of Africa. A thorough study of this pigment showed it to contain 5.8 per cent of copper, and Prof. Church established for it the formula $C_{50}H_{56}O_{19}N$ Cu. Led to seek the source of this strange factor in the animal economy of the Turaco, he succeeded in detecting copper in the fruit of the *Musa sapientum,* which forms the chief article of the bird's diet.

To these few isolated cases of the normal assimilation of copper in the animal Kingdom, Dr. M. Giunti, in the last fascicule of the *Gazetta Chimica Italiana* (vol. ix. p.541), adds a number of interesting and diversified instances.

His attention was first directed to the subject accidentally by finding over one-third of 1 per cent of copper in the guano deposits from bats occurring in certain Italian caves. This led to an analytical examination of the bat, the results of which showed that about four ten-thousandths of the weight of the ashes of this animal consist of cupric oxide. Still bent upon finding a more ultimate source for the metal, Giunti has subjected to analysis quantities of the insects which form the food of the bat, and in all cases he has found copper present in greater or less amount.

SIZING AND MILDEW IN COTTON GOODS

Sizing and Mildew in Cotton Goods. By G.E. Davis, C. Dreyfus, and P. Holland. (Manchester: Palmer and Howe).

The application of a certain kind of science to a certain kind of commerce is rapidly producing a literature of its own. It is not long since that we had occasion to notice a work which treated of the manner in which silks could be "weighted" by chemical means, and the volume now before us is the second of its kind which is concerned with the relations of chemistry and mycology to the manufacture of cotton goods.

It is hardly worth while to take up valuable space by noticing the merits or demerits of a book such as this, the object, or at least the tendency, of which is to show the manufacturer how, by the application of certain scientific facts and principles, he may seek to perpetuate a system which, we honestly think, is simply a gigantic fraud.

The mechanism of protein secretion across membranes

Bernard D. Davis & Phang-C. Tai

Bacterial Physiology Unit, Harvard Medical School, Boston, Massachusetts 02115

Many secreted proteins are synthesised as a large precursor with an additional hydrophobic N-terminal signal sequence that is cleaved by a membrane-bound enzyme. The proteins are secreted as nascent chains. The work leading to the current models of protein secretion is reviewed and the value of bacterial systems in the study of protein transfer across membranes is stressed.

MOST cells, and perhaps all, secrete proteins across membranes—either directly into the extracellular fluid, or into vesicles or organelles. Study of the mechanism began with Palade's discovery, 25 years ago, that animal cells contain ribosomes bound to the membrane of the endoplasmic reticulum, as well as ribosomes free in the cytoplasm[1]. In the next few years various secretory proteins were shown to be synthesised on the bound ribosomes, and various cytoplasmic proteins on the unbound ribosomes (reviewed in refs 2, 3). This distribution suggested that secreted proteins might cross the membrane as growing chains, rather than after completion. In support of this model, Redman and Sabatini[4] used puromycin to induce release of incomplete chains from the ribosomes of microsomes (vesicular fragments of endoplasmic reticulum, spontaneously formed on cell lysis): these chains could then be released by a low concentration of detergent, which suggested that they had been transferred into the lumen of the vesicles.

To explain how the membrane-bound and the unbound ribosomes differed in their selection of messenger RNA, as well as in their location, a difference in structure was proposed. However, no such difference could be detected. It was therefore necessary to consider the alternative possibility that the ribosomes are all alike and bind mRNA randomly, and it is the mRNA that determines their location (as well as their product). In 1971 Blobel and Sabatini[5] proposed that the mRNA might play this role indirectly, by coding for a special sequence near the beginning of the polypeptide chain that might be recognised by a membrane binding factor; the chain would then presumably be secreted while still growing.

Such *N*-terminal signal sequences were subsequently demonstrated on many secretory proteins. Nevertheless, that did not establish whether binding of the signal is followed by cotranslational secretion or whether the chain is first completed, then folds against the membrane surface and is subsequently transferred by engulfment by the membrane after release from the ribosome. In fact, as we shall see, both mechanisms can be found.

Recently cotranslational secretion has been directly demonstrated, particularly through the study of protein secretion in bacteria. Moreover the use of bacterial systems has allowed new approaches to the study of secretion. These approaches are based on the accessibility of the relevant bacterial membrane surface (in contrast to the endoplasmic reticulum of eukaryotic cells), and the isolation of bacterial mutants altered in secretion. In this review we shall emphasise these studies, briefly noting closely related work on eukaryotic cells, and on the formation of membrane proteins.

The signal sequence

In addition to its affinity for membrane, the postulated special signal sequence turned out to have the unpredicted property of being cleaved from a precursor protein during secretion. On this basis the existence of such a sequence was discovered adventitiously, and independently of the suggestion of Blobel and Sabatini[5], by Milstein and coworkers[6] in 1972. Specifically, during a study of *in vitro* translation of mRNA (from myeloma cells) into an immunoglobulin, these workers observed that in the absence of homologous membrane the immunoglobulin light chain was formed not as such but as a larger precursor; moreover, the extra sequence, of MW ~ 3,000, was *N*-terminal. Milstein *et al.* therefore proposed that the extra sequence provided a signal for attaching the growing chain of this secretory protein to the membrane. This group further reported[7] that during protein synthesis homologous membrane fragments can convert the precursor to the ultimate product; but after completion of the precursor the cleavage site evidently becomes inaccessible to the enzyme. Other laboratories also noted the synthesis *in vitro* of a larger precursor of an immunoglobulin chain[8-11].

These findings provided the first evidence that proteins destined for secretion have a special signal sequence, and that this sequence is removed after it has served its function of initiating transfer. Moreover, Schechter and coworkers[10,12,13] showed that the signal sequence of an immunoglobulin light chain precursor has a marked preponderance of hydrophobic amino acids—a property that would fit the proposed attachment of this sequence to the membrane.

Subsequently a series of more refined studies (reviewed in ref. 14) was undertaken by Blobel and coworkers[15-17], culminating in the determination of the complete amino acid sequence of the signal segment of a number of precursor proteins from eukaryotic cells. In some cases the membrane enzyme(s) that cleave this sequence were also demonstrated. These studies led to increased interest in the 'signal hypothesis', and to a more detailed model in which the signal sequence induces aggregation of membrane proteins to form a tunnel around the secreted chain[15].

More recently, precursors with an *N*-terminal signal sequence have also been demonstrated[18-20], or inferred from the corresponding DNA sequence[21], for several proteins that are secreted from bacteria. In addition, both in bacteria[22-26] and in animal cells[27], precursors with cleavable signal sequences have been demonstrated for several proteins destined for incorporation into the membrane, rather than for secretion. The process of incorporation has therefore been viewed as a model for secretion (see, for example refs 26, 28). This view is supported by evidence (see below) that the two kinds of protein compete for the same sites of entry (even though their interaction with the membrane later becomes quite different).

The signal segments for various proteins have been found to vary considerably in sequence, and even in length. Representative examples are presented in Table 1; a more complete tabulation can be found in ref. 28.

Direct evidence for cotranslational secretion

Cotranslational secretion of a protein would be demonstrated directly if one could label the end of the growing chain protruding from a membrane and show that the other end was still attached to a ribosome as peptidyl-tRNA. Such experiments seemed feasible in bacteria (although not in eukaryotic cells), since the far side of the bacterial plasma membrane should be accessible to external modification (Fig. 1).

Efforts to label protruding chains were therefore undertaken in our laboratory[32]. In growing cells of *Escherichia coli* the polysomes were stabilised by rapid chilling plus addition of chloramphenicol; the cells were converted to spheroplasts to increase accessibility of the cytoplasmic membrane; and the spheroplasts were treated with ^{35}S-labelled acetylmethionyl methylphosphate sulphone (AMMP), which reacts with free amino groups (of protein and phospholipid) on the cell surface but does not penetrate cell membranes[33]. The spheroplasts were then washed and gently disrupted by osmotic lysis; and the membrane–polysome complexes were separated, by sedimentation in a sucrose gradient or by gel filtration, from the free membrane fragments and the free polysomes.

The polysomes from the membrane–polysome complexes were freed of membrane by washing with detergent, and they were found to retain about 6% of the initial label in the complexes (2% of the total incorporation). More recently, use of ^{125}I-diazoiodosulphanilic acid, a non-penetrating reagent that labels only tyrosine and histidine residues and not phospholipid, has increased about fourfold the proportion of cellular label that is recovered on polysomes[34]. This label on the polysomes (from either reagent) is evidently attached via peptidyl-tRNA: it was released by low Mg^{2+}; subsequent cleavage by dilute alkali decreased the average molecular weight by about that of tRNA; and the label was also released by puromycin, or by chain completion *in vitro*. Moreover, the product of chain completion, as expected, had an average molecular weight about twice that of the material released by puromycin. (This growth of the labelled molecules is particularly cogent evidence, for it excludes the possibility that the small amount of label in the purified polysomes was merely contamination.) Finally, the demonstration of cotranslational secretion was completed by identifying a periplasmic enzyme, alkaline phosphatase, among the products of completion of the extracellularly labelled growing chains[32].

Using the same procedure, W. P. Smith in this laboratory has since demonstrated cotranslational secretion of several other proteins, in both Gram-positive and Gram-negative bacteria: α-amylase of *Bacillus subtilis*[34], the toxin of *Corynebacterium diphtheriae*[35], and penicillinase of *Bacillus licheniformis* (unpublished data, in collaboration with J. O. Lampen). Thus it seems that simultaneous translation and extrusion is a general (although not necessarily an exclusive) mechanism of protein secretion in bacteria.

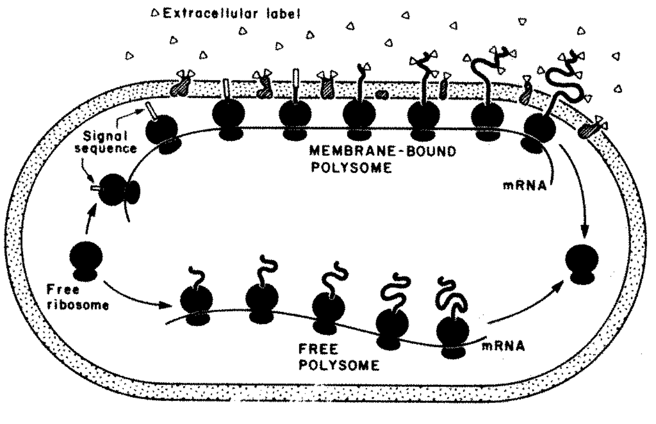

Fig. 1 Use of extracellular labelling of nascent chains to demonstrate secretion of proteins across membrane as growing chains. (Adapted from refs 32, 34.)

Recently, some intrinsic membrane proteins have also been shown to enter the membrane during chain growth, as might be expected from the demonstration[22-26] that such proteins are formed as cleavable precursors with a hydrophobic signal sequence. Thus incomplete protein chains have been recovered from the outer membrane of pulse-labelled *E. coli* cells in steady-state growth[36]. Moreover, in animal cells ingenious experiments have shown that during the insertion of a viral protein into the membrane of the endoplasmic reticulum, the protein can be glycosylated, on the intraluminal surface, only during the early part of chain growth and not later[37,38].

Significance of membrane-associated ribosomes in bacteria

The demonstration of cotranslational secretion (and incorporation into membrane) has incidentally settled the long-standing question of the functional significance of the association of ribosomes with membrane in bacteria. In thin sections of these cells, unlike eukaryotic cells, it has not been possible to distinguish membrane-bound and free polysomes by electron microscopy, because the population of ribosomes is too dense. Hence even though membrane fragments in bacterial lysates have long been observed to contain ribosomes, it has not been certain whether the attachment is functional or is due to artificial trapping. A functional role, like that observed earlier in eukaryotes, is now established.

A functional attachment was also suggested by the finding that the membrane-bound polysome fraction of *E. coli* produces a somewhat greater abundance of a secretory protein (alkaline phosphatase) than does the free fraction[39]. Similarly, Randall and Hardy[40] prepared membrane–polysome fractions whose products were more enriched in several secreted or incorporated proteins, while containing very little of a cytoplasmic protein (elongation factor EFTu). In our laboratory W. P. Smith has achieved a more complete separation, yielding virtually exclusive synthesis of alkaline phosphatase, α-amylase, penicillinase, and diphtheria toxin on membrane-bound polysomes of various organisms, while a cytoplasmic protein (elongation factor G of *E. coli*) was made exclusively on free polysomes.

Synthesis and processing of precursors

Polysomes derived from membrane–polysome complexes have regularly yielded precursors of the secreted or membrane proteins described above, and so they appear to be a good source of precursors and intermediates in protein formation. Precursors have also been formed in purified systems directed by DNA[18,20], and in toluene-treated cells[41]. A number of these products have been shown to be more hydrophobic than the mature proteins.

The penicillinase of *Bacillus licheniformis*, formed by chain completion on membrane-derived polysomes, is a particularly interesting example, since four molecular forms can be recovered (unpublished experiments, with W. P. Smith). One of these evidently corresponds to the familiar extracellular product of MW 29,000 (29K), and another to a membrane-bound form of 33K, which has been reported to contain phospholipid[42,43]. In addition, our 33K product could be separated on decylagarose into a highly hydrophobic and a hydrophilic fraction; and only the hydrophobic 33K fraction contained ^{3}H-glycerol (presumably in phospholipid) when derived from cells carrying this label. Finally, an even larger form (see also ref. 20) was also recovered, and it was more hydrophobic than the secreted product, as expected of a precursor. Evidently secreted proteins in bacteria can go through successive cleavages, like the preproproteins that have been recognised in eukaryotic cells as precursors of protein hormones[44,45]. In addition, and unexpectedly, the successive cleavages of penicillinase can all occur during chain growth. Interestingly, diphtheria toxin also goes through more than one cleavage: one on leaving the bacterial cell[35], and another on entering the target mammalian cell[46].

(Residues are numbered leftward from the cleavage site, ↓)

The enzymes responsible for the cleavage of signal segments are being investigated in several laboratories; so far the distinction between specific and nonspecific cleavage is hard to establish. We shall not review this topic in detail. With Gram-negative bacteria both inner[26] and outer[18] membrane fragments have been found to carry out the reaction in various systems; in some the presence of detergent is required[26,47,48]. Cleavage can occur with some precursors only during formation, but with others even after completion of the protein chain.

Neither the fate of the cleaved segments nor the reason for their removal is known. Perhaps retention of a signal would cause the secreted protein to reattach to the membrane, or, more generally, to have less freedom of motion and specificity of interaction.

Genetic studies

The genetic manipulation of bacteria, to yield mutants or recombinants altered in various functions, provides a powerful tool for the study of the secretory process. Thus alterations in the signal sequence may identify its essential features. In addition, mutants altered either in membrane components, the ribosomes, processing activities, energy transduction, or other, unknown factors should throw light on the mechanism of secretion.

Using an elegant technique for gene fusion[49,50] Beckwith, Silhavy and associates[51–56] have isolated strains of *E. coli* in which an *N*-terminal sequence of a secreted or an incorporated protein, including its signal segment, replaces the *N*-terminus of a cytoplasmic protein, β-galactosidase (for details, see ref. 54). Those hybrid proteins that contained the *N*-terminus of the interpreted (outer membrane) protein, phage λ receptor, were found to be localised either in the cytoplasm or in the outer membrane of the cell, depending on the length of the membrane protein component[51]. In contrast, hybrids with the periplasmically secreted maltose-binding protein were localised in the cytoplasmic membrane, and not in the periplasm, even when they contained almost the entire maltose-binding protein (including its signal segment)[56]. Thus secretion seems to depend not only on the signal sequence but also on the subsequent sequence: evidently some peptide sequences cannot pass through the secretory channel[56].

In these experiments the secretory hybrids that stick in the membrane were also found to interfere with the export of certain normal outer membrane proteins, which then accumulate in the cells in their precursor form[56]. This finding provides evidence that secretory and membrane proteins initially interact with membranes in the same way, that is, enter at the same site(s); presumably a later, probably hydrophobic 'stop' signal in the non-secreted proteins causes them to leave the channel and become embedded in the lipids of the membrane[55]. Such a second signal was already postulated earlier[27,38], on the basis of the similarity of the initiating signal sequences in the two kinds of proteins.

Other interesting classes of mutants have also been obtained. (1) In certain hydrids the function of the signal sequence has been eliminated by partial deletions, and also by various single amino acid substitutions (J. Beckwith, personal communication); the precursor then accumulates in the cytoplasm[53,55]. Moreover, when mutations of either class are transferred genetically to the normal secreted or incorporated proteins, precursors of these proteins also accumulate in the cytoplasm. These results provide direct evidence for the essential role of the signal sequence in the initiation of secretion; in addition, the deletions define the minimal length of an effective sequence. (2) The effects of some of these mutations could be reversed by a suppressor mutation; and it is interesting that this mutation appears to map in a ribosomal protein (S. Emr and T. Silhavy, personal communication; see ref. 54). (3) Another mutation, presumably in a membrane component, greatly decreases the secretion of various periplasmic proteins, and also the incorporation of outer membrane proteins[57]. (4) Finally, a point mutation in the signal sequence of the lipoprotein precursor prevents its cleavage but, nevertheless, allows its incorporation into the outer membrane (although the altered *N*-terminus can no longer be linked to the peptidoglycan)[23]. It thus seems that cleavage is not required for export of a protein to the outer membrane.

Source of energy for cotranslational secretion

The hydrophobicity of the signal segment might lead to its spontaneous insertion between lipid molecules in the membrane. However, the source of energy for the extrusion of the subsequent, largely hydrophilic nascent chain is obscure. Figure 2 illustrates several possibilities.

(a) Chain elongation on an attached ribosome: Part of the energy expended on chain elongation on the ribosome might be used to push the chain through the membrane (Fig. 2*a*). This mechanism would require that the ribosome have a direct attachment to the membrane, to serve as a fulcrum. Purified microsomes from animal cells[59,60], and chloroplasts from plant cells[61], are thought to have such an attachment, since release of the nascent chains from the ribosomes by puromycin did not release the ribosomes from the membrane, unless the salt concentration was elevated or a cytoplasmic detachment factor was provided. However, with purified membrane–polysome complexes from bacteria we found that puromycin released the ribosomes[34,62], even in ionic conditions (high Mg^{2+}, low K^{+}) that might be expected to stabilise a weak association[62]. This finding suggests that ribosomes in bacteria are attached to the membrane solely by their nascent chains. If so, the ribosomes cannot push these chains through the membrane. However, an alternative explanation for ribosome release by puromycin is not rigorously excluded: loss of a growing chain embedded in the membrane might cause a conformational change, either in the ribosome or in a membrane protein, that would disrupt a direct attachment of ribosome to membrane.

(b) Folding of the extracellular chain: After entry of the relatively hydrophobic initial segment into the lipid of the membrane a few residues of that segment, or of a later one in a loop[63], might somehow be forced into the aqueous phase on the far side (Fig. 2*b*); the spontaneous folding of the protruding chain might then progressively pull the rest of the chain after it[34,63]. However, when the chains protruding from protoplasts were excised, by treatment with pronase, the ribosomes remained attached to the membrane[64]; hence they are not held by an extracellular 'knot'. Moreover, alkaline phosphatase of *E. coli* can still be transferred across the membrane even after extensive modification (by mutation, incorporation of amino acid analogues, or premature termination yielding fragments as small as 10%: reviewed in ref. 65). Extracellular folding therefore seems an unlikely source for the energy of secretion.

(c) Embedding of the ribosome in the membrane: If the ribosome, rather than the protein chain, were embedded in the membrane (Fig. 2*c*) the nascent chain leaving it might already be extracellular. However, in electron micrographs membrane-bound ribosomes do not appear to be embedded; moreover, we have shown that the membrane protects part of the growing chain from proteolytic digestion[64].

These experiments on protection from digestion have shed further light on the secretory process, for they have shown that the protected length is uniform for many nascent chains traversing the membrane, and they have defined that length. In these experiments cells of *Bacillus subtilis* were pulse-labelled with a mixture of radioactive amino acids, chilled, and converted to protoplasts, and pronase was used to 'shave' the protruding chains. The membrane (plus ribosomes) protected a length of 49 residues for 50% of the chains[64]. (Most of the rest were longer, and of varying length; they were presumably being folded into the membrane.) In control experiments, membrane-free ribosomes protected a uniform length of 28 amino acid residues, as noted earlier with mammalian ribosomes[66,67]. The difference between 49 and 28 (21 residues) may be taken as the approximate size of the secreted chain surrounded by membrane. As an extended polypeptide chain this number of residues would have the same length, 75 Å, as the commonly observed thickness of bacterial membranes.

(d) An active secretory machinery in the membrane: The most plausible model for cotranslational secretion appears to be one in which an organised membrane structure surrounds the secreted chain and transports it, unidirectionally, by transducing metabolic energy (Fig. 2*d*). As in the active transport of small molecules, the energy could be derived from the proton-motive force or from intracellular high-energy phosphate. Such an active carrier would differ from the passive tunnel that has been postulated previously[15,60,63], but it shares the possibility that the 'channel' is induced, by the signal sequence, to assemble in the fluid membrane from mobile components[15,60].

This model is supported by several lines of evidence. Thus a uniform apparatus would be expected to enclose a uniform length of nascent chain; and the experiments with pronase described in the preceding section yielded precisely this result[64]. Moreover, any machinery for actively transporting a chain, unlike a passive tunnel, would be expected to hold the chain firmly; and indeed, after elimination of the extracellular chains on protoplasts by pronase the subsequently isolated membrane-polysome complexes retain their ribosomes, even when incubated at 37 °C for 30 min[64]. Finally, the postulated apparatus would presumbly contain specific proteins; and in the membrane from the membrane–ribosome complexes of *B. subtilis* we have observed two major protein bands that are absent from the free membrane fraction (D. Marty, P.-C. T. and B. D. D., unpublished).

Nevertheless, the significance of the extra proteins is not certain. Two additional membrane proteins have been observed in the ribosome-bearing fraction of the endoplasmic reticulum in animal cells and have been termed 'ribophorins'[68,69], because they are believed to mediate direct binding of ribosomes. Although our evidence argues against such a direct attachment in bacteria, we have noted that a conformation-dependent attachment would be difficult to exclude; and such an attachment, continuous with a passive membrane channel, would also be consistent with the lines of evidence cited in the preceding paragraph. The question of an active or a passive channel for protein secretion is thus still unsettled.

Alternative mechanisms for export and insertion

Cotranslational secretion, although widespread, is not the only mechanism for protein export. The suggested[70–72] alternative of secretion (or incorporation into membrane) after synthesis in the cytosol, has been demonstrated in both prokaryotes and eukaryotes, with or without formation of a cleavable precursor. We shall only briefly review some key observations.

In prokaryotes cytoplasmic synthesis, in precursor form, has been demonstrated for subunit *A* of cholera toxin[73] (which is later combined with subunit *B* and secreted). Synthesis of a cytoplasmic precursor followed by insertion of a cleaved product into the cytoplasmic membrane has been reported[74], but disputed[75], for a phage coat protein. In eukaryotes, cytoplasmic synthesis of a precursor has been observed for a subunit of the ribulose-bisphosphate carboxylase of the chloroplast interior[76–80], and for several subunits of ATPase[81] and of cytochrome oxidase[82,83] of the mitochondrial inner membrane. The oxidase subunits are formed by several cleavages of a single large precursor, while other subunits of the same transmembrane protein are made within the mitochondrion[82,83]. It is not clear why the cleavable signal segment of certain proteins fails to direct the polysome to become membrane-bound, or what role this segment plays in triggering[84] the interaction of the completed protein with the membrane. Nor is it clear why ATP is required for the incorporation of some cytoplasmically synthesised mitochondrial proteins[85].

Other proteins are secreted or incorporated in the form in which they are synthesised, that is without the need of a precursor form. In bacteria these include colicin E1 and E3[86], and several products of a sex factor[87]: whether these proteins are synthesised by membrane-bound or by free polysomes is not known. In eukaryotes the best example[88,89] is ovalbumin (in contrast to other proteins secreted by the hen oviduct[30,39]). Ovalbumin is particularly interesting: its *N*-terminal region is not highly hydrophobic[88], and a hydrophobic segment in the middle of the molecule may serve as the signal. This conclusion was based on the finding that secretion of another protein (from a precursor) into vesicles *in vitro* can be competitively inhibited by this segment, either exposed in the incomplete or the denatured chain[91], or isolated as a fragment from the molecule[92].

Cytoplasmic synthesis preceding secretion seems to be incompatible with provision of energy by a membrane-attached ribosome; it would be compatible either with embedding of the folded protein in the membrane (followed, for secretory proteins, by release on the other side), or with insertion of the unfolded chain into an active machinery of transport. In addition, if ovalbumin initiates insertion at an internal sequence it would have to be drawn through the membrane as a long hairpin, or as a folded protein; this process also seems incompatible with being pushed by the ribosome through a passive channel.

Membrane morphogenesis

Eukaryotes (and some prokaryotes) have more than one kind of membrane in the same cell, thus raising the broad problem of morphogenetic specificity. Specific signal sequences may well determine the choice of different membranes by different growing proteins—a possible role that enhances interest in these sequences. A good model system with which to study this

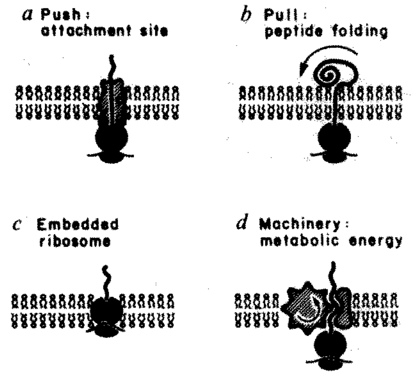

Fig. 2 Models for cotranslational chain extrusion across membrane. *a*, The energy derives from the GTP hydrolysis required for chain elongation on the ribosome; this model requires a firm ribosomal attachment to membrane and a fixed channel in the membrane. *b*, Spontaneous extracellular folding of nascent peptide pulls the chain through the membrane. *c*, Ribosomes are embedded in the membrane, releasing their nascent chains directly to the farther side. *d*, The membrane itself provides a machinery for transducing metabolic energy into unidirectional transfer of the chain. possibility may well be the formation of the inner and the outer membrane of Gram-negative bacteria. Although the proteins of the outer membrane may be secreted across the inner membrane and only then incorporated, after crossing the peptidoglycan layer, it seems more likely that they selectively enter the junctions (adhesion sites[93]) between the two membranes and then move outwards in the two-dimensional fluid of the membrane. Thus matrix protein of the outer membrane is localised initially at adhesion sites[94], and bacteriophage λ receptor protein only at the cell septum[95].

Among the proteins in the periplasm, secretion is reported to occur only during cell division for galactose- and maltose-binding proteins[96,97], but throughout the cell cycle for alkaline phosphatase[96]. These differences provide further evidence for diversity in the mechanisms of transfer.

Discussion

In the past 8 years, since the discovery of the *N*-terminal signal sequence of an immunoglobulin precursor, our knowledge of the mechanism of protein secretion has progressed a good deal. The process is very similar in bacteria and in eukaryotic cells, except that after peptide release, by puromycin, ribosomes remain attached to membrane in preparations from animal cells but not in those from bacteria. This difference might reflect a basic difference in mechanism, perhaps associated with a greater stability of the machinery of secretion in animal cells. On the other hand, the mechanisms might be the same, one of the two observations failing to reflect the physiological process.

The central problem of protein secretion is now the identification of the basic molecular mechanism that ensures unidirectional transfer of the growing chain. The available evidence seems to point towards a specific machinery for active transport of proteins across the membrane; but direct attachment of the ribosome, permitting it to supply the energy, is not rigorously excluded. The decision between these mechanisms must await further information, either on the nature of the contact between ribosome and membrane, or on the source of the energy for transfer of the growing chain. And among other aspects of the process, we do not know whether the signal sequence is first inserted into lipid linearly[15] or as a loop[28,63]; or whether the channel surrounding the chain exists preformed or is induced to assemble from separate molecules in the membrane. Finally, since at least some secreted and some incorporated proteins seem to enter in the same way, the mechanism responsible for their subsequent divergence, presumably triggered by a second, later signal segment, remains to be determined. A possible model for this 'stop' signal is the anchoring of an erythrocyte membrane protein[98], and a penicillin-binding enzyme of the inner membrane of *B. stearothermophilus*[99], by a cleavable COOH-terminal segment. In the latter protein a rather hydrophobic sequence has been determined for the cleaved segment (D. J. Waxman and J. Strominger, personal communication).

It seems reasonable to expect that genetic studies will shed much light on these problems. Another approach is provided by the use of conditions that interfere with secretion by decreasing the fluidity of the membrane[100–102].

In bacteria the presence of a multi-layered rigid envelope presents a special problem for secretion of proteins into the medium: it is not known whether these proteins pass through the successive layers, or through specialised regions of the cytoplasmic membrane that are exposed to the exterior. In addition, the segregation of different proteins into the inner and the outer membrane of Gram-negative bacteria presents a problem of membrane morphogenesis analogous to that of eukaryotic cells.

Knowledge of signal sequences for secretion has recently found practical applications. For example, to increase the yield of insulin in recombinant bacteria the gene for insulin has been fused with the beginning of the gene for the *E. coli* periplasmic *β*-lactamase; the resulting hybrid protein is secreted, and it can then be recovered by osmotic shock and cleaved to yield the hormone[103]. In addition, the bacterial mechanism of secretion can evidently recognise a mammalian signal, since bacteria containing the ovalbumin gene secrete its product[104,105].

The experiments described here illustrate the continuing value of bacteria as model cells, in an era that has seen a large shift away from this approach to cell biology.

We thank J. Beckwith for helpful comments. The work in our laboratory has been supported in part by a grant (GM 16835) from NIH, and a grant from the American Cancer Society.

Sr isotopic fractionation in Ca–Al inclusions from the Allende meteorite

P. J. Patchett*

Department of Geology and Mineralogy, Parks Road, Oxford, UK

True relative Sr isotopic compositions, determined by double spiking on Ca–Al inclusions from the Allende meteorite show up to 1.5‰ per mass unit mass fractionation relative to the Earth and bulk chondrites. All abnormal inclusions are light-isotope enriched. A lack of isotopically heavy Sr in inclusions would place constraints on the time, place and mechanism of origin of these objects.

A FEATURE of much of recent data[1–4] on isotopic anomalies in meteorites is that an arbitrary value for a certain isotopic ratio has been used to correct for mass fractionation in the mass spectrometric analysis. This means that the true isotopes responsible for any anomalous isotopic ratio cannot be uniquely identified, and several interpretations of mixing of nucleosynthetic components are possible[5,6]. The double spike isotope dilution technique, however, corrects for laboratory fractionation, and allows a full comparison between the isotopic compositions of samples[7,8]. The method leads to clear identification of the isotopes involved in nucleosynthetic anomalies, and also any natural mass fractionation processes which occurred in the sample before analysis[9,10].

Two spike solutions, enriched in ^{87}Rb, ^{84}Sr and ^{87}Sr, and differing only in Rb/Sr ratio, were both calibrated in quadruplicate against NBS 987 Sr. The composition for NBS 987 of $^{88}\mathrm{Sr}/^{86}\mathrm{Sr} = 8.37521$, $^{87}\mathrm{Sr}/^{86}\mathrm{Sr} = 0.71014$ and $^{84}\mathrm{Sr}/^{86}\mathrm{Sr} = 0.056584$ was assumed. The spike composition was calculated by means of the double spike mathematical solution[8], where NBS 987 constituted the 'spike' for the determinations, and the eventual spike constituted the 'sample'. As the composition of NBS 987 is a very poor spike for this purpose, the error propagations are large; resulting spike compositions are given in Table 1. The spike allows inter-sample comparison of total isotopic composition, but cannot yield 'absolute' values for external application, because no absolute calibration standard is yet available.

Samples were handled with stainless steel tools in clean room conditions. An HF/HNO_3 bomb dissolution was used, and great care was applied to ensure total solution of the sample after this stage, first in HNO_3 and then in HCl. The total sample was then divided into aliquots in HCl solution and spiked. Completely separate sets of equipment were used for spiked and unspiked

Table 1 Rb–Sr spike compositions

Spike	Rb/Sr	^{85}Rb/^{87}Rb	^{88}Sr/^{87}Sr*	^{86}Sr/^{87}Sr*	^{84}Sr/^{87}Sr*
Rb–Sr-1	0.30005	0.008908	0.088155 ±12	0.0097440 ±14	0.95547 ±40
Rb–Sr-2	0.015265	0.008908	0.088130 ±12	0.0097365 ±14	0.95541 ±40

* Errors are two standard errors of the mean of four calibrations.

sample solutions, thus eliminating the possibility of cross-contamination. Ion-exchange separation was two-stage for Sr in PTFE columns; Rb fractions were further purified[11]. Blanks were <0.1 ng Rb and <0.2 ng Sr; for the small samples ALL-24, 40 and 41, where the first, larger column was omitted, Rb and Sr blanks were <0.03 ng.

Mass spectrometry was performed using a VG Micromass 30, fitted with a Cary 401M amplifier since July 1978. Ion currents corresponding to the most abundant isotopes were at a level of $1.5\text{-}3\times10^{-11}$ A. Isotopic data were collected and reduced as blocks of 10 scans over the mass range; 25–50 such blocks constitute a run. In several cases almost all the Sr on the filament was used in the analysis, and progressive in-run mass fractionation of up to 2% per mass unit was observed; no evidence was seen in any of the runs for detectable departures from linear first-order mass fractionation (compare ref. 10 for Ca).

^{87}Sr was used as reference isotope for data collection and the double spike calculation. The equations for the double spike solution[8] were used to propagate errors in a mathematically rigorous way, using a summation of partial differentials. Only errors in spike composition, which can be disregarded for inter-sample comparison, are excluded from the final uncertainties given in Table 2. Inclusion of this component would result in a ~30% increase in errors on isotopic ratios.

Mean values for 10 runs of NBS 987 over the period of study were $^{87}\text{Sr}/^{86}\text{Sr} = 0.70995\pm3$ $(2\sigma_m)$, $^{84}\text{Sr}/^{86}\text{Sr} = 0.056512\pm16$ $(2\sigma_m)$, when normalised to $^{88}\text{Sr}/^{86}\text{Sr} = 8.37521$. Baselines were always constant over the spectrum to better than 0.2%, and the difference between our values and NBS values represents a bias in amplification of peaks. Results from other laboratories (see refs 3, 12) show comparable variations, particularly in ^{84}Sr/^{86}Sr. As our amplifier tends to overemphasise larger peaks, then the results obtained by double spike analysis of NBS 987 fall around $^{88}\text{Sr}/^{86}\text{Sr} = 8.378$, $^{84}\text{Sr}/^{86}\text{Sr} = 0.05649$, instead of the 8.375 and 0.05658 used for spike calibration. The amplifier contributes a small bias to the analyses towards higher ^{88}Sr/^{86}Sr and lower ^{87}Sr/^{86}Sr and ^{84}Sr/^{86}Sr.

Because this study reports small differences in Sr isotopic composition for Allende inclusions, we need to demonstrate beyond all doubt that no inter-sample bias has occurred. There are only three differences in the way in which samples have been treated: (1) ALL-24, 40 and 41 were passed through only one ion-exchange column instead of two; (2) whole meteorite and Allende matrix samples were analysed with spike solution Rb–Sr-1. Rb–Sr-2 was used for mantle nodules and Allende inclusions; (3) there was large variation of the sample Sr/spike Sr ratio, from 0.07 to 3.09 (Table 2). A value of 0.5 is considered optimum.

Table 2 shows that ALL-24, 40 and 41 are quite uncritical for the overall result of this study, and the minor difference in chemical procedure is therefore insignificant. The test analyses of NBS 987 given in Table 2 are crucial in eliminating items 2 and 3 as sources of bias. These tests were all processed using the same run data for unspiked NBS 987, so that they compare closely the results of four double spike runs. Test 1 was made using spike Rb–Sr-2, and its agreement with the other three tests, made with Rb–Sr-1, shows that there is no bias connected with which of the two spike solutions is used. Tests 2, 3 and 4 were made with Rb–Sr-1, where the sample Sr/spike Sr ratio varied from 0.19 to 1.09. As the results are identical within errors, it is concluded that no bias is associated with change in the sample Sr/spike Sr ratio. Additionally, Sr compositions close to those of NBS 987 were determined for terrestrial analyses where the sample Sr/spike Sr ratio ranged up to 3.09 (Table 2). The small bias introduced by the amplifier is approximately constant for all analyses, in spite of variation of peak sizes between different spiked runs. Hence all the analyses reported here are closely comparable in every respect.

Terrestrial and bulk chondritic Sr

The analyses of chips of four terrestrial mantle nodules and of four bulk chondrites are presented in Table 2. Rb was not analysed for these samples. The Sr isotopic compositions plot in a tight group with the four NBS 987 analyses, and together define the Earth plus bulk chondrite field of Fig. 1.

Allende Sr

All samples were extracted from a single 450 g individual. Diameters of Ca–Al inclusions (CAI) range from 15 down to 1 mm, but none smaller than 2.5 mm were analysed. All fine-grained CAI are pink except ALL-40, which is white; ALL-24, 30, 72 and 76 are colour-zoned, with white margins. Thin sections show that of the coarse-grained CAI, ALL-4, 6, 37, 46, 56 and 70 are clearly type B (ref. 13), while ALL-7 and 68 are apparently intermediate between A and B; ALL-41 and 49 were not examined.

Plotting of the results (Table 2) on an Rb–Sr isochron diagram (not given) shows a scatter of points lying below a 4.6 Gyr line, closely similar to earlier studies[14,15] and possibly reflecting a relatively recent disturbance[12,14–16]. In terms of $^{84\text{-}86\text{-}88}$Sr isotopic composition, the matrix samples plot close to the Earth/bulk chondrite field (Fig. 1), while the CAI define a continuous trend towards lower ^{88}Sr/^{86}Sr and higher ^{84}Sr/^{86}Sr. This trend is completely consistent with the predicted mass fractionation path, and regression of the data gives a slope of -1.05 ± 0.18 (2σ), where MSWD = 2.3. Within error, the same line is obtained if either the coarse- or the fine-grained CAI are regressed alone. A second chip of the most abnormal sample (ALL-76, a fine-grained pink CAI) was dissolved, confirming its general position. The analysis is not an exact repeat because the inclusion was not powdered; indeed, the ^{87}Sr/^{86}Sr ratios (Table 2) and model ages of the two chips are very different probably because of the recent isotopic disturbance. The white margin of ALL-76 has an Sr composition lying approximately half way between that of the pink interior and the Allende matrix (Fig. 1). ^{85}Rb/^{87}Rb ratios for three samples (Table 2) are not regarded as deviating significantly from the accepted terrestrial value of 2.593, because mass fractionation cannot be controlled or reproduced in the runs.

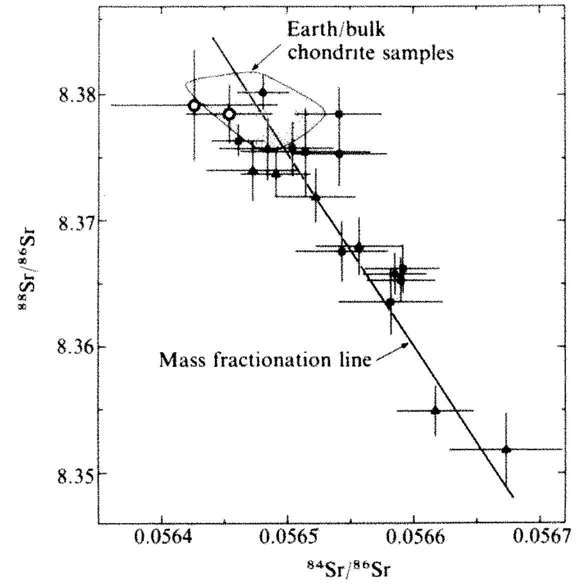

Fig. 1 ^{88}Sr/^{86}Sr–^{84}Sr/^{86}Sr plot for the double-spike analyses reported here. Shaded area includes four NBS 987 analyses, four terrestrial mantle nodules and four bulk ordinary chondrites. All marked points, with errors at 2σ, are from the Allende meteorite, ○, Matrix; ■, coarse-grained CAI; ▲, fine-grained CAI.

Discussion

The results for terrestrial, bulk chondrite and Allende matrix samples demonstrate that the accretion regions of the Earth, ordinary chondrites and Allende matrix were essentially uniform in Sr isotopic composition.

For the Allende CAI samples, an origin for the variation of ^{88}Sr/^{86}Sr and ^{84}Sr/^{86}Sr in the recent isotopic disturbance of the meteorite[12,14–16] can be ruled out because this would only lead to homogenisation of ratios, and could not by itself produce an apparent mass fractionation. Heavy element fission can be ruled out because ^{84}Sr and ^{86}Sr are shielded from all but direct yields. A neutron flux[17] affecting all Solar System Sr except that in some CAI could explain a pattern in which Solar System ^{84}Sr became depleted and Solar System ^{88}Sr enriched relative to the CAI. However, the neutron-capture cross-sections[5,18] show that in a neutron irradiation, burning-out of ^{84}Sr would predominate over all other effects; one-to-one correlation of ^{84}Sr and ^{88}Sr anomalies is almost certainly impossible.

The pattern of Fig. 1 can be produced by certain combinations of nucleosynthetic components. In the case of strontium, ^{84}Sr is thought to be of 100% p-process origin, ^{86}Sr and ^{87}Sr are s-process only (except for a minor contribution to ^{87}Sr from ^{87}Rb), while ^{88}Sr may be 90% s-process plus 10% r-process[5]. The compositions of the abnormal CAI relative to Solar System Sr could be explained by any of excess p plus deficient r, excess p plus smaller excess s, or deficient r plus smaller deficient s. Such nucleosynthetic explanations are unlikely for two reasons. First, in such a model, closely correlated effects are needed in partly independent components, to produce the slope of −1 in Fig. 1. Apart from this *a priori* improbability, Papanastassiou *et al.*[3] have discovered, in two CAI, a nucleosynthetic anomaly in Sr with quite different characteristics. The Sr from these two CAI cannot be plotted in Fig. 1, because of the necessity for normalisation in the runs[3], but the points must lie on mass fractionation lines to the left of that in Fig. 1. Perhaps there are anomalies of nucleosynthetic origin showing good correlation of ^{88}Sr/^{86}Sr and ^{84}Sr/^{86}Sr effects in many inclusions (those of this study), and an additional, uncorrelated component present in only a few (EK1-4-1 and C1), but this seems highly unlikely.

The excellent fit of the data points to a mass fractionation line suggests strongly that mass fractionation is the physical explanation for the variation. Accepting this, the striking feature is that all the samples are either normal or enriched in light isotopes. In contrast, Si, Mg and O from CAI show either heavy-isotope enrichment, or both positive and negative δ-values[19–23]. Although another Allende stone might show heavy-Sr enrichment in its CAI, the observed consistent light-Sr enrichment requires explanation. No clues are derived from other parameters, because the position of points on Fig. 1 is uncorrelated with inclusion type, inclusion size, major mineralogy, Sr content and Rb content. The fractionation has affected both coarse- and fine-grained CAI.

It seems likely that these CAI formed from a vapour which was isotopically lighter than normal Solar System Sr, because mass fractionation effects always lead to formation of an isotopically heavy solid and an isotopically light vapour[24]. If the rate-determining and fractionating step in the Sr accretion process was diffusion of Sr into pre-existing solid Ca–Al objects, then light isotopes might diffuse faster than heavy isotopes, and so produce isotopically light cores plus isotopically heavy rims from normal vapour. If the outer zones were later removed by volatilisation, then overall isotopically light CAI would result,

but I feel that the generation of mass fractionation by diffusion seems unlikely. Vaporisation events, thought by many to be an important part of CAI history[25,26], are for the purposes of isotopic mass effects the reverse of condensation, and are thus also incapable of leaving an isotopically light solid from a normal starting material.

If the CAI formed from a vapour with isotopically light Sr, then they cannot have formed from the bulk of the solar nebula, which had overall 'normal' Sr, as shown here. They could have formed early in some restricted part of an inhomogeneous nebula[24,27], which had attained a light-isotope enriched Sr composition by: (1) prior condensation of materials which are isotopically heavy in Sr. These would have to be unsampled, and at least as refractory as CAI; or (2) vapour transport processes involving a kinetic isotope effect, such that one region of the vapour became enriched in light isotopes.

If the CAI did form in some restricted, fractionated region of the solar nebula, then the fact that the white outer part of the fine-grained CAI ALL-76 is closer to 'normal' Sr than the pink core may either indicate the beginning of equilibration of this anomalous region with the whole, or of the movement of that CAI as a solid object into a more normal region of the nebula. Alternatively, the white zone could merely represent equilibration of CAI with matrix during the isotopic disturbance demonstrated from $^{87}Sr/^{86}Sr$ data.

An entirely separate possibility is that the CAI are in part presolar objects[25,28], so that the Sr compositions are not *a priori* expected to be related to the remainder of the Solar System. Gas–dust fractionation in the presolar interstellar medium has been proposed to account for mass fractionation effects in CAI[29]. In this scheme, the refractory Ca–Al-rich dust and grains, which are isotopically heavy, become separated from the vapour, which is isotopically light, resulting in mass separation of the elements. For the Sr data, this scheme encounters the difficulty that the Ca–Al materials seem to be all isotopically light, inconsistent with their proposed role as isotopically heavy interstellar grains and dust. Note, however, that true type A CAI have not been sampled in this study. Although the bulk Sr of the environment where the sampled CAI formed could have been isotopically light ($^{88}Sr/^{86}Sr < 8.35$), it would then be remarkable that this presolar bulk Sr composition was related to the Solar System Sr composition along a mass fractionation line.

I thank J. W. Arden and N. H. Gale for discussions and NERC for financial support. Mantle nodules were made available by A. J. Erlank, J. B. Dawson and J. J. Gurney, and chips were extracted by E. Butler.

Sill intrusions into highly porous sediments in the Guaymas Basin, Gulf of California, lead to low-grade metamorphism, thermal alteration and migration of organic compounds, marked changes in interstitial water chemistry, and large-scale expulsion of heated pore fluids. The latter process creates space for the intruding magma and initiates a hydrothermal system, which can explain the observed hydrothermal deposits around fault scarps on the basin floor.

STUDIES of the genesis of several land-based ore deposits show that their formation is due to the intrusion of basaltic magma into deep water marine sediments[1,2]. Many geologists exploring such ore bodies believe that the sources of ore-forming elements are the sediments adjacent to the hydrothermal deposits[3,4]. Due to subsequent faulting, folding and metamorphism, however, the mechanisms of magmatic intrusions into soft sediments and their possible effects on the formation of hydrothermal deposits are not yet fully understood.

Hydrothermal deposits associated with mid-oceanic spreading centres, such as the Galapagos Rift hydrothermal system[5–7], occur generally in conditions where sedimentation rates are

0028-0836/80/050441—05$01.00

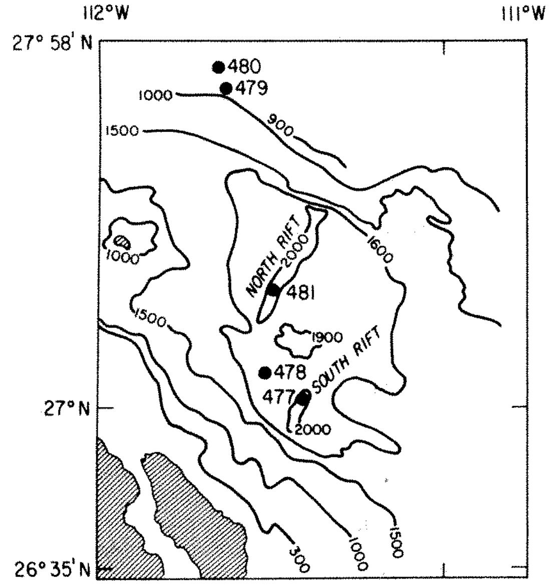

Fig. 1 Map of Guaymas Basin, depth contours in metres.

relatively slow and where magma extrudes onto the sea floor. There is strong evidence that seawater circulating through the basalts of Layer II is the convecting fluid in most mid-ocean ridge systems[5-8]. Hydrothermal waters are occasionally trapped in brine pools to form ore deposits, as has been discovered in the Red Sea[9].

At a time when studies of marine hydrothermal systems at ocean ridge crests are gaining momentum by the discovery of hydrothermal mounds and discharge vents[7], Leg 64 of the Deep Sea Drilling Project (DSDP) has drilled a hydrothermal system in the Guaymas Basin of the Gulf of California in a very different setting. In the Gulf of California, which represents a newly evolving ocean basin characterised by high sediment accumulation rates, oceanic basement is formed in a manner different from the more normally observed ophiolite, pillow basalt sequence of the later stages of ocean evolution.

Observations

The Guaymas Basin was formed during approximately the past 3.5 Myr by ocean floor spreading[10]. Two rift depressions (Fig. 1) lie in the otherwise flat floor of the basin, offset about 20 km by a transform fault. Both the north-east and south-west margins of the basin are the scarps of longer transform faults which connect to spreading axes in the next basins to the north and south. The entire basin and both rifts have been well explored by seismic and heat-flow measurements[11-13]. Three drilling sites were occupied in the basin during Leg 64—Sites 477, 478 and 481 (Fig. 1).

All three sites drilled thick sections of turbidites, composed of muddy diatomaceous oozes and plagioclase-rich terrigenous sands to muds[14]. Accumulation rates exceed 1,200 m Myr^{-1} on the basin floor and may be higher in the rift depressions. In four holes (477, 477A, 478 and 481A) basaltic to coarse-grained doleritic sills were encountered—several at shallow burial depths[14] (Fig. 2).

Site 477 in the southern rift consisted of two holes, offset by only 165 m. In Hole 477 the sill consists of altered dolerite, and in Hole 477A a less altered dolerite sill was encountered at shallower depths. Conductive heat flow was estimated from shipboard measurements to be at least 20 heat-flux units (HFU = 10^{-6} cal cm^{-2} s^{-1}), similar to that measured in the immediate vicinity by Lawver *et al.*[13]. Temperatures increase gradually with depth below the sills, thus indicating the presence of a major heat source below the drilled section of this site. Substantial increases with depth occur in dissolved chloride, lithium and manganese, especially below the sills (Fig. 3). Dolomite, anhydrite and pyrite occur in fine-grained, clay-rich sediments below the upper sills. Below 180 m the mineral paragenesis includes epidotes (4–10% Fe), quartz, albite and chlorite. These hydrothermal minerals indicate temperatures up to 300°C (ref. 15). Carbon/nitrogen ratios of organic matter increase rapidly with depth below 150 m and the organic matter is devoid of nitrogen below 200 m. The expulsion of all organic nitrogen also indicates very high temperatures.

Site 478 is located outside the present rift zones and therefore its sediments and basaltic intrusions are probably older. Heat flow is estimated at 3.65 HFU. Only minor increases in dissolved chloride and lithium occur, and dissolved manganese values are near the detection limits (<5 μM). Various changes have occurred in the sediments around the sills, including the remobilisation of silica, the formation of dolomite, and the recrystallisation of clay minerals. No higher temperature minerals have been observed.

Site 481 in the northern rift is characterised by a heat flow of about 4 HFU. Dissolved chloride and lithium concentrations (Fig. 3) clearly indicate the influence of the uppermost sill complex. No dissolved manganese was detected (<5 μM). Hydrocarbon (C_2–C_5) gas data show a thermal component above and below the sills, with a series of three maxima above the sill. These observations are similar to those in DSDP Site 368[16,17]. Carbon/nitrogen ratios of organic matter in Sites 478 and 481 do not change dramatically near the sills, indicating that sediments in the vicinity of the sills were not heated excessively. Oxygen isotopic analysis of recrystallised calcite, at a distance of about 1 m above the sill of Hole 481A, indicates a temperature of formation of ~150 °C.

Hydrothermal system

The following observations in the sediments above the doleritic intrusions are evidence of the sill-like nature of these intrusions: (1) decreases in porosities (Fig. 2); (2) disappearance of diatoms;

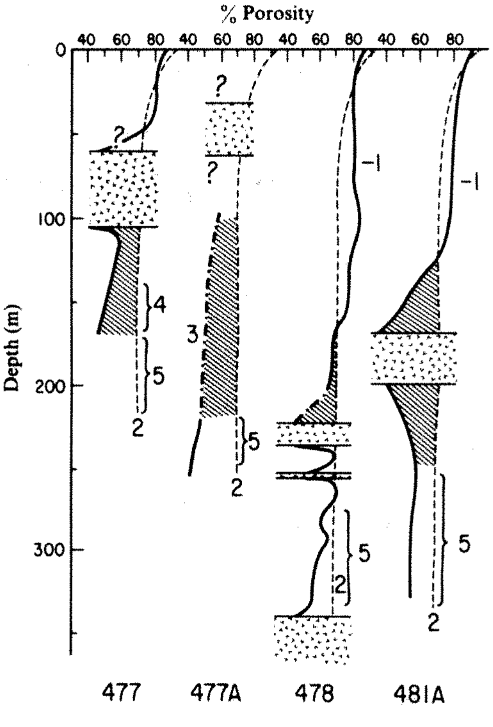

Fig. 2 Sill-induced reduction of porosity (hatched areas) in Guaymas Basin drill sites. 1, Shipboard porosity measurements; 2, shipboard porosity Site 479 (reference line); 3, porosity curve Hole 477A, deduced from density log; 4, porosity reduction due to deeper intrusions? 5, sections not considered for calculation of water loss (Table 1), though some effect may be caused by compaction due to upper sill load (in Site 478, definitely affected by lower sill).

Table 1 Reduction of porosity and water loss by intrusion of the uppermost sill (compare Fig. 2; for symbols and formulae, see text)

Hole	Thickness of sediment sections influenced by uppermost sill h_2	(m)	Loss of water (as height of water column) h_p (m) From single sections	Total	Thickness of uppermost sill (m)
477	Above sill	?13	7.3		
	Below sill	7	3.0	~44	45
		69*	33.4		
477A	Above sill	?	?		
	Below sill	35	?	At least 75	30
		120†	75.6		
478	Above sill	56	12·3	~14§	17
	Below sill	12	1.5		
481	Above sill	45	24.9	~53	30
	Below sill	50	28.6		

* Part of the porosity decrease of this section may be the result of a deeper hot intrusion. On the other hand, the sediments below those that were drilled are also affected by the load of the uppermost sill.

† Porosity deduced from density log. The cored section from 220 to 260 m with $n_2 \sim 45\%$ may be influenced by a deeper sill and is therefore not considered.

‡ Including thin sill at ~250 m depth. It is assumed that this sill has intruded simultaneously with the uppermost sill.

§ Minimum value, since real porosity reduction was probably larger than indicated by reference line (2) in Fig. 2.

(3) dolomite formation and calcite recrystallisation at elevated temperatures; (4) clay mineral recrystallisation and (5) organic matter decomposition.

The sharp decreases in porosity above and below the sill intrusions are particularly interesting. These decreases are clearly related to the effects of the intruding hot magmas, which cause the migration of pore waters away from the sills. The upper limits of the zone of reduced porosity presumably define the minimum thickness of sediment above the sills at the time of sill intrusion.

On intrusion of the sills, temperatures at the sill-sediment contact may rise to as high as 400 °C (the critical point for a pure 3·5% sodium chloride solution is 304 bar and 408 °C). In ridge-crest geothermal systems estimated temperatures at which seawater rock interactions occur are at least 300 °C[7]. Thus the pore waters in the immediate vicinity of the sills will rise to the boiling point. Most of the heat contained in the sill between 1,200 and 400 °C will be removed by the steam. Rough calculations indicate that for a sill of 30 m thickness, temperatures at the outer rims of the sill will drop to below the boiling point within a period of five years. From then on, heat will be lost from the sill by conduction through the sediments. Cooling of such a sill to 15 °C will be accomplished in ~50,000 yr. At sedimentary contacts in exposures on land, where original porosities may have been much lower, heating of material surrounding the intruding sills can be considerable, as evidenced by coal seams turned to cinder coal[19], fusion of sediments[20], and clastic dykes of liquified material intruded in the sills from the underlying sediments[21].

From the reduction in porosity in the contact zones, the amount of expelled pore water can be calculated in terms of the reduction in sediment thickness; this requires an estimate of the porosities before the occurrence of the sill intrusion. For Holes 477, 477A, 478 and 481A it has been assumed that the original porosities were similar to those in Site 479 (at the northern end of the Guaymas Basin, Fig. 1) at corresponding depths. These sediments have not been affected by intruding magma, and their composition resembles that in the basin sites. If there is a difference, the porosities in the basin sites were higher than in Site 479 because of their more turbiditic character and their faster sedimentation rates. Therefore, our calculations represent minimum values for the water losses.

The height h_p of expelled pore water can be found using the formula

$$h_p = h_1 - h_2 = h_2\left(\frac{100-n_2}{100-n_1}\right) - 1$$

where h_1, n_1 are the original height and porosity of a certain sediment section; and h_2, n_2 are the present (reduced) height, porosity of same sediment section.

It follows from the above formula that h_p is not a linear function of the reduction in porosity. If the porosity is reduced from 80 to 70%, $h_p = 0.5\ h_2$, that is, if $h_2 = 10$ m (present height of sediment section), 5 m of pore water has been lost and the original height of the sediment column was 15 m. If a decrease from 60 to 50% in porosity occurs, h_p is only $0{\cdot}2\ h_2$, and so on. Using an integrative model, the water loss from the contact zones above and below the uppermost, presumably youngest, sill was calculated (Table 1).

From the results of these calculations two principal conclusions can be drawn:

(1) At all sites the total water loss from the sediments caused by the uppermost sill is of the same order of magnitude (in height of sediment column) as the thickness of the sill. This suggests that the water removal from the neighbouring sediments creates space for the intruding magma and that a sill intrusion into highly porous sediments does not necessarily cause a large change in relief at the sea floor.

(2) If a sill of 30–40 m thickness can expel, on average, a water column of ~40 m (10 m above and 30 m below the sill), and if it occupies (perhaps together with neighbouring sills) an area of 1 km², ~40 × 10⁶ m³ of pore fluid are forced to the sea floor. This water migrates through somewhat tilted beds of relatively good permeability, for example, the sandy base of turbidites, until it reaches one of the many faults known from seismic records. These act as conduits leading the heated waters upwards (Fig. 5). At some later stage, some of the turbidites may become lithified and form cap rocks. But fissures within these layers or in the cooling sill create sufficient permeability for water to escape laterally. The sill also provides additional overburden pressure on the underlying sediments, causing compaction and thus further water expulsion. Sediments precompacted

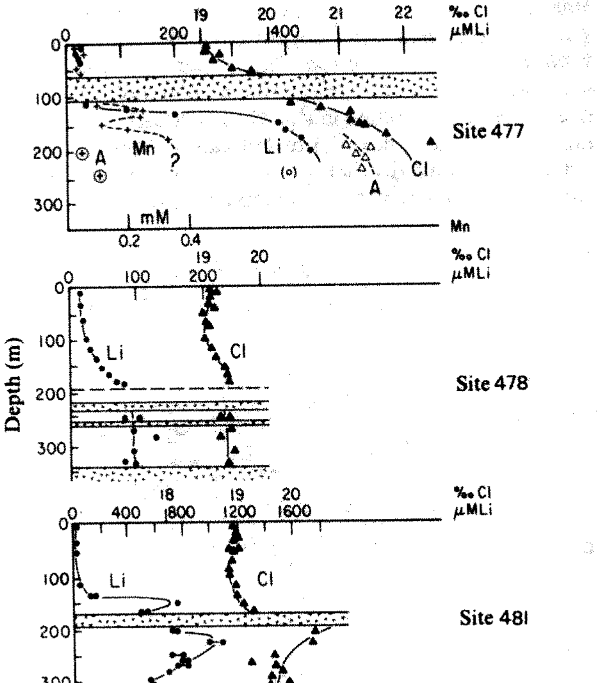

Fig. 3 Distribution of interstitial water lithium, chloride and manganese in Sites 477, 478 and 481.

by the intrusion of older, deeper sills probably are only slightly affected by the younger intrusions.

Preliminary data on the inorganic chemistry of the pore fluids of these sites indicate that with the expulsion of pore waters and the incomplete reaction of magnesium, substantial quantities of magnesium, silica, calcium and perhaps manganese, iron and phosphate, can be brought to the sea floor. This in turn can lead to the formation of hydrothermal deposits similar to those observed in the northern trough (talc, pyrrhotite, copper and zinc sulphide, manganese oxides)[22]. Preliminary calculations suggest that the emplacement of a 40 m thick sill could lead to the expulsion via the pore fluids of Ca, Mg and SiO_2 of the order of magnitude of $1–50\times10^6$ kg and $\sim0.01–0.1\times10^6$ kg of phosphate per km^2 of sill.

Geochemistry of hydrothermal sediments

Hydrothermal alteration of basalts at oceanic spreading centres leads to large increases in ^{3}He, Li, K and Ca in the hydrothermal fluids[7,23,24]. The data presented in Fig. 3 also indicate large increases in dissolved lithium. Although the source for this lithium may partly be due to hydrothermal alteration of the sediments, the enhanced ^{3}He levels observed in the bottom waters of the Guaymas Basin[25] indicate some magmatic contribution to the hydrothermal waters. Reversals in Li above and below the sill complex are probably related to the uptake of lithium into the sills from the pore fluids during present low-temperature alteration processes. Increases in dissolved chloride can be explained in terms of steam formation as well as by hydration of the sills.

The hydrothermal system of Site 477 is of particular interest. In this site, hydrothermal acitivity is associated with a deeper-seated heat source and not with the upper sills, which apparently have already cooled down considerably. Hydrothermal activity has probably been a long continuous process, leading to noticeable amounts of hydrothermal minerals, to increased metasomatism, and to the formation of high temperature phases such as epidote, albite, and chlorite. In Sites 478 and 481A, during and shortly after the intrusion of the igneous sills, heat flow must have been higher than at present. Most of these sills are considerably thinner than those observed in Holes 477 and 477A, so that cooling of these sills must have occurred at relatively rapid rates. This may explain why, in these circumstances, only moderate-temperature authigenic minerals (100–200 °C) have been detected, for example, dolomite, recrystallised calcite, recrystallised clay minerals. Also, only minor thermal decomposition of organic carbon has occurred in these sites. The three maxima in (C_3–C_5) hydrocarbon concentrations above the sill complex of Site 481 can be explained in terms of probable upward distillation (in three pulses) of C_3–C_5 hydrocarbons due to successive sill emplacements.

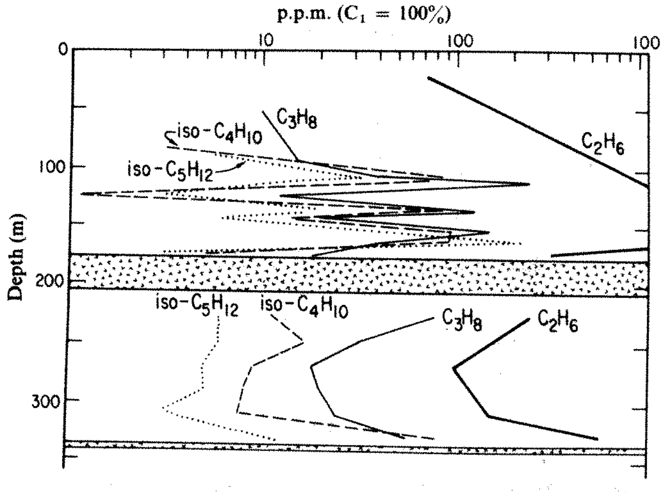

Fig. 4 Distribution of C_2–C_5 hydrocarbons, Site 481.

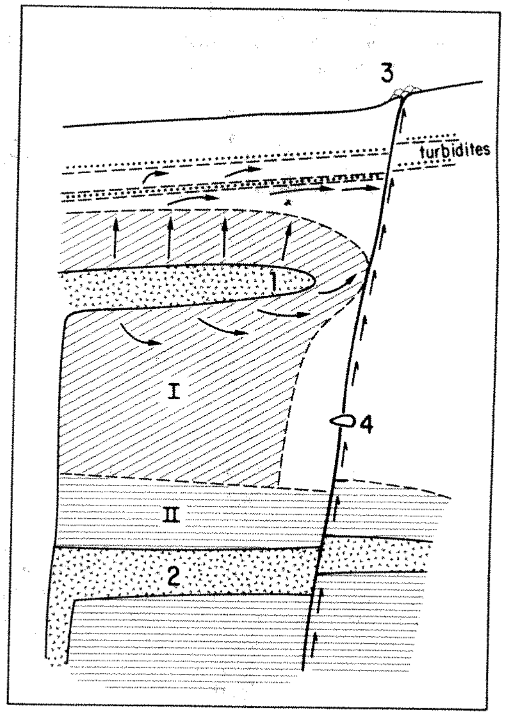

Fig. 5 Model of water expulsion due to porosity reduction as a result of intruding sills. 1, Uppermost sill; 2, older lower sill; 3, hydrothermal deposits around fault scarp; 4, Older, buried hydrothermal deposits. Conclusions

Drill sites in the Guaymas Basin in the Gulf of California demonstrate that during the initial stage of opening of some ocean basins, basaltic magma forming new oceanic basement intrudes as sills into rapidly deposited soft sediments in deep rift basins, thus creating a basement quite different from the normal ophiolite model concept[10]. Interaction between the hot sills and the surrounding sediments results in large changes in pore fluid composition (increases in dissolved lithium, chloride, manganese), in alteration of organic matter, in the formation of hydrothermal minerals, and in the large reduction in porosities in the sediment–sill contact zones. Large decreases in porosity imply substantial migration of heated pore fluids out of the sediments. This type of hydrothermal system is unlike those previously described on continents or at oceanic spreading centres. On the continent, hydrothermal systems are fed by recharge of meteoric water from neighbouring highlands, for example, the Salton Trough hydrothermal field[26]. At oceanic spreading centres without rapid accumulation of sediment, seawater circulates convectively through the basalts of Layer II. Our suggested mechanism does not require recharge of seawater into the sediments.

The dissolved constituents of the upward-migrating pore fluids deliver sufficient material for the precipitation of large amounts of magnesium silicates (as talc) and smaller quantities of iron and manganese compounds as oxides or sulphides, as well as minor amounts of phosphates and trace metals.

While the sills cool, the expulsion of pore waters slows down and finally ceases. The hydrothermal deposits formed at the sea floor are rapidly buried by younger sediments. New hydrothermal activity starts with the intrusion of younger sills into the overlying sections of unaltered sediments. Younger sills tend to develop on top of older ones because the magma can penetrate more easily into soft sediments than into sediments compacted by older sills.

Coding potential and regulatory signals of the polyoma virus genome

Eiichi Soeda*, John R. Arrand, Nina Smolar, Jane E. Walsh & Beverly E. Griffin

Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2, UK

The complete DNA sequence of the A2 strain of polyoma virus has been determined. It consists of 5,292 base pairs. The sequence is analysed in terms of its coding potential and sites of possible functional significance or structural interest. The polyoma virus genome is compared with those of related tumour viruses, simian virus 40 and BK virus.

POLYOMA virus is a small DNA tumour virus which was first isolated by Gross[1]. Polyoma virus grows in culture in a variety of mouse cell lines. It transforms other rodent cells (such as hamster or rat) in culture and can produce tumours in rodents. It is now considered reasonably certain that it codes for six proteins. These are the three 'early' proteins which have been designated as small, middle and large T antigens, and the three 'late' capsid proteins designated as (virus proteins) VP1, VP2 and VP3. Whether these are the only proteins encoded within the viral DNA and whether all the proteins are entirely virus coded is not known. Only a few distinct viral mRNA species have been identified, and, as yet, no early mRNA has been directly correlated with an early protein. The great interest in the 'early region', that is, the region transcribed before DNA replication occurs, follows from the fact that it is this region, or part of it, which seems to be responsible for the transformation *in vitro* of cells or for tumour formation *in vivo* (for general reviews see refs 2, 3).

Study of viral functions has been hampered by the fact that they are difficult to distinguish from those of the host cell. For example, infection with polyoma virus results not only in viral DNA replication, but also in the stimulation of cellular DNA replication. Thus, at the same time that viral functions begin to be expressed, many cellular functions are probably also switched on. There is also the problem, for instance, that virus proteins and messenger RNAs represent only a small proportion of the total proteins and mRNAs in a cell.

The DNA, on the other hand, is in relative terms, easier to study. The genome exists as a small, double-stranded, closed-circular molecule, the physical properties of which allow it to be isolated free from cellular DNA and characterised by the techniques of modern molecular biology. In sequencing polyoma virus DNA, we hoped to circumvent some of the problems mentioned above, estimate potential coding capacity of the virus, and assign parts of the genome to specific proteins. We also hoped to use the virus to elucidate control signals used in eukaryotic cells since it seemed reasonable to suppose that it might mimic its host.

An additional purpose in sequencing polyoma virus DNA was to compare the genome with that of closely related monkey and human viruses, simian virus (SV) 40 and BK virus. Much comment has been previously made of the similarities between the mouse (polyoma) and monkey (SV40) viruses. Although their hosts are different, the overall organisation of their DNAs has appeared to be remarkably similar[2]. This conclusion has been based primarily on the alignment of their respective messenger RNAs and their origins of replication relative to their DNAs, and on studies with a comparatively small number of mutants. However, attempts to hybridise the DNAs from the two viruses with each other in stringent conditions has revealed very little homology between the molecules.

The DNA sequence data, considered together with existing data on the viral proteins and mRNAs, now allow a more detailed description of the polyoma virus genome in functional terms. They also provide a predictive capacity not hitherto available for the virus. Moreover, a considerable homology with SV40 over about 80% of the genome is revealed, but large differences appear in the remaining 20%. These differences may be especially relevant since they appear to involve a transforming function[4] or regions which appear to have regulatory functions.

General features of polyoma virus DNA

The A2 (large plaque) strain of polyoma virus is composed of 5,292 base pairs. The DNA sequence is given in Fig. 1 and regions of special significance are listed in Table 1. The DNA contains 47.3% guanine–cytosine base pairs. An earlier estimate of this value, based on analysis of restriction endonuclease fragments, gave 47.0% (ref. 5). More than 90% of the viral DNA appears to be used in coding for proteins. The corollary to this is that somewhat less than 10% of the sequence may serve other functions, probably involved with control and regulation of viral expression. Data available at present suggest that a part of the sequence between the viral origin of replication and the initiation signal for early proteins may be dispensable[6], but there are no corresponding data about the sequence which lies between the origin of replication and the initiation signal for late

```

Fig. 1 The total sequence of polyoma virus DNA (A2 strain ref. 45), which contains 5,292 base pairs. The top strand contains a sequence with the same polarity as early mRNAs and the bottom strand contains a sequence with the same polarity as late mRNAs (ref. 46). The location of the eight *Hpa*II restriction endonuclease sites are indicated (for example, 3/5, 5/4). Using the convention previously adopted[11], the centre of the *Hpa*II 3/5 junction (CC↓GG) has been designated zero and nucleotides are numbered proceeding in a clockwise direction on the physical map (see Fig. 3). This *Hpa*II site probably includes the viral origin of replication, and such numbering allows easy comparison with the SV40 sequence of Fiers *et al.*[7], or the sequence as renumbered by Buchman *et al.*[47]. The location of the 11-base pair deletion found in the A3 strain of the virus[45], between nucleotides 43 and 55 (ref. 11), is indicated on the sequence by arrows (▼). The probable ATG initiation codon for the early proteins (position 173) and for the late proteins VP1(4074), VP3 (4657) and VP2 (5002) are shaded. Other sites of known or postulated significance are given in Table 1 and Fig. 3. Most of the sequence was derived using either the chemical sequencing procedure of Maxam and Gilbert[48], or the dideoxy method of Sanger *et al.*[49]. Over parts of the genome, both methods were used. Moreover, for most of the genome, both strands were sequenced. Details are given elsewhere[11,12,26,27]. Over 95% of the sequence was derived from studies on a single preparation of polyoma virus DNA, using a stock of A2 strain virus made from an isolate which was twice plaque purified.

proteins. With polyoma virus, for example, there are no extensive sequence duplications such as are found in the late region of SV40 (refs. 7, 8). For further consideration, the DNA is divided into 'coding' and 'noncoding' regions, and specific features are discussed in the relevant sections.

The coding regions

The early coding region extends from about 74.0 to 25.5 units clockwise on the physical map of polyoma virus DNA (ref. 9) and consists of about 2,700 base pairs. Assuming a co-linear relationship between DNA, RNA and protein, this amount of DNA would contain the coding capacity for proteins with a total molecular weight (MW) of about 100,000, and any splicing of the viral RNA molecules would reduce the estimate. However, the three known early proteins of polyoma virus, the small t, middle T and large T antigens, have been assigned combined MWs of about 175,000 (see ref. 10 and Table 2). The T antigens appear to be genuine virally coded proteins, so it is obvious that the virus needs extra coding sequences. From the DNA sequence, this appears to be accomplished by using more than one coding frame in a particular region of the DNA, that is, proteins are encoded in overlapping genes[11]. The coding potential of the early region is illustrated schematically in Fig. 2*a*. If the DNA is divided into its three coding frames and a solid block is placed within a frame whenever one of the triplet codons TAA, TAG or TGA (the putative termination signals) appear in the sequence, it is apparent that between 74 and 85 map units there is only one open coding frame. This has been designated frame 1. This frame is then closed, and between about 85 and 99 map units the other two frames (frames 2 and 3) are open. From 99 map units to the end of the early region, only one extensive frame (frame 2) is open, although short open areas are found in the other two frames. Thus, coding throughout the early region requires frameshifts[12,13]. These data are summarised in Fig. 2*a*, and protein assignments allowed by these and other data[14] are illustrated in Fig. 2*b*. From other studies of the proteins themselves, studies on mutants, and by analogy with SV40, frame 1 is believed to code initially for all three of the early proteins and they are thought to share common N-termini[15–17]. The bodies and C-termini of middle T antigen and large T antigen are encoded in frames 3 and 2, respectively. The C-terminus of small t antigen may lie in frame 1. Additional data taken from the DNA sequence (Fig. 1) which predict the location of the termination codons for each protein, postulate splices which occur in the mRNAs to produce the relevant proteins, and suggest the location of other significant or novel sites on the DNA are summarised in Table 1*a*. Some of these data have been published elsewhere[11–13].

One interesting aspect of the DNA sequence is that there is a strong bias in the distribution of termination codons. Whereas the termination signals TAA, TAG and TGA appear with about equal frequency through most of the early region in frames which are probably not being used for coding, this is not so for the region in frame 1 between about 86 and 95.5 map units. In this region, the only termination codon found in the DNA sequence is TGA. Were an occasional 'readthrough' of this signal to occur, a protein with MW of about 40,000 could be made entirely from frame 1, allowing, that is, for a suitable splice in the mRNA to remove the termination codon triplet (TAG) encoded in the DNA in this frame at position 806 (85.7 map units). This point is made not only because of this unusual

Table 1 Landmarks on polyoma virus (A2 strain) as suggested by DNA sequence

a, Early region (from about 1 to 2,920 nucleotides, see top strand, Fig. 1)

feature of the sequence, but also because a protein of MW 39,000, although not yet completely characterised, is frequently found together with the other polyoma virus early proteins[15]. Similarly, it is interesting to speculate that a second large T antigen observed on polyacrylamide gels, which has an MW slightly greater than usually found[18], could be due to read through of the UGA termination codon for large T antigen. Precedence for this suggestion appears in studies on the phage Qβ where a low level of readthrough of the UGA codon for the coat protein occurs to produce a longer, functional protein[19]. An alternative, and attractive, explanation is that TGA may not always specify a termination codon. In two mitochondrial systems, it has recently been suggested that UGA, instead of functioning as a termination codon, may code for tryptophan[20,21]. If either readthrough of UGA occurred or in polyoma virus UGA were a coding triplet, it is clear that this virus could specify more proteins than those which are known at present.

The late coding region extends from about 65 to 25.5 units anticlockwise on the physical map of polyoma virus DNA and consists of about 2,100 base pairs. This is enough information to code for proteins of approximate total MWs 77,000 in a co-linear fashion. The three known late proteins (VP1, VP2 and VP3) of polyoma virus have been assigned combined MWs of about 105,000 (see Table 2). However, it would appear that although they seem to be derived from independent mRNAs (ref. 22), all the amino acid sequences present in VP3 are also present in VP2. Therefore, the late proteins essentially require coding information for an MW of only about 80,000, which roughly corresponds to the prediction from the DNA sequence.

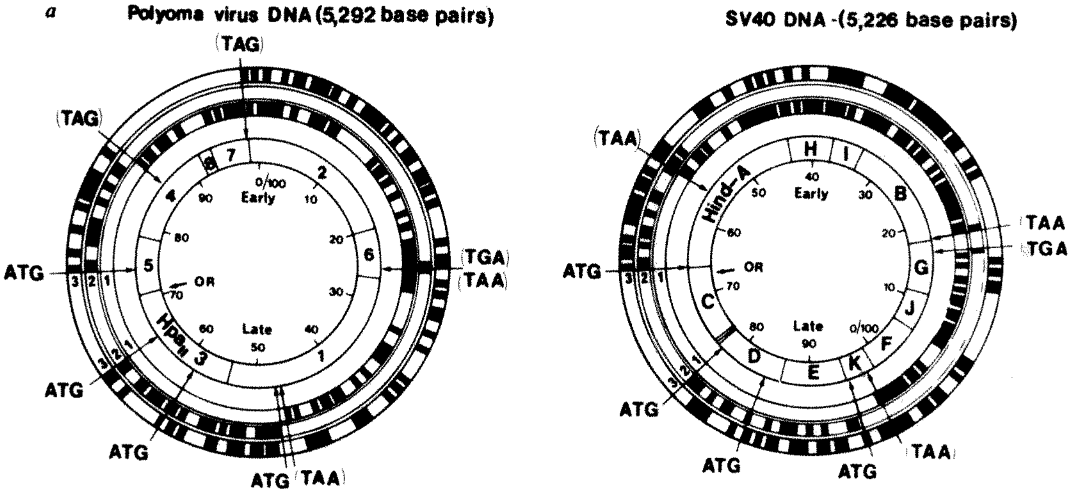

Fig. 2 *a*, A schematic diagram which divides the DNAs of polyoma virus and SV40 into three coding frames relative to their respective conventional physical maps. For polyoma virus, there are eight *Hpa*II fragments and the map is divided into 100 units with the *Eco*RI site at 0/100 map units[5]; for SV40, there are 13 *Hin*dII and *Hin*dIII fragments[7] and the map has been similarly divided with the *Eco*RI site at 0/100 map units. The conventional SV40 map (ref. 50) has been reorientated to allow a direct comparison with polyoma virus to be made. In each case, the viral origin of replication (OR) is also indicated. Whenever a termination codon (TAA, TAG, TGA) appears in the sequence within nine triplet codons (or 27 nucleotides) on the appropriate coding strand of the virus this is indicated by a block (■). For each virus within the early coding region, frame 1 begins at the A of the ATG codon which corresponds to the initiation codon (AUG) for the early proteins; consequently, coding frame 2 begins at the T and frame 3 at the G. By analogy, in the late region, frame 1 begins at the A of the ATG which specifies VP2, frame 2 at T and frame 3 at G. Since the early products of polyoma virus are transcribed off one strand of the DNA and late products off the other[51], early coding frames do not correspond to late coding frames. For polyoma virus, starting at the origin of replication and proceeding clockwise on the outside of the circle, are shown, in order, the single ATG initiation codon for the early proteins, and the TAG, TGA and TGA termination codons of small t, middle T and large T antigens, respectively. Proceeding anticlockwise (and from the opposite strand) the ATG initiation codons for VP2, VP3 and VP1 respectively, and the TAA termination codons for VP2/VP3 and VP1, respectively are shown. The diagram for SV40 corresponds in organisation to that of polyoma virus except that there are no signals for a middle T antigen. *b*, Landmarks on polyoma virus. The conventional *Hpa*II physical map is shown[5]. It has been divided into 100 units with the single *Eco*RI site at 0/100 map units. All other numbers refer to nucleotide numbers in Fig. 1. The postulated location on the genome of the six known virally coded proteins (the three early proteins, small t, middle T and large T antigens, and the late capsid proteins, VP1, VP2 and VP3) are indicated in the appropriate curved bars (see Table 1). Location of parts of messenger RNAs not coding for proteins are indicated as single, curved lines. DNA sequences absent in mRNAs, which have probably been removed by splicing, are indicated by jagged lines (ᨓ). Data for this diagram are found in Table 1. The coding region for the C-termini of small t antigen is assigned to the sequence between nucleotides 795 and 805, since this allows a protein with a size appropriate to this antigen[10] to be specified. Note that bodies of middle T and large T antigens are encoded in two differerent frames as are VP2/VP3 and VP1. There is an alternative splice for middle T antigen at a position between 747 and 800 map units; S_1 nuclease mapping data suggest that this is probably the correct one[14]. The coding frames used for each protein are shown in *a*.

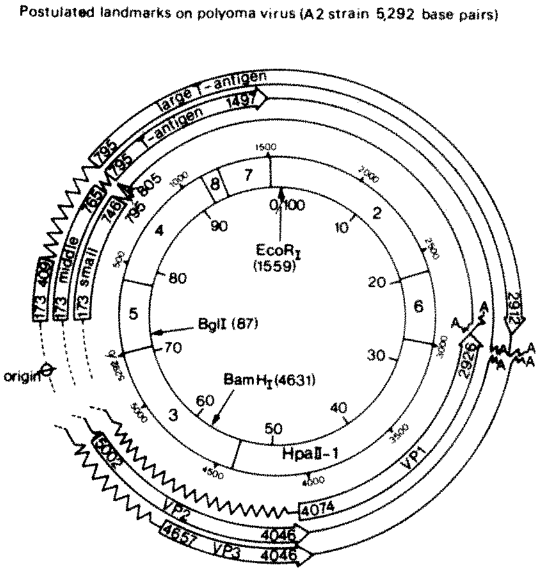
b



The sequences of the N-termini of the three late proteins have been determined[25]. It is thus possible to position them accurately on the DNA sequence. As above, the coding potential of the late region sequence is illustrated schematically in Fig. 2*a*. It can easily be seen that proceeding anticlockwise on the physical map from the origin of replication, only one reading frame (designated frame 1), between about 65 and 47 map units, contains no termination codons. This frame is then closed, and between about 46.3 to 25.5 map units only frame 2 is open for any extensive region. Thus, coding over the entire late region requires two reading frames. There are other unblocked regions within each frame over the entire late region which could be used for coding small polypeptides although no proteins other than the three mentioned above are known. The protein assignments on the genome are shown in Fig. 2*b* and the data are summarised in Tables 1*b* and 2. In coding terms the late region generally contains no surprising features and an analysis of it has been given elsewhere[26,27]. As in SV40 (refs 7 and 8), the C-termini of VP2/VP3 overlap the N-terminus of VP1 although the overlap in polyoma virus is less extensive than that predicted for the former (see Fig. 2).

The codons used by polyoma virus are given in Table 3. What is immediately apparent is the small use made of any codon which incorporates CG. Although CGN and NCG are occasionally used, their use is well below average, whereas CG when it appears between codons (NNC–GNN) occurs with average frequency (data not shown). This result is consistent with earlier studies on the dinucleotide composition of polyoma virus DNA[28]. A surprising feature is the low use of the codon AUC for isoleucine or GUC for valine, and to a lesser extent CUC for leucine, although the same discrimination against NUC codons is observed with SV40 (refs 7 and 8).

In summary, polyoma virus contains more coding information than a co-linear relationship between DNA, RNA and proteins would suggest. In several parts of the genome, notably in about half of the early region, more than one coding frame is used. The DNA sequence allows data from studies on viral mutants, mRNAs and proteins to be correlated. It should be emphasised that the latter data are by no means extensive and it is possible that our ideas about the coding potential of polyoma virus will later appear too restricted. The sequence seems to imply this. As a by-product of these studies, which allow the DNA sequence to be aligned with the (known) polyoma virus proteins, we should now be able to construct mutants to test the current model for the functional viral genome, as illustrated in Fig. 2*b*.

The non-coding or control regions

There appear to be two noncoding regions in the polyoma virus genome interspersed between coding regions. One lies entirely within the early region, probably between nucleotides 746 and 795 (Fig. 1), and the other lies around, and includes, the viral origin of replication. The presumption with the former is that it contains the information which regulates splicing events so that they occur in such a way as to produce functional messengers for the three early proteins, the small t, middle T and large T antigens. The dinucleotides GT and AG are thought to be important splicing signals[29] and the coding strand of this region, as well as the sequence which immediately precedes it, has a number of these dinucleotides. Between positions 724 and 794 there are seven GT and five AG dinucleotide sequences. Note that the entire region under consideration can adopt a moderately stable secondary structure which resembles a clover-leaf (Fig. 3*a*). The hypothesis that a GT dinucleotide lies at the 5′-side of an intervening sequence and an AG lies at the 3′-side seems now to be supported by data from a wide variety of sources (for review, see ref. 30). The assumption can therefore be made that any one, or all of these dinucleotides, could theoretically be used in the recognition events that lead to RNA splicing, but it is not known if structures such as that shown in Fig. 3*a* are important. Although the preferred splicing sites for the three proteins, as deduced from S_1 single-strand specific nuclease studies[14], are given in Table 1*a*, it can be envisaged that through either error or some subsequent selection procedure, other sites might be used during the growth cycle of the virus. These could lead to a variety of messengers being produced which specify proteins with only slightly modified sequences[12]. At the level of sophistication being used to study the viral proteins, this would not be noticed. Nonetheless, small changes in amino acid sequence at a crucial site in the protein could easily alter the tertiary structure and thereby the function of a protein. By such a route, a small virus could greatly extend its coding capacity. Whether this is the case with polyoma virus, or whether, because of other structural factors the virus uses only a minority of its potential splicing signals, is not known.

The second noncoding region must contain control signals for viral replication and for the initiation of transcription. It should also contain information for the correct splicing events which produce functional late mRNAs[31,32]. This region extends from positions 172 downstream along the sequence given in Fig. 1 to, and including, position 5,003. Some of the nucleotides around the two *Hha*I restriction endonuclease sites at positions 85 and 96 (about 72 map units) are not essential to the virus[6]. Both these sites and the regions around them can be deleted, and the resulting mutants appear both to replicate and to transform cells with a facility which approximates that of the wild-type virus. Without further direct evidence, it may be assumed that the rest of the sequence in this noncoding region serves some function. A number of sites of possible relevance to control and regulation of the virus are pointed out in Table 1. One of the most important is, of course, the viral origin of replication. It has been suggested that the origin probably lies around, and may include, the *Hpa*II restriction endonuclease junction between fragments 3 and 5 (refs 5 and 11). The sequence from this region can form either a stable hairpin loop or an interesting four-stranded conformation[11]. Moreover, it shows considerable homology with sequences from around the origins of replication of SV40 and BK virus. On the late side of the putative polyoma virus origin of replication, that is, within the 290 nucleotides that lie between positions 5,003 and 5,292 (Fig. 1), there are a number of AT-rich regions. These might facilitate the separation of the DNA strands through interaction with either an RNA molecule (see below) or a protein and allow the DNA to function at any given time essentially as a single-stranded species. Since the major mode of replication in polyoma virus is bidirectional and proceeds from a single site (or region) on each of the two strands, initial strand separation may be an important event in DNA replication.

Table 2 Calculated and measured molecular weights of polyoma virus proteins

Protein	Measured MW	(ref.)	Calculated MW*	Amino acids (no.)
VP1	45,000–48,000	(23, 24)	42,404	385
VP2	35,000	(24)	34,761	319
VP3	23,000	(24)	22,866	204
Large T antigen	88,000–100,000	(10, 56)	87,991	785
Middle T antigen	55,000	(57)	49,710 (48,566)†	432 (421)†
Small t antigen	22,000–23,000	(56)	22,785	195

*Based on DNA sequence.

†Depending on which splicing signals are used to produce the mRNA (see Fig. 2*b*).

The polyoma virus late mRNAs appear to consist of a noncoding 5′-'leader' sequence which, by some mechanism not yet understood, appears to be amplified, probably during transcription[31]. This sequence is attached to the main body of the mRNA in a process that involves (presumably) RNA splicing. The DNA sequence which corresponds to the late leader sequence appears to lie between nucleotides at positions 5,094 to 5,019. A part of this sequence, as deduced from a predicted ability to form base pairs, has a high degree of complementarity with the sequence which immediately precedes the initiation codon for VP3. That is, of the 46 nucleotides that lie between positions 5,092 and 5,046, 31 residues can form base pairs with the nucleotides that lie between positions 4,657 and 4,699. Moreover, part of the leader sequence can form a fairly strong secondary structure with the sequence which precedes the VP1 initiation codon[27]. Whether these long-range potential structures have any significance, and, if so, whether the significance lies at the DNA level, with DNA exercising control over transcription by these means, or at the RNA level, with precursor RNA controlling its own splicing (and thus translation), or with the mRNA controlling translation by its own secondary structure, is not known. It seems unlikely, however, that their potential presence within the genome is fortuitous.

If it is assumed that the sequence around the *Hpa*II-3/5 restriction endonuclease junction plays a part in viral DNA replication, and the sequence near the late coding region is of importance for the initiation of transcription, there are still about 150 nucleotides between positions 5,260 and 5,110 (Fig. 1) to which a function must be assigned. Within this region, the only assignment made (Table 1*b*) is to a potential promoter, that is, a sequence which resembles a so-called 'Hogness-box'. There is, however, a sequence which lies within this region which would allow the DNA, if transcribed, to produce an RNA which can adopt a cloverleaf configuration. This is illustrated in Fig. 3*b*. Such a structure was sought within the DNA because, as discussed above, it was apparent that if the UGA termination codon could be suppressed, a large amount of coding information would become available to polyoma virus. As some strains of *Escherichia coli* are known to contain a UGA suppressor, a tRNA^{Trp} (ref. 33), a search was made for a sequence in the virus which might specify a UGA suppressor. Since a viral gene specifying a tRNA might contain intervening noncoding sequences, such a search is not completely straightforward. One surprising result, however, was the considerable secondary structure found to be inherent in the DNA, and therefore to reflect structures which could exist in transcription products. The cloverleaf structure shown in Fig. 3*b* was one of the most stable structures observed and it could be formed from the nucleotides between positions 5,231 and 5,160. It does not, however, contain the appropriate anticodon for a UGA suppressor tRNA. The structure illustrated here as DNA has

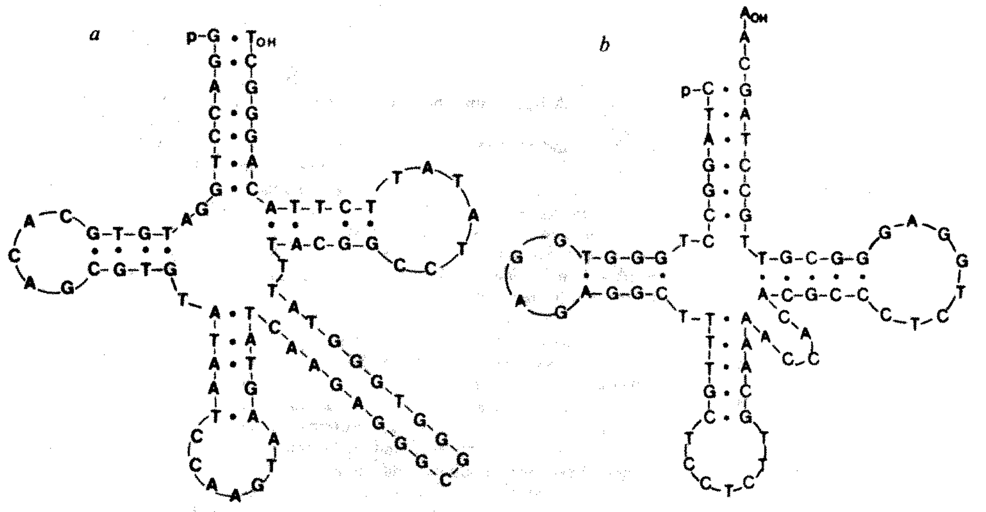


Fig. 3 *a*, Secondary structure of the DNA which lies in the early region of the genome between positions 715 and 799 (see Fig. 1). This region is of special interest because it appears to contain information which specifies some of the splicing signals in the early mRNAs[12,14]. *b*, An unusual clover-leaf structure allowed by the sequence of the DNA in a noncoding part of the polyoma virus late region, using nucleotides which lie in the late strand between positions 5,231 and 5,160. (It is doubtful, however, that the left hand loop, as such, would exist since it is stabilised by only two base pairs.) The anticodon loop has a similar, but not identical, sequence to postulated ribosomal binding sites[11,53] (see Table 1). An analogous kind of structure could be drawn for the complementary strand. This structure and the one above were found by a computer search using an unpublished computer program of R. Staden.

many, but not all of the features, of tRNA (for review see ref. 34). For example, it can be seen that the D-loop (left hand loop) could form hydrogen bonds with the TψC-loop (right hand loop). On the other hand, no tRNA has yet been described that has an anticodon loop composed entirely of pyrimidines (or on a corresponding structure from the other strand of the DNA, all purines). The comparison and contrast could be extended, but is of academic interest only unless it can be shown that polyoma virus codes for a tRNA. At present, it is not known whether the virus codes for any low molecular weight RNA molecules.

Apart from the question posed about viral tRNAs, nothing is known about the initial steps in viral DNA replication and transcription. It is conceivable that an RNA with a structure which corresponds to that shown in Fig. 3*b* might be involved in one or the other of these processes.

A comparison with SV40 and BK virus

It now appears that although much of polyoma virus resembles SV40, in some aspects the two viruses show profound differences. Since BK virus has been shown to be very similar to SV40 (refs. 35–37), much of what is said about the latter is presumably also true for the former.

Dealing first with similarities, the late coding regions in polyoma virus and SV40 have many features in common. Both viruses code for three late proteins which have similar sizes and appear to contain many homologous amino acids. Potential coding similarities between the two genomes themselves are illustrated in Fig. 2*a* and between their DNAs and predicted amino acids in Fig. 4*a* and *b* respectively. The latter also includes a comparison with BK virus. The greatest homology lies near the C-termini of the VP1 proteins. This conclusion, which is based on DNA sequences alone, is supported by the finding that the VP1 proteins of polyoma virus and SV40 are immunologically cross-reactive[38]; none of the other proteins has been found to be related in a similar way. In the region which contains the overlapping genes for parts of VP2/VP3 and VP1 (see Table 1*b*), 19 of the 32 base pairs (60%) in polyoma virus are homologous with nucleotides found in the similar position in SV40 (ref. 26). Although a region which codes simultaneously for parts of two proteins might be expected to be highly conserved in related viruses, the homology is, in fact, no greater than that which exists in similar lengths of sequence in many other parts of the genomes which code for one protein only, notably, for example, in regions near the N-termini of the large T antigens and the VP1 proteins. This may suggest that the sequence within the overlap is of little functional significance; on the other hand, it may emphasise the importance of retaining the sequence not only of the overlapping genes, but also in other regions in order to conserve diverse functions of the proteins. It has previously been argued, for example, that the quarter of large T antigen nearest its C-terminius may be important in viral DNA replication[12].

Over a large part (about 80%) of the early coding region, there is considerable homology between predicted amino acid sequences of two of the early proteins of polyoma virus and the two corresponding proteins (small t and large T antigens) of

Table 3 Codons used in polyoma virus genes

These data are taken from the coding sequences for VP1, VP2, middle T antigen and the part of large T antigen encoded in frame 2 (Fig. 2*a*). (All sequences present in VP3 are present in VP2 (ref. 24). Most of the sequence in small t antigen is also present in middle T antigen (refs 11, 15, 16), as is the frame 1 sequence of large T antigen.) These data are tentative since neither the exact splicing to create the mRNAs for middle T and large T antigens nor the sequence coding for the C-terminus of small t antigen are known. However, the data should at least be a very close approximation of the codons used. The bias against the use of CG is notable in codons specifying Ser, Pro, Thr and Ala but less notable in codons specifying Arg. Overall, this bias is much less than is observed in the case of SV40 (refs 7 and 8).

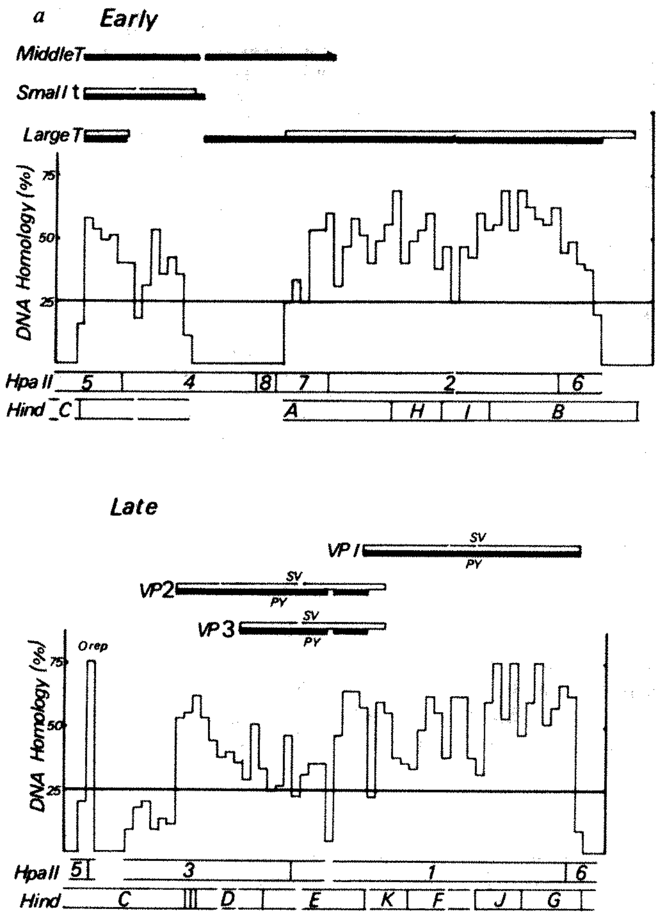

Fig. 4 *a*, A histogram which compares the homology in the genomes of polyoma virus and SV40, as derived from their DNA sequences (see Fig. 1 and refs 7 and 8). The polyoma virus and SV40 physical maps (Fig. 2*a*) are linearised about their respective origins of replication and divided into early and late regions. Gaps are left in the physical maps either where there is no corresponding sequence in the two genomes or where necessary in order to maximise homologies in adjoining regions. The location of the viral proteins relative to the genomes is shown. Percentage DNA homology, calculated for every 45 nucleotides, is plotted against sequence location in the genome. Homology becomes meaningful when it exceeds the 25% random expectation, and this is indicated by a solid line drawn across each figure. *b*, A comparison of the amino acid homology presumed to be present in individual proteins of polyoma virus and SV40. The polyoma virus and SV40 physical maps (see Fig. 2*a*) have been linearised about their respective origins of replication and divided into early and late regions, that is, regions coding for T antigens, and capsid proteins, respectively. From the DNA sequences (see Fig. 1 and refs 7 and 8), the amino acid compositions for each protein have been deduced and compared. A homologous amino acid occurring in the same protein among the two viruses is indicated by a black line (▌). Thus, black areas represent homologies and colourless areas non-homologies. Gaps are left whenever necessary in order to maximise homology. Dotted lines indicate regions of the DNA which are noncoding for any part of a particular protein under consideration. In a similar fashion, polyoma virus has been compared with the predicted protein compositions of BK virus (MM strain) as deduced from its DNA sequence[37]. The late region of SV40 has a number of duplicated sequences outside the coding region for which there is no counterpart in polyoma. This is indicated by a gap in the polyoma virus physical map. In the early region of polyoma virus DNA, there is a sequence which appears to have no counterpart in SV40. This is indicated in a similar manner by leaving a gap in the SV40 physical map. Neither SV40 nor BK virus appears to code for a protein which corresponds to the middle T antigen of polyoma virus, the body of which is encoded within the polyoma virus early sequence, indicated by cross-hatching (/ / /). The assessment of per cent homology between viruses is subject to the uncertainties inherent in the alignment of the genomes. When polyoma virus and SV40 are aligned in the manner shown here, leaving ocasional gaps but rearranging no sequences, genes coding for small t and large T antigens and the VP2 proteins had between 36 and 38% nucleotide homology, and the VP1 genes had about 53% homology (see *a*).

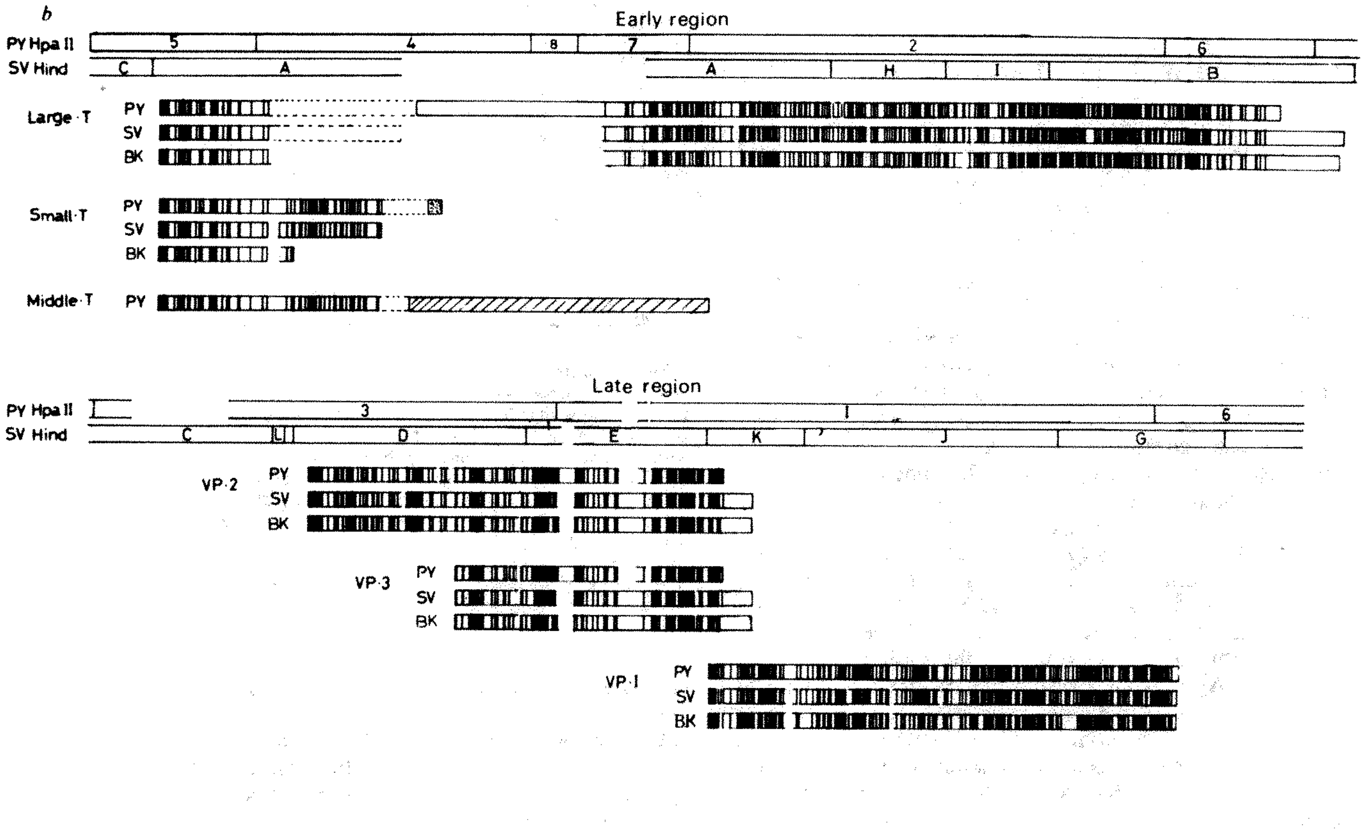

SV40, as shown in Fig. 4*b*. Similarity is also found in the overall organisation of the two early coding regions, as illustrated in Fig. 2*a* as well as in the regions immediately around their origins of replication[11]. However, nowhere in the two genomes does the homology over any length observable by electron microscopy exceed 60–70%. This may explain why earlier hybridisation studies failed to reveal homologies between the two viral DNAs and only in exceptional conditions was any heteroduplex formation observed[39]. In the latter case, the heteroduplex involved the DNA sequences which lie in a part of the polyoma virus and SV40 VP1 genes which code for the N-termini of the proteins and this is not even a region of exceptional sequence homology. Thus, earlier studies have probably not given a fair estimate of the similarities of the two viral genomes. This conclusion has been reached from studies on SV40 and its much closer relative, BK virus[36]. However, recent hybridisation studies, in less stringent conditions than previously used, do reveal limited regions of homology between polyoma virus and SV40 DNAs (ref. 40). Sequencing the genomes of similar viruses thus emphasises how little is actually known about the chemistry behind heteroduplex formation, or that involved in liquid hybridisation studies, and presents a more accurate account of relationships between species.

The similarities between polyoma virus, SV40 and BK virus are very striking and if these viruses evolved from a common ancestor, it becomes apparent which portions of the genomes have been conserved during evolution just as data discussed below may indicate changes in the genome which occurred during evolution. The differences among the viruses are also very noticeable (see Fig. 4) and may ultimately be found to be of considerable biological importance. These differences appear to lie in three parts of the genome: at the end of the early and late regions, and in a part of the early coding region. Considering first the ends of the early and late regions, SV40 has a large (about 2% of the genome) noncoding region between the portion of its genes which code for the C-termini of large T antigen and VP1 (refs. 7 and 8) (see Fig. 2*a*). No such large coding gap is found in the polyoma virus. In the latter, sequences which code for the C-termini of large T antigen and VP1 are separated by only seven base pairs. Further, in the noncoding regions around the viral origins of replication of the viruses, although there is considerable homology in the small portion of the sequences which may define the initiation of replication[11,41,42], there appears to be little sequence homology in the rest of these regions. Note that for polyoma virus, the region under consideration is somewhat less than 9% of the genome, whereas in SV40, it is about 13%. However, a search for homologies is somewhat hampered by the fact that much of the sequence in the noncoding part of SV40 consists of DNA repetitions[7,8]; a large part of the region can be deleted without affecting the viability of the virus[43]. It is not yet clear which sequence is redundant and which is essential in SV40. With polyoma virus, there appears to be much less, if any, analogous sequence redundancy. The noncoding regions around the origins of replication in the viruses may essentially be a control area of each virus. As such, it may be expected that the region might resemble a functionally related region in its host genome rather than another virus, even a related one, with a different host.

Finally, there also exists what currently appears to be the most important biological difference between the viruses, which is represented by the part of the early region in polyoma virus between about 86 and 99 units on the physical map. This region appears to code for the unique part of middle T antigen, as well as for part of large T antigen (refs 4 and 17). It seems that there is no comparable region in SV40 and without extensive sequence rearrangements, it is not clear how SV40 (or BK virus) could code for a protein comparable to the polyoma virus middle T antigen (see Figs 2 and 4). Studies with mutants indicate that this region in polyoma virus seems to be of critical importance in the virally induced transformation of cells and in tumour formation[4]. If polyoma virus has a gene which is responsible for the transformation of cells, and there is circumstantial though by no means conclusive evidence to suggest that it has, the middle T antigen is the best candidate for the product of this gene. If this proves to be the case and if SV40 does not code for a similar protein, then transformation may proceed by entirely different pathways, or involve different proteins, in the two viruses. An understanding of the differences between the two viral genomes may be essential in ultimately defining this property of the viruses. The known DNA sequences should now allow proper viral mutants to be constructed, by site-specific mutagenesis[44] or other procedures, which can establish the direct structural and functional relationships of these oncogenic viruses.

We thank our colleagues at the ICRF for discussion during this work, Drs R. Kamen and Y. Ito for allowing us to compare our DNA data with their transcription and protein data, Drs R. C. A. Yang and R. Wu for allowing us to see their BK virus sequence before publication, Drs B. G. Barrell and T. Maruyama and Mr R. Staden for computer analyses, and Mrs C. Maddock and Mr S. Barrett for technical assistance.

Amino acid sequence changes in the haemagglutinin of A/Hong Kong (H3N2) influenza virus during the period 1968–77

W. G. Laver, G. M. Air, T. A. Dopheide* & C. W. Ward*

Department of Microbiology, John Curtin School of Medical Research, Australian National University,
PO Box 334, Canberra City, ACT, 2601, Australia

Haemagglutinin molecules from nine strains of A/Hong Kong/68 (H3N2) influenza virus, isolated between 1968 and 1977, were examined for changes in amino acid sequences. At least 18 changes, 9 of which were located precisely, occurred in the soluble tryptic peptides of the large haemagglutinin polypeptide (HA1) during this period. These peptides contained 262 residues (82% of HA1). In HA2, only two changes in 129 residues (58% of HA2) were detected. Sequential changes at a particular locus were not found; and as far as we can tell, once an amino acid changed, it did not change again in any subsequent variant examined.

INFLUENZA persists as an uncontrollable infection in man largely because of the high frequency with which antigenic changes occur in the surface proteins of the virus. Both influenza A and B viruses have two distinct surface antigens, the haemagglutinin (HA) and neuraminidase (NA). These may undergo a gradual change (antigenic drift) under increasing antibody prevalence in the population. Significant drift in the HA antigen is often associated with influenza epidemics of varying impact which occur without any regular time intervals. Occasionally, the HA and NA antigens of influenza A virus may abruptly undergo a complete change (antigenic shift) and bring about an influenza pandemic. Two recent influenza pandemics occurred, in 1957, when both the HA and the NA antigens changed ('Asian 'flu'), and in 1968, when only the HA antigen changed ('Hong Kong 'flu'). Influenza B viruses undergo antigenic drift, but are not known to undergo antigenic shift and have not been associated with pandemics.

Antigenic drift in type A influenza virus is believed to occur by the selection, in an immune population, of mutant virus particles with altered antigenic determinants on the HA and NA proteins. Peptide maps have shown that antigenic shift is associated with major differences in the amino acid sequence of the HA, and drift with minor differences[1].

Antigenic drift in the Hong Kong subtype

Since the appearance of the Hong Kong (H3N2) subtype of influenza type A virus in man in 1968, drift has occurred, resulting in the appearance of new variants, several of which are listed in Table 1. The original A/Hong Kong/68, and some of these variants, such as A/England/42/72, A/Port Chalmers/1/73, A/Victoria/1/75 and A/Texas/1/77, became widespread, causing epidemics in many countries, but most of the others were associated with only minor outbreaks and quickly disappeared[2]. Antigenic relationships between the viruses listed in Table 1 have been described previously[3,4].

In this study, we have examined the HAs of these nine Hong Kong variants for amino acid sequence changes, by matching the compositions of their soluble tryptic peptides with the known amino acid sequence of the homologous peptides from the Hong Kong variant, A/Memphis/102/72 (ref. 5).

The HA monomer is coded by a single, monocistronic segment of RNA[6,7] and is synthesised as a single polypeptide chain which is then normally cleaved by proteolytic enzymes to give two chains, HA1 and HA2, held together by disulphide bonds[8]. These two chains can be readily separated by column chromatography or density gradient centrifugation after denaturation and disruption of the disulphide bonds. HA1 is the N-terminal portion of the HA[9], has a molecular weight of 47,000 (ref. 10) and contains most of the carbohydrate[10,11]. HA2 is the C-terminal portion of the HA[9], has a molecular weight of approximately 30,000 (ref. 10), carries very little carbohydrate[10,11] and contains the hydrophobic tail by which the HA is attached to the viral membrane[9,12,13].

Sequence changes in HA1

Maps of the soluble tryptic peptides from HA1 of A/Hong Kong/68 and A/Memphis/102/72 viruses showed several differences[14]. Therefore, a detailed study of the changes occurring in nine different Hong Kong variants (Table 1) was carried out.

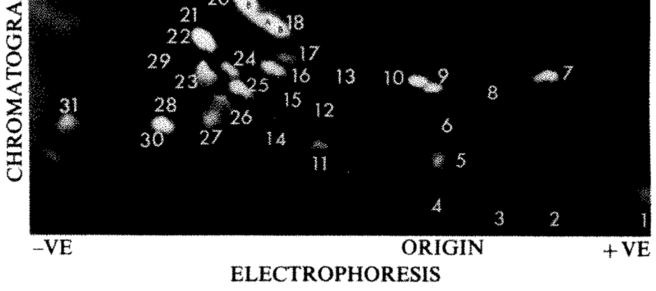

Fig. 1 Map of the soluble tryptic peptides from *S*-carboxymethylated HA1 of A/Memphis/1/71 influenza virus. Virus was grown in the allantoic sac of 11-d-old chick embryos and purified as described previously[22]. Haemagglutinin was isolated by electrophoresis of SDS-disrupted virus on cellulose acetate strips[19]. Heavy (HA1) and light (HA2) chains were separated by centrifugation on a guanidine hydrochloride–dithiothreitol density gradient[8]. The isolated chains were *S*-carboxymethylated as previously described[20], dialysed and precipitated with 3 volumes of ethanol. Digestion with trypsin (TPCK treated; Worthington), and mapping of the peptides soluble at *p*H 6.5 were as described elsewhere[14]. Peptides were located by staining with fluorescamine (10 μg per ml) in acetone containing 0.5% pyridine[21], eluted from the maps with 6 M HCl, hydrolysed in sealed, evacuated tubes for 22 h at 105 °C and analysed on a Beckman 119CL amino acid analyser. Tryptophan was qualitatively determined by staining duplicate maps with Ehrlich reagent. These methods were followed to prepare maps of HA1 and HA2 from the H3N2 viruses listed in Table 1. These viruses were grown as recombinants with the neuraminidase from A/Bel/42 (H0N1).

Fig. 2 Comparative partial amino acid sequences of the HA heavy chains (HA1) from nine different Hong Kong influenza A variants isolated between 1968 and 1977. The amino acid sequences were determined for the A/Memphis/102/72 strain (ref. 5 and C. W. W. and T. A. D., unpublished). Sequences for the other strains were deduced from the amino acid composition of their tryptic peptides. Boxed areas indicate regions of identical sequence and the residues which changed are indicated. It is not known which of the two Gly residues of Vic/75 peptide 17 changed to Ser in Texas/77, nor how one of the two Ser residues in Aichi/68 peptide 25 changed to Gln in Eng/187/70. Peptide numbers refer to the spots shown in Fig. 1. The four zig-zag lines denote regions of sequence associated either with the large peptides 1 and 3, which have not been fully sequenced and which therefore were not reliably analysed by single hydrolysis, or with two large insoluble tryptic peptides which we were unable to separate and analyse. The sequence of one of these (between peptides 25 and 20b) for the Mem/102/72 strain has been published[5] but no sequence data for this peptide from the other strains are available. We have previously found that variants of A/Memphis/1/71 virus selected with monoclonal antibodies showed single amino acid sequence changes[15]. These were in peptide 11, where the Asn at position 4 changed to Lys; peptide 16, where the Ser changed to Tyr; peptide 17 (26) where the Pro changed to Ser, Leu, Thr or His, and peptide 25, which was missing in one monoclonal variant, although the change responsible was not determined.

Figure 1 shows a map of the soluble tryptic peptides from *S*-carboxymethylated HA1 of A/Memphis/1/71. The assumed sequences and locations of these A/Memphis/1/71 peptides, based on their amino acid composition[15] and the available sequence data for the closely related A/Memphis/102/72 strain[5], are shown in Fig. 2 with the corresponding data for the soluble HA1 tryptic peptides from the other eight Hong Kong influenza A variants examined.

Figure 2 shows that most of the primary structure of Hong Kong virus HA remained unchanged during the period 1968–77. In the soluble tryptic peptides, which contained 262 amino acids (82% of HA1), 18 changes in sequence could be detected. Of these, nine were located precisely, but in the four large peptides (1, 2, 3 and 4), where changes in composition were seen, we cannot know the exact number of sequence changes without more detailed analysis of sub-fragments. There may be more changes in sequence than detected by composition analysis. The regions of sequence not covered in this report are associated with two large insoluble tryptic peptides that will require additional enzymatic digestion before sequence analysis.

In most cases, once an amino acid residue had changed, it did not change again in any of the other variants subsequently isolated. Exceptions to this were seen in four cases where apparent reversion to the original amino acid was seen. Thus, in peptide 12, the arginine in position 1 in A/Aichi/2/68, A/England/878/69, A/England/187/70 and A/Memphis/1/71 was replaced by glycine in A/England/42/72 but is arginine in the subsequent strains. A likely explanation is that this isolate of A/England/42/72 was not the virus that gave rise to the 1972–77 variants. As reported previously[1], peptide 25 from HA1 of A/Queensland/7/70 virus had the leucine residue replaced by glutamine. Although this change was not found in

Table 1 Hong Kong (H3N2) variants examined

A/Aichi/2/68	A/Memphis/102/72
A/England/878/69	A/Port Chalmers/1/73
A/England/187/70	A/Victoria/1/75
A/Memphis/1/71	A/Texas/1/77
A/England/42/72	

All these viruses were obtained from WHO reference laboratories, with the exception of the Memphis strains, which were local isolates. The viruses were grown as recombinants with the neuraminidase from A/Bel/42 (H0N1). The recombinants were cloned twice at limit dilution before analysis.

any of the Hong Kong strains examined in this report, the Eng/187/70 strain had a Ser → Gln change in the same peptide (see Fig. 2). The most likely explanation is that the A/Queensland/7/70 and Eng/187/70 strains did not persist in nature and did not give rise to subsequent strains. The third example is in peptide 4, where in Mem/1/71 there is a Gly → Gln change not seen subsequently. The fourth example of apparent reversion back to the original residue can be seen in peptides 17/26 where the glycine at position 4 is replaced by aspartic acid in the 1969 and 1970 England variants, but not in the 1971 American strain, A/Memphis/1/71. All subsequent variants (1972–77) have aspartic acid in this position. Although the nine variants studied here represent Hong Kong variants isolated in chronological order, they do not necessarily represent an exact geneological series. Variants showing this Gly → Asp change in peptides 17/26 apparently arose first in England, then spread to, or arose independently in, the US.

Almost all the changes we have observed in compositions of small peptides can be accounted for by a single nucleotide change. One exception is in peptide 25 of Eng/187/70 (and no other strain we have examined), where there is a Ser → Gln change. It would be interesting to sequence this peptide, because the sequence could show two changes, for example,

A A
CUG UCG

Gly - Leu - Ser - Ser - Arg

↓ ↓

Gly - Gln - Leu - Ser - Arg

A A
CAG UUG

The Leu → Gln change has been found in Qld/7/70, although peptide 25 in subsequent strains is the same as in 1968 and 1969 strains until Texas/1/77, where the peptide disappears (indicating some other change).

The other 2-base change appears in peptide 19 of Eng/42/72 and Mem/102/72, and persists through to Texas/1/77, being Thr → Tyr

$$\mathrm{ACX} \rightarrow \overset{\mathrm{U}}{\mathrm{UAC}}$$

In the large peptides 4 and 2, several of the observed changes in composition would require at least two nucleotide changes in the RNA.

Sequence changes in HA2

Figure 3 shows the map of the soluble tryptic peptides obtained from *S*-carboxymethylated HA2 of A/Memphis/1/71 virus. Using the sequence data available for A/Memphis/102/72 (ref. 5) it was possible to deduce the sequences of most of these A/Memphis/1/71 peptides from their amino acid compositions[15]. The location of each of these peptides in the partial sequence of HA2 is shown in Fig. 4. These peptides account for 129 residues (58% of the total HA2 sequence), the rest being insoluble and not examined.

Although we have not been able to characterise the exact changes, the data presented in Fig. 4 show that in the 20 soluble HA2 peptides examined, only two differences could be detected between the first and last Hong Kong strains. This suggested that extensive variation would not be found in the intermediate strains, and therefore these were not examined.

Relationship between sequence changes and antigenicity

The analysis of amino acid sequence changes in natural influenza variants may not necessarily indicate which portions of the sequences make up the antigenic determinants. Some of the changes observed may be unrelated to the antigenic differences between the various HAs. Considering the large antigenic difference between Hong Kong/68 and Texas/77 viruses[3], and the large number of antigenic sites on the HA molecule[16], the number of sequence changes found associated with antigenic drift was surprisingly small. In most cases, only one or two amino acid changes were seen between neighbouring drift strains. The heavy chain (HA1) from the last member of the series, A/Texas/1/77, differed from that of the first, A/Aichi/2/68, by about 18 out of 262 residues, whereas the light chain (HA2) showed only two amino acid substitutions in the soluble tryptic peptides during antigenic drift in this period.

We do not know which of the changes in sequence found to occur between 1968 and 1977 were responsible for the changes in antigenicity which occurred in the Hong Kong virus during this period. In a previous study[15], influenza variants of A/Memphis/1/71 were selected with monoclonal hybridoma antibodies and examined for changes in amino acid sequence and antigenicity. These variants showed dramatic changes in antigenicity, having completely lost the capacity to bind the monoclonal antibody used for their selection. These changes were found to be associated with a single amino acid substitution in HA1, which in every case required only a single base change in the RNA. No changes were seen in HA2. The HA1 tryptic peptides in which alterations occurred in the variants were the same as those in which changes occurred in the field strains, but in every instance the amino acid changes in the monoclonal variants were different from those found in the field strains (Fig. 2).

The recombinant viruses we used as the source of HA were cloned twice at limit dilution before analysis; this may have led to the separation of variant viruses with sequence changes in the HA. Furthermore, HA molecules of viruses isolated late in the Hong Kong era, antigenically related to the 'Victoria' and 'Texas' strains, may well have a number of sequence changes from the Victoria and Texas strains we examined. Asian (H2N2) viruses isolated in different parts of the world in 1968 at the end of the H2N2 period showed considerable differences in their HA1 and HA2 tryptic peptide maps[17].

Electron microscopy of antibody molecules attached to the HA has shown that some (and possibly all) of the antigenic determinants are situated in a region just below the tip of the HA spike[18]. In the present work we have found changes along the whole length of the HA polypeptides, which may reflect the way in which the polypeptide chains are folded within the HA spike.

On the other hand, we do not know which of the sequence changes are responsible for the antigenic differences between the various viruses and which are not. Neither do we know if the sequence changes responsible for the antigenic changes occur in

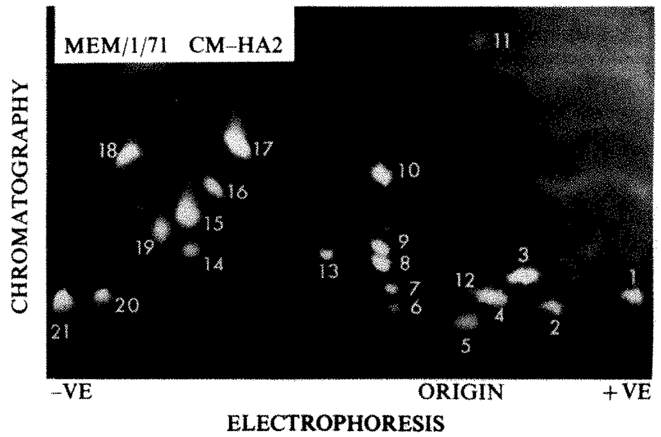

Fig. 3 Map of the soluble tryptic peptides from *S*-carboxymethylated HA2 of A/Memphis/1/71 influenza virus. The methods for virus growth, HA2 purification, enzyme digestion and peptide mapping are described in Fig. 1 legend.

Fig. 4 Comparative amino acid sequences of A/Memphis/1/71, A/Memphis/102/72 and A/Texas/1/77 HA light chains (HA2). The amino acid sequences have been determined for the A/Memphis/102/72 strain[5]. Sequences for the other two strains were deduced from their amino acid compositions. The peptide numbers refer to the corresponding spots shown in Fig. 3. The regions of residues 1–25 and 89–117 and much of the C-terminal sequence involve large insoluble tryptic peptides not analysed in this study. In peptide 18 the sequence has been revised and corrected from that given previously[5].

those amino acids which constitute the antigenic determinants, or whether the sequence changes occur elsewhere in the molecule and cause conformational changes which alter the antigenic determinants.

We thank Jean Clark and Donna Boyle for technical assistance. The viruses were supplied by Dr R. Webster. This work was supported by grants AI-15343 and AI-42510 from the National Institutes of Allergy and Infectious Diseases.

IR sources in the Southern Coalsack

M. J. Smyth
University of Edinburgh, Department of Astronomy, Edinburgh

M. E. Sim
Royal Observatory, Edinburgh, UK

A preliminary survey of four dark globules in the Southern Coalsack, an area of conspicuous obscuration in the southern sky, has revealed seven IR sources, which are most probably heavily obscured background stars. We report here that the wavelength dependence of extinction is not significantly different from that in the general interstellar medium. Spectroscopy of these stars, and of still more heavily obscured stars that should be revealed by a deeper survey, would permit detailed analysis of 'proto-protostellar' material. Although these are probably background stars, the numbers found in our small sample at least suggest association with the globules themselves; there is growing evidence for star formation within or associated with dense dark globules.

Bok[1] has reviewed the important role of dark globules in our understanding of star birth in the Galaxy, and has suggested the use of IR photometry to probe these heavily absorbing 'proto-protostars'. The Southern Coalsack, the finest dark nebula in the southern Milky Way, contains many globules, which appear as roundish, sharply bounded dark nebulae a few arc-min in diameter. Bok, Sim and Hawarden[2] have superimposed blue–green and far-red photographs of Globule 2 of the survey of Tapia[3], the far-red images revealing peripheral reddened background stars invisible on the blue–green photographs.

We have used the 0.75 m telescope of the South African Astronomical Observatory to make a quick survey of four Coalsack globules, numbers 1, 2, 3 and 9 in Fig. 1 of ref. 2, at a wavelength of 2.2 μm (*K* magnitudes). The areas scanned were squares of 7 × 7 arc min in each case. For illustrations we again used two photographs taken with the SRC 1.2 m Schmidt telescope at Siding Spring, Australia. Their star images were almost superimposed in a modified Zeiss blink comparator, and Fig. 1 shows photographs of the four globules taken from the TV monitor. Black images correspond to stars in the far-red photograph ($\lambda \sim 0.8$ μm), and displaced white images to those in the blue–green photograph ($\lambda \sim 0.5$ μm); again, far-red images unaccompanied by blue–green images can be seen within the globule boundaries, representing heavily reddened background

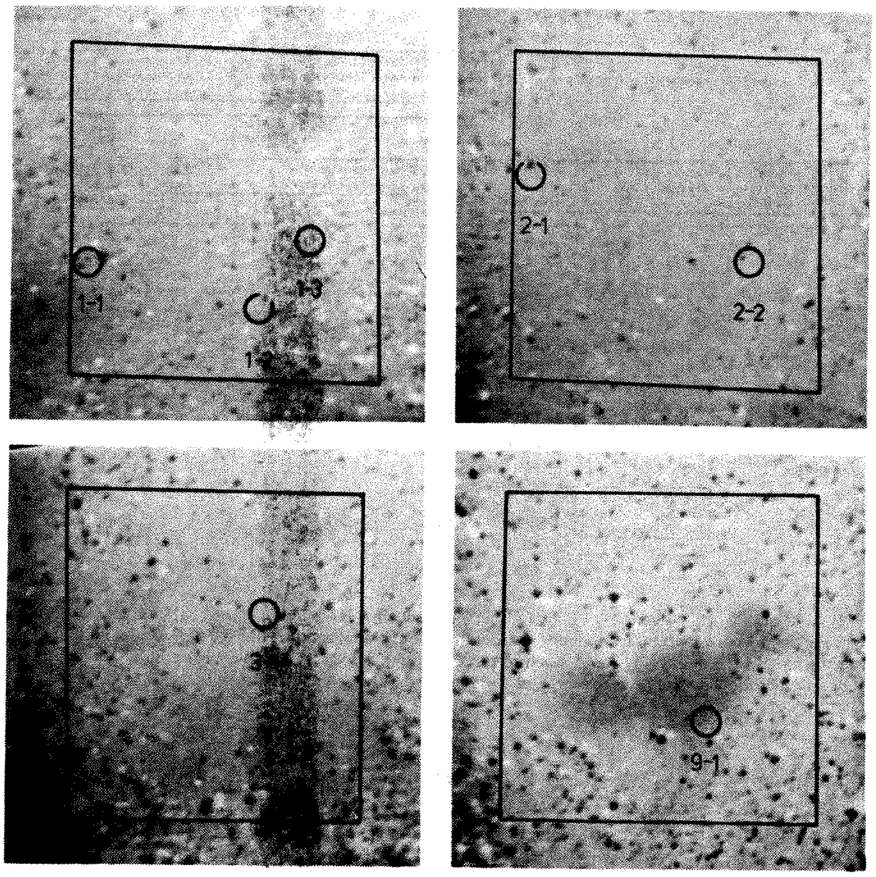

Fig. 1 TV monitor displays of the globules observed. Squares (7 × 7 arc min) show the areas scanned, and circles the locations of IR sources found. North is at the top, east to the left. Images from the far-red photograph are shown in black, those from the blue-green photograph in white.

stars. Boundaries of the square areas scanned are indicated, and circles enclose the locations of the brighter IR sources found, whose positions are listed in Table 1. In no case was any star visible in the photometer fields centred on the sources. The 3σ detection limit of the scans was $K \sim 8.5$. Several sources were detected, and results of subsequent J (1.25 μm), H (1.6 μm), K (2.2 μm), L (3.4 μm) photometry of the brighter ones are given in Table 2. Errors are of order 0.03 mag for J, H, K and 0.1 mag for L.

On the assumption that these are background stars whose light has been reddened by passage through the globules, we compare in Fig. 2 their (J–H, H–K) colours with those of an unreddened $M0$ star[4]. They lie on a locus close to that predicted by the normal interstellar extinction law (Table 12 in ref. 5). It is statistically most likely that random background stars are cool giants of spectral type K or M, but the assumption of early spectral type would force the extinction line through the origin and imply an abnormally steep slope. Elias[6] also finds a normal extinction law in studies of extended dark cloud complexes.

To use the normal law to deredden the observed colours we require spectral types, giving intrinsic colours. In the absence of IR spectrophotometry we have estimated the probable range of total absorption on the basis of a range of spectral types from $G5$ to $M5$; the resulting ranges of total visual absorption A_V and intrinsic apparent magnitude V_0 are listed in Table 2. With the exception of source 1–1 near the edge of a scanned area, the total absorptions almost certainly exceed 10 mag. Note that these heavily obscured sources were the brightest objects located in the scans at 2.2 μm.

Table 1 Location of brighter IR sources

Source	α (1975)	δ (1975)
1–1	12 h 32 min 28 s	−63°34′.4
1–2	12 h 31 min 52 s	−63°35′.3
1–3	12 h 31 min 42 s	−63°33′.8
2–1	12 h 30 min 33 s	−63°35′.7
2–2	12 h 29 min 47 s	−63°37′.4
3–1	12 h 28 min 39 s	−63°39′.1
9–1	12 h 34 min 39 s	−63°04′.2

These quite large absorptions are found for stars that lie 1 or 2 arc min from the centres of the globules, where presumably the absorption is considerably higher. Bok[1] has conjectured that core absorptions at 1 μm do not exceed 7 mag, implying $A_V \leqslant 19$; our observations of peripheral IR sources suggest that higher central absorptions may occur. From star-counts, Bok *et al.*[2] estimated $A_V \sim 5$ in an outer annulus of Globule 2.

The ranges of deduced intrinsic magnitudes in Table 2, in conjunction with absolute magnitudes of giant stars from $G5$ to $M5$, imply distance moduli between 5.5 and 12, that is distances between 125 and 2,500 pc. The stars could thus lie within the

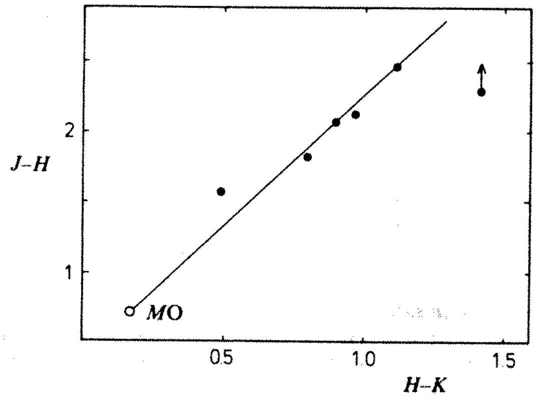

Fig. 2 IR colour indices $J-H$, $H-K$ for six of the heavily reddened sources, compared with those of a normal $M0$ star. The slope of the reddening line is 1.8, close to the normal interstellar value.

Table 2 Deduced intrinsic magnitudes

Source	J	H	K	L	A_V	V_0
1–1	8.23	6.65	6.16	5.94	6.5–9.5	7–12
1–2	9.72	7.58	6.61	6.03	13–16	7–11
1–3	10.03	8.20	7.40		10–13	7–11
2–1			8.60			
2–2	10.09	7.61	6.49	5.88	16–19	7–11
3–1	9.15	7.07	6.17	5.56	12–15	7–11
9–1		9.53	8.11			

globules (the estimated distance of the Coalsack is 175 pc) but more probably lie beyond them. On the other hand, the cumulative source–count model of Elias[6] gives a probability of ~0.3 for finding a star intrinsically brighter than 7.5 (or $K < 8.5$ with $A_K = 1$) within one of the scanned areas, whereas in fact seven sources were found in four areas. It is thus tempting to suggest that the heavily reddened stars are physically associated with the globules. There is indeed increasing evidence for star formation associated with globules: Bok[7] supports this view and gives an example of Herbig–Haro objects located within a dense globule. Our preliminary survey, in revealing the presence of intrinsically bright stars, and unexpectedly high absorption densities, again points in the direction of recent star formation in some globules.

We have surveyed only four of our Galaxy's population of dark globules, and cannot draw strong conclusions from this small sample. Evidently IR photometry should be used to probe a significant fraction of the observable globules. High-resolution IR spectrometry should be attempted for the brighter sources located, to provide absorption spectra of proto-protostellar material.

For locating heavily reddened stars, array detectors working at shorter wavelengths may ultimately prove more powerful than single detectors scanning at, for example, 2.2 μm. At 1 μm the very large number of picture elements and high detection efficiency of a silicon CCD array will outweigh the lower globule absorption at 2.2 μm, except perhaps in the densest globule regions. R. Albrecht, B. J. Bok and G. Gozza (personal communication) have experimentally photographed Coalsack Globule 2 with such a device, and have indeed recorded stars close to the centre. But we have demonstrated that, until such devices become more widely available, scanning with an efficient InSb detector produces valuable results with a reasonable expenditure of telescope time.

We thank the PATT committee of the SRC for allocation of telescope time, R. M. Sharples and M. Tapia for assistance at the telescope, and the staff of the UK Schmidt Telescope Unit for the photographic plates.

Coronal Faraday rotation during solar occultation of PSR0525+21

M. K. Bird, E. Schrüfer & H. Volland

Astronomical Institutes, University of Bonn, Auf dem Hügel 71, 5300 Bonn, FRG

W. Sieber

Max Planck Institute for Radio Astronomy, Auf dem Hügel 69, 5300 Bonn, FRG

The apparent position of the pulsar PSR0525+21 is within 1.3° (4.72 $R_\odot$) of the south solar pole on or about 13 June of each year. During these times of superior conjunction, the linearly polarised component of the pulsar radiation is subjected to an additional Faraday rotation due to the high electron density and strong magnetic field of the solar corona. We report here measurements of this coronal Faraday rotation in 1978 and 1979 at the 100-m radio telescope of the Max-Planck-Institut für Radioastronomie in Effelsberg which compared pulsar polarisation profiles at $\lambda = 17.4$ cm ($f = 1{,}720$ MHz) for times before, during and after occultation by the Sun. A significant residual rotation measure, which exceeded the interstellar value, was observed both years at times close to that of minimum solar approach.

Pulsars were recognised early as potential sources of probe signals for coronal investigations[1,2]. Group delay time measurements, from which one may determine coronal dispersion measure (DM) by recording arrival times of pulses in well separated frequency bands, were first performed using the Crab Pulsar in 1969 at NRAO[3] and Arecibo[4]. The additional delay in arrival time is proportional to the columnar electron content in the corona along the ray path pulsar/Earth, and is a very small fraction ($\simeq 10^{-4}$) of the total delay due to interstellar dispersion. The Arecibo experiment was repeated in 1970, 1971 and 1973 to determine changes in the corona at later phases of the solar cycle[5,6]. Higher electron densities were measured at polar heliographic latitudes during solar maximum than during solar minimum.

In addition to measurements of coronal DM, a linearly polarised source could be used to determine the coronal rotation measure (RM) simply by tracking the source polarisation angle during occultation. The additional Faraday rotation of the plane of polarisation is proportional to the integrated product of electron density times the component of magnetic field along the line-of-sight in the corona. Values comparable with interstellar rotation measures can be achieved at solar elongations ≤ 2°. An experiment of this type was first attempted by Golnev *et al.*[7] in 1962 using the Crab Nebula. Successive experiments on the same source were carried out by Sofue *et al.*[8] and Berlin *et al.*[9]. Passive Faraday rotation experiments were also performed at low heliographic latitudes using the linearly polarised carrier signals of Pioneer 6 (ref. 10) and the two Helios spacecraft[11].

The first coronal Faraday rotation experiment using a pulsar as the source of the probe signal is described here. One decisive advantage of pulsars over continuously emitting sources is the built-in compensation for background noise (mainly from solar sidelobe interference), which can sometimes be several orders of magnitude more intense than the pulsar. The background is eliminated with a measurement during the 'off' phase of the pulsar period without having to drive the antenna off source. Preliminary measurements were taken in January 1978 when the pulsar PSR2045−16 came to within 5.6 $R_\odot$ of the Sun[12]. The results of this first run were indicative, but not entirely convincing, that a coronal contribution was present.

Reliable measurements of coronal Faraday rotation were obtained, however, at the June occultations of PSR0525+21 in 1978–79. The occultation geometry for the two years is shown in Fig. 1. The apparent position of PSR0525+21 moves by the Sun from east to west at 1° per day in a plane parallel to the ecliptic. The UT start of days 11–17 June is marked by the series of large dots and the observation intervals are indicated by the heavy bars along the path. The paths of the intrinsically weaker pulsar PSR0540+23, which was used primarily as an ionospheric sounder in this experiment (see below), are also shown.

0028–0836/80/050459—02$01.00

A stable integrated pulse profile of PSR0525+21 and two non-occulted 'control' pulsars (PSR0540+23 and PSR0823+26) was established using measurements for times well separated from the Sun. This profile, consisting of total intensity, linear intensity and polarisation angle at 256 equally spaced points across the pulse window, was termed the 'master' profile. During solar occultation the pulses were integrated just long enough to obtain what was felt to be a stable 'test' profile, which ideally differed from the master profile only in the absolute polarisation angle. This difference, after compensation for possible ionospheric effects, was attributed to the interposed solar corona. Only points within the test and master pulse windows with a high degree of linear polarisation were used in the determination of the mean weighted polarisation angle difference for a given test profile. The accuracy in determining this differential Faraday rotation is a function of integration time, solar offset (background noise) and intrinsic source intensity during the recording of each test profile. A typical error using this technique (one standard deviation of the weighted mean coronal rotation measure) was of the order of ±1 rad m^{-2}.

When possible, the correction for the ionosphere was made using observations of PSR0540+23, whose ray path penetrates virtually the same ionospheric regions as that of PSR0525+21. It was originally thought that PSR0540+23 was not sufficiently intense for coronal sounding measurements. However, aside from the scintillation fading that occasionally degraded the signals of all pulsars, PSR0540+23 was determined *a posteriori* to be only slightly worse adapted for this experiment than PSR0525+21. The minimum offset distance for PSR0540+23 is the smallest of all known pulsars[13], and is the only one available for coronal sounding at low heliographic latitudes.

The coronal rotation measure of the signal from PSR0525+21 on 12–15 June 1978–79 (ionospheric correction included) is presented in Fig. 2. One degree of Faraday rotation yields a rotation measure of 0.58 rad m^{-2} at the observing frequency of 1,720 MHz. The apparent distance of the pulsar from Sun centre (solar offset) is given for both years at the top of the figure.

The data for the two years are remarkably similar, particularly when one considers the adjustment for the two solar offset scales. A large negative Faraday rotation (mean coronal field directed away from observer), essentially symmetric about the point of closest approach, was recorded on both occasions. This coronal contribution first becomes large at solar offsets $<5\ R_\odot$, which is approximately the solar distance at which the solar wind undergoes a transition from a rapidly divergent flow (number density n goes as r^{-6} in semi-empirical models) to one which is purely radial ($n \sim r^{-2}$). This may help to explain the undramatic observations of PSR2045–16 in January 1978 (ref. 12), which did not approach the Sun closely enough. The magnitude of the coronal effect in Fig. 2 was comparable with that recorded in the ecliptic at the same solar offset even though the polar regions of the Sun are dominated by considerably less dense coronal holes[10,11].

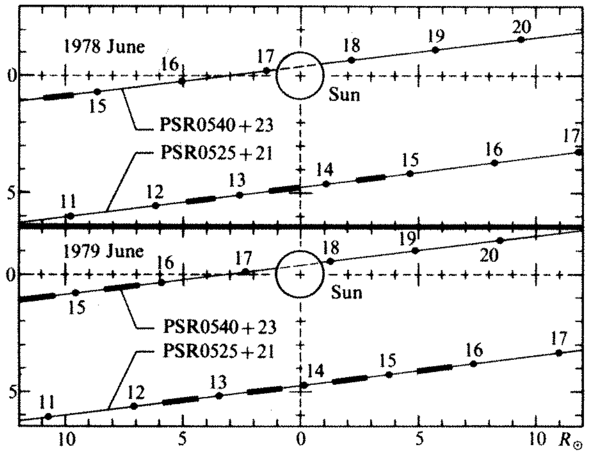

Fig. 1 Apparent paths of the pulsars PSR0525+21 and PSR0540+23 during their solar occultations in June 1978–79. The ray path pulsar/Earth moves parallel to the ecliptic from east to the west solar limb in this solar equatorial projection. The dots mark the start of a UT day, the associated number giving the June date for each year. The heavy bars along the path denote the observation intervals at the Effelsberg telescope.

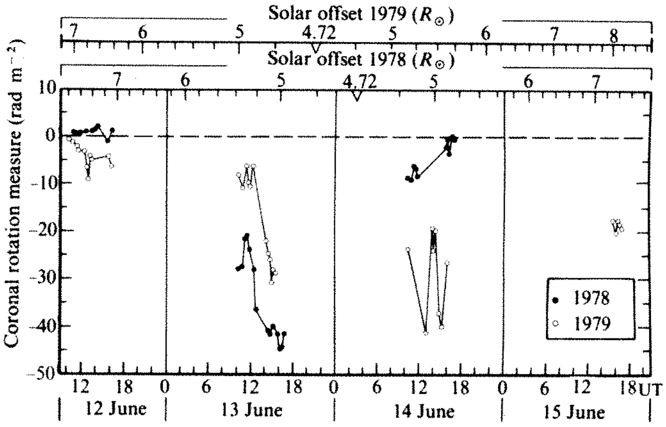

Fig. 2 Coronal rotation measure of the signal from PSR0525+21 during its solar occultations in 1978–79. The solid (open) points display the results obtained in June 1978 (1979). The minimum apparent solar offset of PSR0525+21 (4.72 $R_\odot$) is attained at a slightly different UT each year as shown in the two scales at the top.

The solar rotation measure is seen to be a continuous even function about the point of closest approach, so it may be assumed that the main contribution stems from a monopolar magnetic region situated over the south pole. This contrasts with previous spacecraft occultations in the ecliptic[10,11], where a field reversal about the mid-point of the occultation was observed (odd functions). As the south solar pole has a towards polarity in this phase of the present solar cycle, regions on the near side of the Sun (viewed from Earth) will cause the negative Faraday rotation that is observed. It is concluded therefore that either the polar hole region is greater in extent or contains higher electron density times magnetic field on the nearer Earth leg of the coronal ray path.

These observations have demonstrated that pulsars are the best natural sources available for the coronal Faraday rotation experiment. The highly polarised pulsed emission could be used for simultaneous recording of solar DM and RM, although no single ground facility is ideally instrumented for such observations. It is planned to coordinate a joint observational programme at Effelsberg and Arecibo for the 1980 tandem solar occultation of PSR0525+21 and PSR0540+23, which will occur during the Solar Maximum Year (SMY) and would thus profit from independent support not only from other ground-based observatories, but also from the Solar Maximum Mission (SMM), which will be in full operation by that time.

Photo-sputtering of ice and hydrogen around Saturn's rings

R. W. Carlson

Earth and Space Sciences Division, Jet Propulsion Laboratory,
California Institute of Technology, Pasadena, California 91109

Rocketborne UV spectroscopic measurements have shown that a surprisingly dense cloud of atomic hydrogen surrounds Saturn[1,2] which has been interpreted as being associated with the Saturn ring system. Verification of an UV emission cloud related to the rings is given by Pioneer 11 flyby measurements[3]. Several ring sources of atomic hydrogen have been proposed[4–7], but abundance and lifetime estimates given below require a source which is much more potent than those previously considered. An alternate mechanism which satisfies this source requirement is proposed here, and involves photodissociation of surface water molecules on the icy ring material.

The rocket measurements of Weiser *et al.*[1,2] show hydrogen Lyα emissions outside the disk of Saturn with a mean brightness of 200R ± 50%. If this emission is produced by resonance scattering of the incident solar Lyα line with an efficiency[8] of 2.3×10^{-5} s^{-1} atom^{-1}, then the total number of atoms within their viewing aperture is $N\approx8\times10^{33}$ atoms (assuming optically thin conditions). The mean density is $n\approx400$ cm^{-3}. One can relate this abundance to a production rate through the hydrogen atom lifetime as discussed below.

Loss of H atoms can be caused by many processes, including photoionisation and charge exchange. However, the major loss of H atoms produced in, or near, the rings is through collisions and absorption by ring particles. Laboratory measurements[9] of the reflection of H atoms by low temperature ice show reflection coefficients of 78%, that is, 22% of the collisions will result in loss of a hydrogen atom. The low density of the gaseous ring 'atmosphere' implies that molecular collisions are infrequent and that atoms follow keplerian orbits about Saturn. The trajectories of atoms created near the rings will pass through the rings generally once per orbit, twice if the orbital eccentricity is small. As the optical thickness of the rings is about unity[10], then the probability of an atom striking a ring particle is $\approx(1-e^{-1})=0.63$. For most of these collisions, the atom will be reflected, but roughly one impact in five will result in loss of an atom. For a nominal keplerian orbital period of $T=4\times10^4$ s, the resulting lifetime is $\tau=T/(0.63\times0.22)=3\times10^5$ s. With this lifetime, the source rate Q required to satisfy the observations is estimated to be $Q=N/\tau=8\times10^{33}/3\times10^5=3\times10^{28}$ atom s^{-1}. Note that this derived source rate is insensitive to the actual trajectories. If the orbits extend beyond the field-of-view of the rocket aperture (which was used for the abundance estimate) then the fraction of time that an atom spends within the field is less than unity, and the orbital period T is also greater. As both the total abundance and lifetime estimates are increased, then the derived source rate is approximately the same.

The first investigations of H atom production by the rings were presented by Blamont[4] and Dennefeld[5], who considered several sources, including sublimation and dissociation of ring material, and bombardment by meteoroids, the solar wind, and interstellar gas. Their calculated source rates are summarised in Table 1 and are evidently too small to account for the required value of 3×10^{28} atom s^{-1}. Cheng and Lanzerotti[6] proposed sputtering by high energy ions as a ring erosion mechanism. Assuming that peak jovian fluxes can be used to describe the saturnian magnetosphere, they predicted a hydrogen atom source rate $\approx1.2\times10^{27}$ s^{-1}. However, the Pioneer 11 flyby has shown that the Saturn magnetosphere is much less intense than that of Jupiter, and the peak fluxes used by Cheng and Lanzerotti should be reduced by a factor of at least 20, and probably more, based on measured saturnian proton and electron fluxes[11,12]. Furthermore, proton fluxes[12] in the vicinity of the rings are $<10^{-2}$ of the peak values, which results in an ion-sputtering rate of $<6\times10^{23}$ atom s^{-1}. An additional mechanism has been proposed by Ip[7]—neutralisation by ring particles of the photoelectron–ion flux flowing out from the Saturn ionosphere along magnetic field lines. The magnitude of this source is also insufficient to account for the observations (see Table 1).

Table 1 Ring H atom production rates

Mechanism	Q (atom s^{-1})
Photo-sputtering	1.5×10^{28}
Photoelectron–ion neutralisation	9×10^{23}–9×10^{24}
Sublimation, dissociation	2.2×10^{24}
Meteoritic bombardment	1.8×10^{24}
Magnetospheric ion sputtering	$<6\times10^{23}$
Solar wind	1×10^{23}
Interstellar gas	2.2×10^{22}

Harrison and Schoen[13] pointed out that UV radiation ($1{,}000\leqslant\lambda\leqslant1{,}800$ Å) will dissociate water molecules on ice surfaces and emit hydrogen atoms and hydroxyl radicals. Similar processes have been found to occur on UV irradiation of glasses and semiconductors[14,15]. For photo-absorption which occurs in the outer few molecular layers of an ice crystal, the probability of escape from the crystal is high. At the orbit of Saturn, the molecular photodissociation rate[16] due to solar UV radiation is 1.1×10^{-7} s^{-1} molecule^{-1}. If we assume that only the single outermost monolayer of molecules (1×10^{15} molecule cm^{-2}) of the icy ring material will contribute to the flux escaping from the solid, then we find a hydrogen atom flux of 1.1×10^8 atom cm^{-2} s^{-1}. Although the initial energy distribution cannot be accurately determined, most of these atoms should possess less than the 3 eV of energy required for escape from the Saturn system, due to simultaneous vibrational and electronic excitation of OH, collisions with other surface molecules, and subsequent collisions with ring particles.

The projected area of the A + B rings at the time of the rocket measurements was 1.4×10^{20} cm^2, resulting in a total source rate of $Q=1.5\times10^{28}$ atom s^{-1}. This value is compared with other mechanisms in Table 1.

The source rate for the mechanism proposed here is within a factor of two of the required value and is within the experimental error of the measurement. Considering the spirit of the calculations, the agreement is quite satisfactory, arguing that the proposed mechanism is a viable explanation for the observed Lyα glow. It may be possible to test this, and other, source hypotheses through the recent Pioneer 11 and forthcoming Voyager flybys. For the present mechanism, the source strength during these flybys will be smaller due to the smaller inclination of the ring plane relative to the Sun.

This paper presents the results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under contract NAS 7-100.

Cooling-rate dependence of thermoremanent magnetisation

J. M. W. Fox & M. J. Aitken

Research Laboratory for Archaeology,
Oxford University, 6 Keble Road, Oxford, UK

In using the thermoremanent magnetisation (TRM) of material heated in antiquity (usually pottery, bricks, stones or lava) to evaluate the magnitude of the geomagnetic field at the time of heating, little attention (apart from an observation by Thellier[1]) has been given to the possibility that results are affected by the rate at which the sample is cooling while the TRM is being acquired. We report here an experimental observation of the effect in archaeological baked clay; it parallels the theoretical prediction of Dodson and McClelland-Brown[2] in respect of geological material.

The effect was first noted during a calibration experiment in which samples of Peruvian pottery[3] were refired to 720 °C in a known laboratory field. The TRM acquired during the 7-h cooling from this refiring was then analysed routinely using the zero-field variant of the Thellier[4] method. In this the cooling-times were of the order of 30 min. The samples were in the form of disks, (diameter 25 mm; thickness 8 mm) and before the experiment they had been thermally stabilised by prolonged baking. Magnetisations emplaced during the analysis were in the same direction with respect to the sample as the magnetisation being analysed; hence any effects due to sample shape or fabric anisotropy[5] were avoided. The samples were measured on a Digico fluxgate archaeomagnetic-head magnetometer.

The results are given in Table 1, for both the Peruvian pottery and for samples fabricated from Oxfordshire clay. The field magnitude evaluated by the Thellier analysis is higher than the known field in which the samples had cooled during acquisition of the TRM being analysed, on average by 6% and 12% respectively. The values for the known field were obtained with a fluxgate magnetometer which had been calibrated against a proton magnetometer. The fields used in the course of the analysis were within 0.5% of 48.3 μT.

Table 1 Evaluation by TRM of field intensity used for refiring

Specimen no.	Specific magnetisation ($\times 10^{-3}$ A m^2 kg^{-1})	F^{A}* (μT)	
P12P01P	2.5	52±1	Av. 53
Q	2.4	53±1	
Y	2.5	54±2	
Z	2.5	54±1	
P43C01T	4.6	51±1	Av. 53
U	3.3	55±1	
Y	4.8	50±3	
Z	3.7	55±1	
Islip 02	4.3	54±2	Av. 54
03	5.5	54±1	
04	3.4	53±1	

The cooling time after refiring was 7 h. The cooling times during TRM analysis were ~30 min. For the Peruvian sherds, P12P01 and P43C01, the field intensity used for refiring was 50 μT; for the Islip specimens it was within 0.2 μT of 48.3 μT. F^A is the value deduced for the refiring using Thellier zero-field analysis of the TRM acquired during cooling down from refiring.

* ±1 s.d.

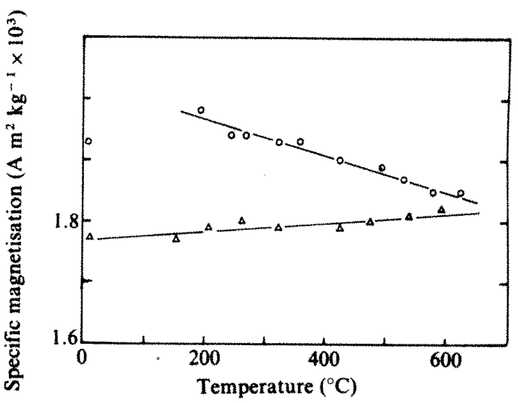

Fig. 1 Remagnetisation of Peruvian pottery sample (P12P10Y) following refiring to 720 °C. The TRM was measured (at room temperature) after remagnetisation during cooling from various reheating temperatures. Two sets of remagnetisations are shown: the first (○) followed a refiring in which the cooling time was 7 h, the second (△) followed a refiring in which the cooling time was half an hour. The latter was also the maximum cooling time for the remagnetisations. The magnetic field was 48 μT in all cases.

In the above analytical procedure, at each temperature step the sample cools in zero field before being remagnetised. To avoid possible interference by a memory effect the following more direct experiment was carried out. After refiring to 720 °C, either with a cooling time of 7 h or of 30 min, the sample was reheated to successively increasing temperatures and cooled rapidly, in ~30 min, the reheating and cooling being in the same field as for the 720 °C refiring. After each step the magnetisation of the sample was measured (at room temperature); a typical result is shown in Fig. 1. Whereas for the 30-min cooling the sample shows a slight overall increase, by <1%, as the reheating steps proceed; for the 7-h cooling there is a decrease, by ~8%.

Figure 2 shows the results of a similar experiment carried out using the SQUID magnetometer (and its associated oven) developed for archaeomagnetic work by Walton[6]. In this the sample (a small 3-mm diameter by 3-mm thick core of Greek pottery) does not have to be demounted from its quartz presentation rod between in-field heating and measurement (at room temperature). After rapid cooling from 600 °C, in a few minutes,

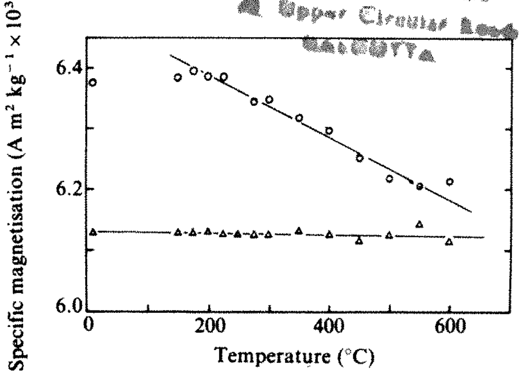

Fig. 2 Remagnetisation of Mycenaean pottery sample (1632a6) following refiring to 600 °C. The TRM was measured (at room temperature) after remagnetisation on cooling from various reheating temperatures. Two sets of remagnetisations are shown: the first (○) followed a refiring in which the cooling time was 2.5 h, the second (△) followed a refiring in which the cooling time was a few minutes. The latter was also the maximum cooling time for the remagnetisations. The magnetic field was 74 μT in all cases.

0028–0836/80/050462—02$01.00

Table 2 Effect of different cooling times on TRM evaluation of field intensity used for refiring

Sample reference	Overestimate relative to 5-min cooling times	
	For 2-h (%) cooling time	For 16-h cooling time
32a6.1 (Attic)	2	7
35a1.1 (Late Minoan)	7	11
P18 L03 (Peruvian)	9	14

TRM evaluation was by means of the Thellier method, using a SQUID magnetometer. Refiring was done in a small non-inductively wound oven external to the magnetometer which was lowered over the sample. For the 5-min cooling time the oven was lifted off the sample; for the 2-h cooling time it was left in position with the heater current switched off; for the 16-h cooling time the heater current was turned down at a uniform rate (by means of a motor driven Variac). For each sample a 5-min cooling time run was done initially and finally. The TRM evaluations from these pairs agreed to within ±1%.

reheating and cooling (also in a few minutes) in the same field produced no change in magnetisation as successively increasing temperatures were used for the reheating. On the other hand, when the sample was cooled slowly from 600 °C, in 2.5 h, the subsequent magnetisation was 5% higher than for quick cooling, and as the reheating steps proceeded (each followed by quick cooling) the excess disappeared. For the slow cooling the heater current for the oven was turned down manually. The oven was non-inductively wound and the a.c. field at the sample site was <20 μT. In the large-sample experiments there was no current in the oven for the slow cooling, the fast cooling being achieved by blowing air on the samples after lifting off the oven.

The effect has also been observed[7] with other samples (see Table 2); in all cases the TRM acquired for slow cooling is greater than for fast cooling. This is as Dodson and McClelland-Brown[2] predicted in considering samples in which the magnetic carriers are monodomain grains of haematite and magnetite. The basis of their prediction is that for a given group of grains the effective blocking temperature is lower in the case of slow cooling and therefore the fractional alignment that is blocked-in is higher, both because of the reduced thermal agitation at the lower temperature and because of the intrinsic increase of activation energy. Dodson and McClelland-Brown[2] consider very slow, geologically-relevant, cooling rates, in the range 6 °C min^{-1} to 3 °C Myr^{-1}; they predict a 7% increase in TRM for an order of magnitude decrease in cooling rate. Our results accord with this prediction. The magnitude of the effect will depend on the magnetic mineralogy of the sample and hence it is not to be expected that it will be quantitatively the same for all samples. This aspect is under investigation.

In general, archaeological pottery and bricks fired in kilns will have cooled down after a couple of days[8]. The cooling times used routinely in this Laboratory for Thellier analysis are either 30 min or a few minutes. Hence the magnitude of the ancient field so evaluated may be larger than the true value by 10–20%; for laboratories employing longer cooling times, or for samples that cooled quickly after the archaeological firing (for example, in an open hearth or in a clamp kiln), the effect will be less. Clearly it would be desirable to investigate the strength of the effect in each type of sample and to make an appropriate correction, or to use laboratory cooling times of the same order as the presumed archaeological cooling time.

The significance for existing determinations of ancient intensity is that they are also liable to be overestimates. This will be significant when calculating the global radiocarbon content. If, for instance, the magnitude of the geomagnetic moment was in general 10% less than indicated by the global curve of Cox[9], the historical radiocarbon production rate will have been ~5% more than currently assumed.

We thank Dr N. Gunn for help in the initial calibration experiment reported in Table 1 while he was at the University of Liverpool Department of Geophysics, also Dr M. Dodson for helpful discussion, and Professor R. Wilson for drawing to our attention the observations in ref. 1. We thank the NERC for a research grant, and a studentship to J.M.W.F.

Bubbles and breaking waves

S. A. Thorpe

Institute of Oceanographic Sciences, Wormley, Godalming, Surrey, UK

P. N. Humphries

Department of Physics, Surrey University, Guildford, UK

The physical processes which control the transfer of gases between the atmosphere and oceans or lakes are poorly understood. Clouds of micro-bubbles have been detected below the surface of Loch Ness when the wind is strong enough to cause the waves to break. The rate of transfer of gas into solution from these bubbles is estimated to be significant if repeated on a global scale. We present here further evidence that the bubbles are caused by breaking waves, and discuss the relationship between the mean frequency of wave breaking at a fixed point and the average distance between breaking waves, as might be estimated from an aerial photograph.

It has been suggested[1] that there may be a causal relationship between whitecaps, or breaking waves, on the surface of a freshwater lake and the individual clouds or bubbles which have been detected acoustically below the surface. The clouds appear with a typical frequency of about 1 per min in wind speeds of 10 m s^{-1} and penetrate to depths of at least 5–10 m. To investigate the relationship, and other phenomena, we measured breaking waves in Loch Ness using a capacitance wire probe[2] and time-lapse photography.

The capacitance wire probe was placed on a mooring connected to shore[3] in a water depth of ~160 m and 250 m from the shore, where the fetch for north-east or south-west winds is some 10 km. The wind speed was measured by an anemometer on a tripod in the loch. As the slope of the water surface in a breaking wave is large, the electronic circuit used with the probe was designed to detect large gradients in surface height. The signal voltage from the probe, proportional to the wave height, was passed through a differentiator and the output compared with a reference level which could be set according to the wave conditions. When the differentiated signal exceeded the reference, a spike generator was triggered which marked the record.

The slope, $\partial h/\partial x$, of the water surface is related to the time derivative, $\partial h/\partial t$, of the wave height measured at a point, by

$$\frac{\partial h}{\partial t} = c\frac{\partial h}{\partial x} \tag{1}$$

where c is the phase speed of the waves. For small deep-water waves $c = c_0 = gT/2\pi$, where T is the wave period and g the acceleration due to gravity[4]. For large amplitude waves the

0028–0836/80/050463—03$01.00

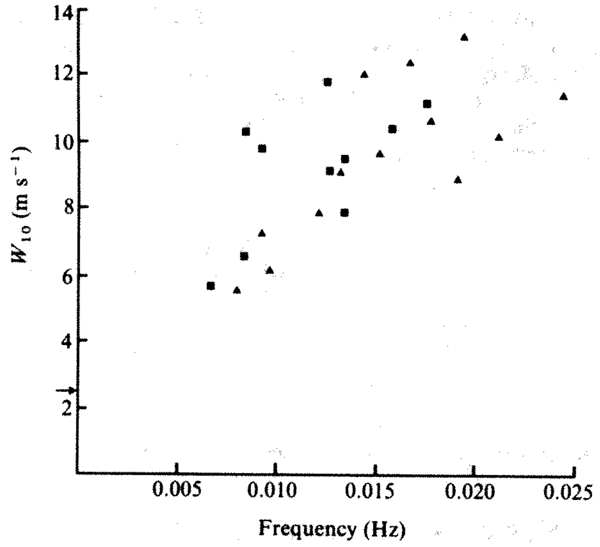

Fig. 1 Wind speed, W_{10} (corrected to 10 m) versus frequency f, of bubble clouds seen on a sonar record[1] (■), or frequency of breaking waves (▲), only one wave being counted when neighbouring waves break as the sonar record cannot resolve a time scale corresponding to individual waves, the bubble clouds from neighbouring waves are expected to merge. Observation periods of at least 20 min were used. The mean standard deviation of the number of waves in a five minute period is ~2.6. The arrow marks the approximate wind speed at which whitecaps and bubbles are first observed.

phase speed is a function of the wave slope. The maximum slope of a regular progressive wave train in deep water[5] is close to 30° when the phase speed[6], $c = 1.0923c_0$, and hence the maximum value of the time derivative is approximately

$$\frac{\partial h}{\partial t} = 0.1004gT \qquad (2)$$

(The greatest wave speed is estimated[6] at $c = 1.09295c_0$ and hence equation (1), with $c = c_0$, may be used with an error of <10%).

The capacitance wire probe was used to measure the mean wave period, T, estimated from the zero-crossing interval, and equation (2) used to estimate $\partial h/\partial t$ for a limiting wave. In practice the reference level setting was set empirically to trigger 'spikes' on an ink-plotting pen when a breaking wave could be seen at the probe, and considerably smaller values than the theoretical equation (2) were found to be suitable. Trouble was encountered by spikes being triggered near wave nodes where the wave slope is large but where no breaking or bubble entrainment occurs. Waves tend to break near their crests and these spurious spikes were avoided by incorporating a circuit which passed the signal spike only if the wave height exceeded a certain level, which was set in relation to the observed height of the existing wave field.

The success of the system in identifying breaking waves was tested by taking cine film of the probe and water surface from shore and by comparing the record of wave height and spikes with the photographic record. In calm weather tests were also made by artificially creating breaking waves in the wake of a boat which passed close by the probe. The detection system was insensitive to brief spikes of the order of 25 ms or less in which $\partial h/\partial t$ just exceeds the threshold. Waves less than the probe dimensions, ~10 cm, were not resolved either by the probe or by the camera, but larger waves with crest lengths exceeding this dimension were detected.

For wind-waves Loch Ness is effectively an enclosed basin, and swell from distant storms which might, at sea, induce wave breaking[7], is absent. A relationship might therefore be expected between the frequency of wave breaking and the local wind speed. Figure 1 shows the average frequency of wave-breaking events and individual bubble clouds seen in the sonar records[1], plotted against wind speed. There is considerable scatter, arising partly from the uncertainty in identifying individual bubble clouds in the sonar records and partly from the unsteadiness of the wind. There is an upward trend in both sets of points, commensurate with a zero value at a wind speed of ~2.5 m s^{-1} when whitecaps and bubble clouds are first observed. Whilst the frequencies are similar, the number of wave-breaking events exceeds that of the bubble clouds. A contributing factor may be that some waves, breaking 'gently', do not produce bubbles which penetrate below the depth of the pre-existing cloud.

The average period between the occurrence of breaking waves at the probe was compared with the mean distance between breaking waves approaching the probe. The latter was derived from time-lapse photographs of the water surface taken from the hillside above the loch. The width of the camera frame was established by taking photographs of a rubber boat of known dimensions. The time interval between frames was such that groups of waves would travel a distance well exceeding the frame width during the time interval, and thus be filmed only once. With the assumption that their statistics were uniform, the mean distance between whitecaps, $\bar{x}$, was found by dividing the number of breaking waves observed to intersect a line along the loch axis (approximately the mean direction of wave advance) into the total effective frame length.

The large and steep waves which break, forming whitecaps, occur in groups. It was very rare to see two neighbouring waves break simultaneously and when this happened only one wave was included in the count. Figure 2 shows estimates of $\lambda/\bar{x}$, where λ is the mean wavelength estimated from using the relation[4] $\lambda = gT^2/2\pi$. Also shown are estimates of $\bar{t}/T$, where $\bar{t}$ is the average time interval, measured by the capacitance wire probe, between successive groups which contained breaking waves. About 58% of the groups which passed the probe with breaking waves contained more than one (none more than three). There is again much scatter in the observations (again variation in wind conditions may have contributed) but evidence of an increase in both $\lambda/\bar{x}$ and $T/\bar{t}$ with wind speed. This is partly due to an increase in T (and hence λ) with wind speed from an average of 2.58 s at wind speeds of 6.17 m s^{-1} to 3.05 s at winds of 12.4 m s^{-1}. On average the values of $\lambda/\bar{x}$ are significantly greater than those of $T/\bar{t}$ at the same wind speeds. (Mean values are 0.076 and 0.056 respectively at a mean wind speed of 9.9 m s^{-1}).

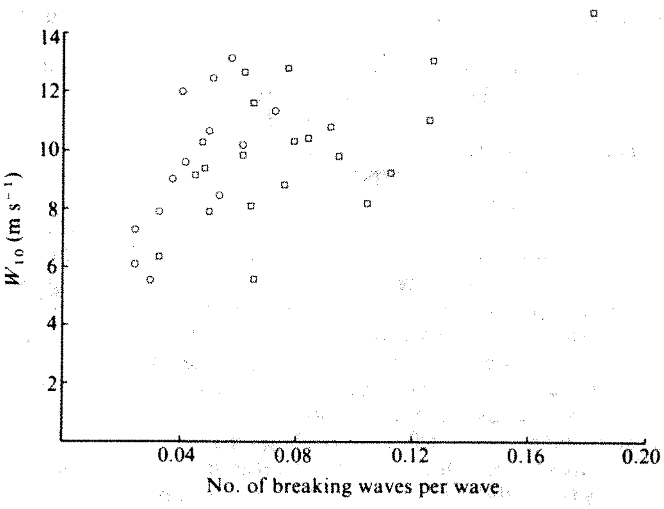

Fig. 2 Wind speed, W_{10} (corrected to 10 m) versus ○, $T/\bar{t}$ or □, $\lambda/\bar{x}$, the number of breaking waves per wave, groups counting once only (see text). $\lambda/\bar{x}$ was calculated over an effective horizontal length of at least 2,280 m.

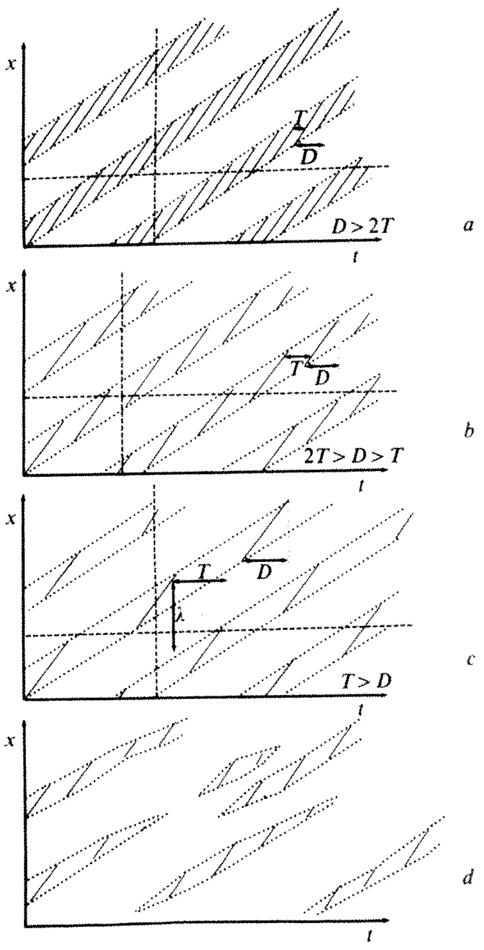

Fig. 3 Space (x)–time (t) diagram of the movement of breaking waves and groups. The heavy lines are breaking waves and the dotted lines are groups. Idealised diagrams when: *a*, $D>2T$; *b*, $2T>D>T$; *c*, $T>D$; *d* is a sketch of a more realistic situation in which the groups break intermittently. The groups of breaking waves have been drawn closer together than they are in reality. The dashed lines x, constant; and t, constant indicate the way in which the breaking waves are sampled by the probe and by photographs respectively. In *a* these lines cut at least one breaking wave in each group. In *b*, t, constant misses, but x, constant always intersects, one or two of the breaking wave tracks, whilst in *c* both lines occasionally miss and more than one breaking wave in the same group is never sampled.

The regions of large waves, and hence whitecaps, advance at the group velocity[8], which, in deep water, is half the phase speed of the waves. Figure 3*a*,*b*,*c* shows the waves in space–time coordinates. The individual breaking waves, advancing at the phase speed, are shown as solid lines of slope $c=\lambda/T$. The groups containing breaking waves advance at the group velocity and are indicated by a succession of these lines, forming a patch outlined by dotted lines with slope $c/2$. If the duration of persistance of a whitecap, D, is more than double the wave period (Fig. 3*a*) each group with breaking waves will contain at least one breaking wave when it is observed at constant time (by a photograph) or as it passes a constant position (the wave probe). If only one breaking wave in each group is counted, the ratio r of the mean distance between such successive observations at constant time and their mean period will be the group velocity, $c/2$. Hence the ratio

$$\chi \equiv (\lambda/\bar{x})/(T/\bar{t}) = \frac{c}{r} = 2 \qquad (3)$$

If, however, $2T>D>T$ (Fig. 3*b*), whilst each group containing breakers will be recorded by at least one breaking wave at the probe (constant x), there are times when no waves at all will be breaking in a particular group, and hence $\chi<2$. Moreover at most one wave at a time will be breaking in a group. If, as is often observed, $D<T$, then groups containing breaking waves may pass the probe with no breaking event registering. Groups containing multiple breaking waves are more likely to be recorded at a fixed location than to be seen in a photograph, as is indeed observed. The occurrence of multiple breaking waves at the probe suggests that D frequently exceeds T, whilst their absence in photographs implies that D is usually less than $2T$.

The observed mean value, $\chi=1.65$, is consistent with this argument. Because the breaking waves are unlike the idealised model (but resemble Fig. 3*d*) there seems at present no obvious way in which χ may be related to the simple statistics of the wave field. A working value of χ would, however, be useful as it would then be possible, by finding $\bar{x}$ and T (or λ)[8] from aerial photographs, to estimate $\bar{t}$ and hence to determine how often a stationary structure, for example, an oil rig or wave power device, would be subject to groups of breaking waves.

Whilst there is at least circumstantial evidence for a causal relationship between breaking waves and bubbles, more research is needed. Progress might be made by using narrow-beam upward-pointing sonar which could resolve details of the wave surface during wave breaking.

The breaking-wave detection circuit was created by Professor M. S. Longuet-Higgins and Dr B. S. McCartney. Their idea, and the generous assistance of other members of I.O.S. staff, are gratefully acknowledged.

Gallium porphyrins in bituminous coal

Raymond Bonnett & Franciszek Czechowski

Department of Chemistry, Queen Mary College, Mile End Road, London E1, UK

Metalloporphyrins are minor constituents in crude oil and its relatives[1] but their presence in coal is not clearly established. This is surprising as such complexes are thought to arise from chlorophyll, and coal is largely of plant origin. Although coal samples were among the earliest examined in this context[2,3], most later workers[1,4] followed Treibs[5] in mainly considering crude oils, asphaltenes and shales. Weigelt and Noack[2] presented early evidence for chlorophyll derivatives in fossilised leaves from brown coal, while Treibs[3] found trace amounts of metal-free porphyrins in various coals. Uspenskii and Gorskaja[6] confirmed the latter finding, but observed that the porphyrin content of sapropelic coals such as cannel coal was much higher than that of hard coals. Metalloporphyrins in fossil plant material are important because they provide information on the geochemical transformations of chlorophyll. Moreover, metal complexes with organic ligands (such as the metalloporphyrins) are of particular interest in contemporary coal chemistry because they are probably extracted by the organic solvent in the conditions used in certain coal liquefaction processes, and hence may modify the activity of catalysts used in subsequent chemical reactions with the coal extract. We report here the isolation of a metalloporphyrin fraction from a British bituminous coal, and show that the principal metal present in the isolated material is gallium.

0028–0836/80/050465—03$01.00

Table 1 Metal analysis of metalloporphyrin fraction isolated from Daw Mill coal

Metal	%
Gallium	5.7
Sodium	0.49
Iron	0.36
Potassium	<0.2
Magnesium	<0.2
Aluminium	0.17

Powdered dried coal (92 kg) from Daw Mill Colliery (South Midlands, Int. Code No. 811) was extracted with 7% v/v sulphuric acid in methanol for 12 h. The filtrate was diluted and much of the organic material was transferred into chloroform, which was washed (aqueous $NaHCO_3$, water) and taken to dryness (42.8 g). This crude extract was submitted to column chromatography on silica gel, the elutriant being benzene–methanol. Porphyrin-containing fractions were combined and submitted to preparative TLC on silica gel irrigated with benzene–ammoniacal methanol. Three red bands, barely separated, appeared at $R_F \sim 0.5$–0.55. These were combined, extracted and submitted to further purification by TLC. Finally the orange-red material was extracted with dichloromethane. The extract was filtered, concentrated and treated with petroleum ether to give the metalloporphyrin concentrate (17.8 mg, representing 0.19 p.p.m. of coal).

The metalloporphyrin concentrate thus obtained was a purple solid, not obviously crystalline but possessing a metallic sheen, and it did not melt below 300 °C. Metal analysis by thermal neutron activation (AERE, Harwell) showed that gallium was the principal metal present, with much smaller amounts of sodium, iron, potassium, magnesium and aluminium (Table 1). These latter metals possibly represent inorganic impurities, although iron and aluminium may both be present as metalloporphyrins.

A solution of the metalloporphyrin fraction in chloroform was red, and had a brilliant orange-red fluorescence in UV light (365 nm). The absorption spectrum (Fig. 1), with a Soret band at 405 nm, and visible peaks at 532 and 570 nm was typical of a metalloporphyrin, and resembled that of hydroxogallium(III) octaethylporphyrin ($\lambda_{max}^{CHCl_3}$ 404, 533 and 571 nm). The NMR spectrum accorded with that expected for a polyalkylporphyrin complex of a diamagnetic ion. The signals were broad, however, and this is attributed to the presence of a mixture of such complexes and to the effect of small amounts of paramagnetic ions.

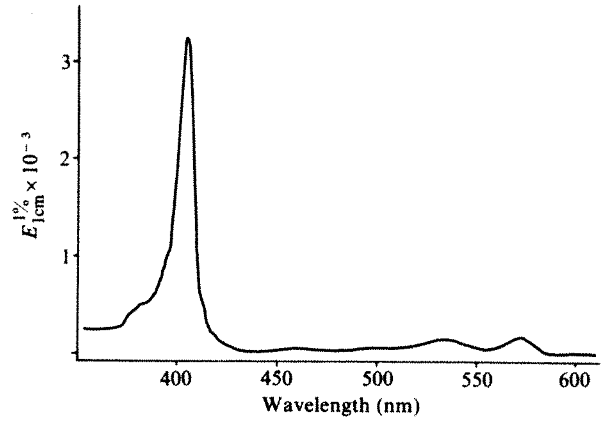

Fig. 1 Absorption spectrum of the metalloporphyrin fraction from Daw Mill coal. Solvent, chloroform.

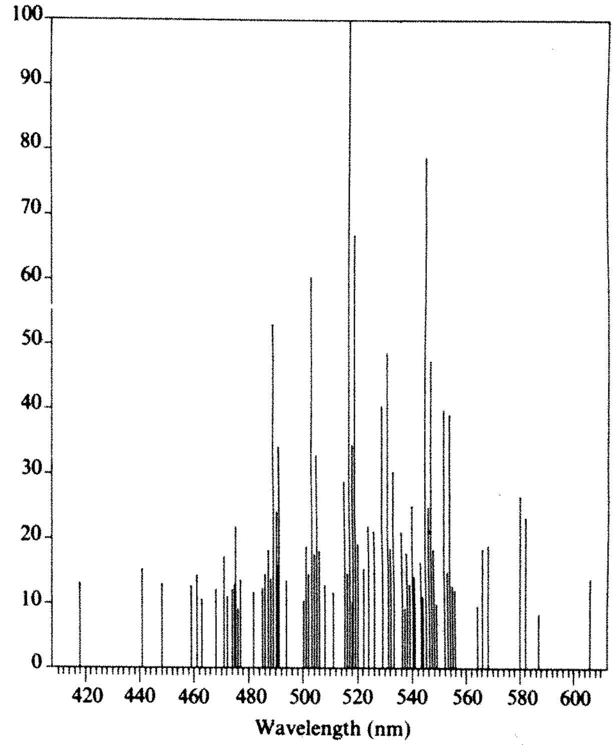

Fig. 2 Mass spectrum of metalloporphyrin fraction from Daw Mill coal. The sample was introduced with a direct insertion probe, with a source temperature of 300 °C (measured at PCMU, Aldermaston).

The mass spectrum (Fig. 2) was very informative, and clearly indicated a mixture of homologous metalloporphyrins. The largest peak, *m/e* 517.185, corresponded to $C_{30}H_{32}N_4\,^{69}Ga$ (the axial ligand having been lost), and was attended (natural distribution[8] of gallium isotopes $^{69}Ga:^{71}Ga = 60.4:39.6$) by a second peak at *m/e* 519.188 ($C_{30}H_{32}N_4\,^{71}Ga$). These molecular formulae correspond to complexes of didemethyletioporphyrin, or an isomer of this. Some other components of this homologous series are given in Table 2, from which it is seen that the second most abundant pair of ions (*m/e* 547, 545) correspond formally to the gallium complex of tetraethyltetramethylporphyrin (etioporphyrin). Although each ion may well represent an isomeric mixture, the formulations suggested above are favoured on geobiogenetic grounds and the general analogy with the petroporphyrins[1]. Support came from HPLC (Fig. 3) using a reverse phase system[7] which proves to be very useful in the analysis and separation of polar porphyrins such as the gallium complexes. This revealed several components, one of which had the same retention time, within the resolution of the column, as synthetic hydroxogallium(III) etioporphyrin I.

Small-scale experiments on other coals gave similar but not identical results. Three other British bituminous coals (Annesley, South Nottinghamshire, Int. Code No. 633; Bersham, Western Region, Int. Code No. 634; and Linby, South Nottinghamshire, Int. Code No. 732) contained metalloporphyrins with similar properties, as did a Turkish lignite (Ankara-Beypazari). However, samples of a German brown coal and a Polish brown coal (Konin) contained a porphyrin fraction with different properties. With the amounts of porphyrin detected (<0.6 p.p.m.) it is important to appreciate the dangers of contamination, especially in a laboratory where porphyrins have been studied for many years. The different results obtained with the brown coal samples argue against this possibility, and it turns out that gallium porphyrins had not been prepared in our laboratory before this work. Moreover the gallium complex of octaethylporphyrin (a common ligand in our laboratory) was not present in the metalloporphyrin concentrate from coal (its

Table 2 Some accurately measured ions in the mass spectrum of the metalloporphyrin fraction from Daw Mill coal

Observed mass	Abundance	Formula	Calculated mass
547.220	47.3	$C_{32}H_{36}N_4{}^{71}Ga$	547.219
545.218	78.7	$C_{32}H_{36}N_4{}^{69}Ga$	545.220
533.205	30.3	$C_{31}H_{34}N_4{}^{71}Ga$	533.203
531.200	23.0	$C_{31}H_{34}N_4{}^{69}Ga$	531.204
519.188	66.7	$C_{30}H_{32}N_4{}^{71}Ga$	519.188
517.185	100	$C_{30}H_{32}N_4{}^{69}Ga$	517.188
505.171	32.8	$C_{29}H_{30}N_4{}^{71}Ga$	505.172
503.169	60.2	$C_{29}H_{30}N_4{}^{69}Ga$	503.173

489.155	53.0	$C_{28}H_{28}N_4{}^{69}Ga$	489.157
477.140	13.6	$C_{27}H_{26}N_4{}^{71}Ga$	477.140
475.137	21.7	$C_{27}H_{26}N_4{}^{69}Ga$	475.141

Measured at PCMU, Aldermaston, on a Kratos (AEI) MS50 mass spectrometer with a DS-50SM data system. Direct insertion, 300 °C at 70 eV.

presence would have been revealed by a pair of peaks m/e 601 and 603 in Fig. 2).

Contamination with gallium is perhaps less likely. Nevertheless, we have felt it necessary to carry out control experiments in which the chromatographic materials were treated in appropriate conditions with trace quantities of octaethylporphyrin. The latter substance was recovered, but the gallium complex was not detected. Nor was gallium incorporated when basic gallium acetate was treated with octaethylporphyrin in 7% H_2SO_4–MeOH (18 h at room temperature, that is approximating to the conditions of the coal extraction). This experiment is important, as gallium is one of several trace metals present in coal[9,10]: indeed, processes are described for the isolation of the metal from this source[11].

Because of the possibility of fractionation during the coal extraction, we do not consider that we have isolated all the metalloporphyrins present in the coal sample, and clearly several minor peaks in the mass spectrum remain to be assigned. These will be discussed elsewhere. The mass spectrum does suggest, however, that the ratio between gallium complexes of the etioporphyrin series ($M \pm 14n$, $M = 545$, 547) and the analogous complexes of the presumed 13^2,15-cycloetioporphyrin III (deoxophylloerythroetioporphyrin) series ($M' \pm 14n$, $M' = 543$, 545) is generally high. This, and the low abundance of the metalloporphyrins in bituminous coal compared with that in many crude oil deposits, is consistent[12] with the more drastic thermal conditions believed to be necessary for coal to form. Indeed, it seems reasonable to suppose that coal rank may be inversely related to available metalloporphyrin content.

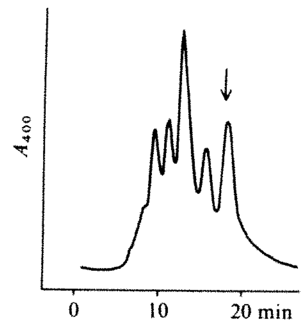

Fig. 3 HPLC of metalloporphyrin fraction on reverse phase column (Waters, Bondapak C_{18}/Porasil B) eluted with MeOH:H_2O = 72.5:27.5. The arrow indicates the component with a retention time indistinguishable from that of synthetic hydroxogallium(III) etioporphyrin. The column resolves homologues, not isomers, of polyalkylporphyrins.

The presence of gallium in coal porphyrins is unexpected: the abundance of gallium in the Earth's crust (15 p.p.m.) is an order of magnitude less than that of vanadium[8], and, although some organisms accumulate gallium[13], the biological function of this does not seem to be understood. The vanadyl porphyrins which occur in crude oil are thermodynamically and kinetically stable, and it may be argued that once formed they persist through geological time. Whether a similar argument can be applied to gallium porphyrins is not known: they are chemical rarities and require further study.

We thank the National Coal Board for financial support and for samples; Mr G. O. Davies, Mr W. F. Wyss and Dr T. G. Martin of the National Coal Board for their help and advice, and the SRC for the provision of research facilities (at QMC and PCMU).

No-flow equilibration and adsorption dynamics during ionic transport in soils

V. Murali & L. A. G. Aylmore

Department of Soil Science and Plant Nutrition, University of Western Australia, Nedlands, Western Australia 6009, Australia

Methods for predicting the movement of adsorbing chemicals such as fertilisers, pesticides, herbicides and heavy metals in soils have received increasing attention because of their importance in relation to the efficiency of fertiliser usage and in the control of agricultural and industrial pollutants[1]. Because of the difficulty in coping with the complex non-linear partial differential equations necessary to describe the dispersive–convective–adsorptive flow process, analytical solutions have been largely limited to the assumptions of instantaneous equilibrium and simple linear adsorption isotherms[2–5]. We demonstrate here the need to incorporate adsorption dynamics to describe adequately practical situations, particularly those involving intermittent flow.

In reality the movement of water through soils rarely, if ever, occurs continuously or at uniform flow velocity for any length of time. For example, the water content of the soil described as 'field capacity'[6] results from the much slower redistribution of water following infiltration. Consequently there is a period following infiltration when flow is negligible but adsorption/desorption processes may continue. Thus, rather than being able to assume a constant or average pore water velocity and instantaneous equilibration between solute and adsorbent, it is imperative to consider the effects of the 'go–stop' nature of water movement where adsorption dynamics are concerned.

The importance of this effect is illustrated by our recent studies of the influence of adsorption dynamics on the movement of adsorbing ions in soil columns. The term 'adsorption dynamics' is used here to include not only adsorption kinetics at

0028–0836/80/050467—03$01.00

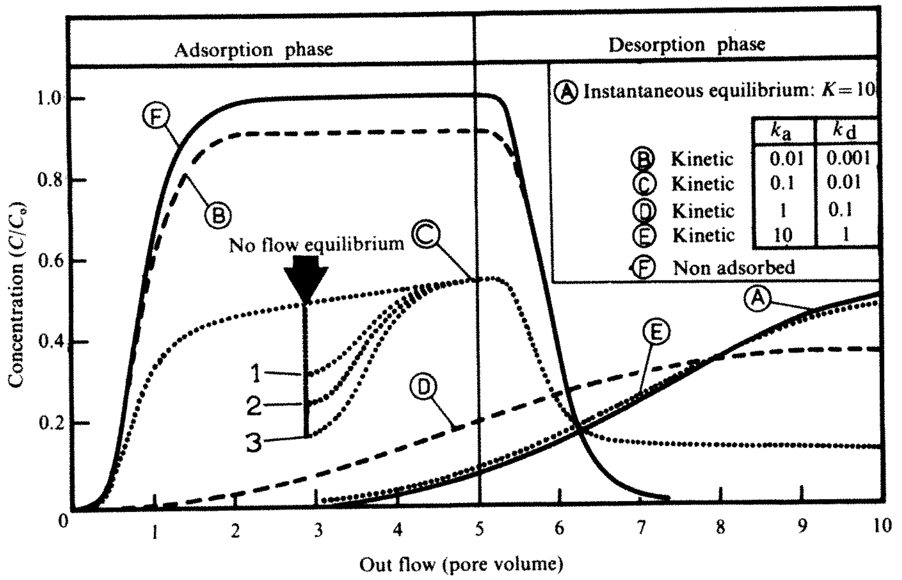

Fig. 1 Simulation of adsorption–desorption breakthrough curves for instantaneous equilibrium (curve A), kinetic models (B, C, D, E) and non-interacting solute (F). Effects of no-flow equilibrations are shown on curve C for increasing periods equivalent to the time taken for the outflow of 2, 4 and 10 pore volumes respectively.

solid surfaces, but also any intermediate steps which may influence the rate at which chemicals are exchanged between solution and adsorbed phases. In particular this includes diffusion from the centres to the walls of hydrodynamic pores (that is, pores responsible for hydrodynamic dispersion) but excludes intra-aggregate diffusion which can be viewed as a separate process.

A standard technique for studying the movement of ions in soil[7,8] is the measurement of 'breakthrough curves' which describe the change in the outgoing solution from a soil column with outflow volume following a change in input concentration. Figure 1 contrasts the breakthrough curves, predicted by computer simulations using numerical methods, for non-instantaneous equilibration involving a range of different adsorption and desorption rates (k_a and k_d respectively), with that obtained for instantaneous equilibration (at the same equilibrium constant) using a simple linear isotherm. The simulations depict the passage of five pore volumes of solution containing the ion into a column of soil saturated with water (adsorption phase) followed by five pore volumes of ion free water (desorption phase). The value of the equilibrium constant K at relevant soil solution concentrations is generally greater than unity and $K = 10$ has been used as a suitable example.

The assumption of instantaneous equilibrium means that for two ionic species having the same or similar equilibrium isotherms, identically shaped and positioned breakthrough curves (curve A) will be predicted for the passage of their concentration pulses through a soil column. However, the rates of approach to adsorption and desorption equilibrium may vary considerably between different species and this will result in a range of markedly different breakthrough curves depending on the relevant rate coefficients (for example, curves B, C, D and E).

The consequence of different 'no-flow equilibration' periods on the breakthrough curves predicted in any case involving adsorption dynamics is particularly relevant. This is illustrated by the depressions in outgoing concentration for curve C corresponding to no-flow periods of increasing length. The assumption of instantaneous equilibration (curve A) will, of course, obscure this effect completely.

In the previous simulations simple linear adsorption kinetics were used to demonstrate the effects of time dependency of the adsorption/desorption processes. However, in other simulations we have shown that the same considerations are relevant regardless of the type of isotherm involved, for example, Freundlich and Langmuir.

The considerable practical significance of this effect is demonstrated by the breakthrough curves in Fig. 2 obtained for solutions of phosphate (2.5 mM), selenite (1.0 mM) and sulphate (1.0 mM) ions, and tritium labelled water including a 24 h no-flow equilibration period. The soils used were in a finely-ground state and the depressions in outgoing concentration for phosphate and selenite following no-flow periods cannot be attributed to intra-aggregate diffusion. This is verified by the absence of measurable depressions in the case of the sulphate despite the measurable adsorption of this ion and for the effectively non-adsorbed tritium ion. Thus it is clear that adsorption dynamics as previously defined, can be particularly important in controlling ionic transport in real conditions. The significant difference in the shapes of the breakthrough curves for sulphate and tritium, despite the absence of no-flow depressions for both, clearly demonstrates that adsorption kinetics form only part of the total adsorption dynamics influencing ionic movement. Other studies demonstrate that in aggregated systems the involvement of intra-aggregate diffusion before surface interactions, introduces no-flow depressions in outgoing concentrations for even non-adsorbed species and greatly enhances those for adsorbing species.

Such intermittent flow/no-flow measurements apparently provide a simple and convenient technique for checking the pertinence of adsorption dynamics for any particular ion–soil system, solution concentration and flow velocity, and we are not aware of any previous such demonstration in non-aggregated systems.

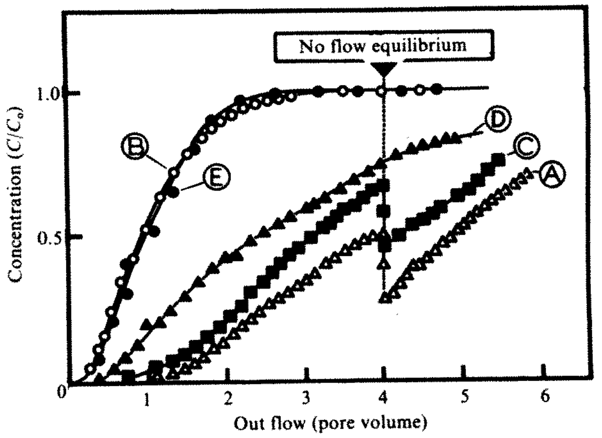

Fig. 2 Experimental breakthrough curves for phosphate (A) and tritium (B) movement through Yalanbee sandy loam and selenite (C), sulphate (D) and tritium (E) through York sandy loam showing effects of 24-h no-flow equilibration. Flow velocity equivalent to 0.3 pore volumes per hour.

The nature of the rate determining steps in these studies will require further investigation. While studies on equilibrium distributions involving agitation and high solution-to-solid ratios generally indicate extremely fast ion–soil interactions[9], the present observations demonstrate that such measurements of adsorption kinetics may be of little relevance in relation to ionic transport. There is increasing evidence that considerably slower rates are involved in actual soil systems[10,11].

These observations form part of a much more detailed study of ionic transport through soil systems involving computer simulations using numerical methods and experimental determinations in soil columns being undertaken in this Department.

3,360-Myr old gneisses from the South Indian Craton

R. D. Beckinsale

Institute of Geological Sciences, Gray's Inn Road, London WC1, UK

S. A. Drury & R. W. Holt

Department of Earth Sciences, Open University, Milton Keynes, UK

Reliably dated continental crust older than 3,000 Myr is only known from restricted segments of cratons in southern Africa, Greenland–Labrador, and Minnesota (summarised in ref. 1). These rare Archaean nucleii are very important in constraining the timing and mechanism of the differentiation of continental material from the mantle. We report here preliminary Rb–Sr whole rock data for Archaean gneisses from the Gorur-Hassan area, South Indian Craton which yield the oldest age yet reported from the Indian sub continent (3,358±66 Myr) with a very unradiogenic initial $^{87}Sr/^{86}Sr$ ratio (0.7000±0.0004) which implies that the igneous precursors of these gneisses were derived from a relatively Rb-depleted source within the mantle.

The gneisses of the Gorur–Hassan area (Fig. 1) are components of the polyphase Archaean Peninsular Gneisses of the South Indian Craton. They are unconformably overlain by the low grade volcanic-sedimentary association of the Dharwar supergroup, represented locally by the Bababudan and Shigegudda belts[2]. Their relationship to the supposed pre-Dharwar, high grade volcanic–sedimentary association of the Holenarsipur belt[2,3] is, as yet, ill defined. The areas to the west and east are characterised by marked late or post-Archaean shear belts in which gneisses and supracrustals are deformed together. To the north-west, the gneisses have undefined relations with a foliated granitoid mass, the Chickmagalur Granite, which is also unconformably overlain by the Dharwar supergroup of the Bababudan belt. Both the gneisses and the Holenarsipur supracrustals are intruded by a small post-kinematic granitoid mass the Mavinkere Granite, which may also post-date the major shear belts (Fig. 1).

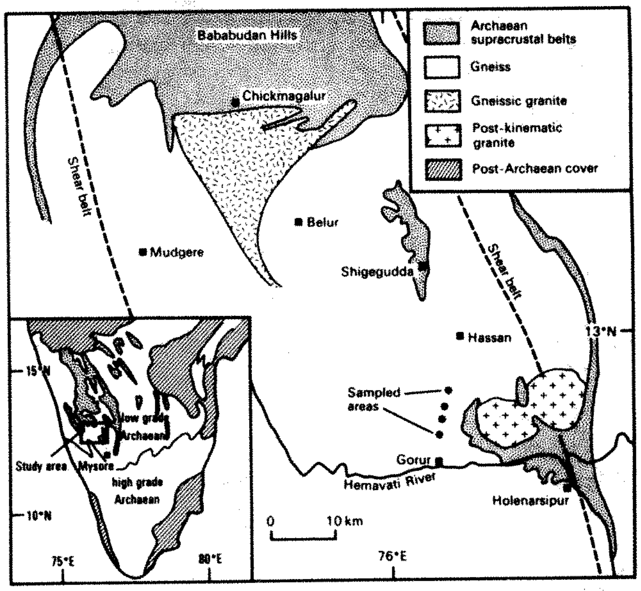

Fig. 1 Geological sketch map of parts of Hassan and Chickmagalur Districts, Karnataka.

The gneisses described here were chosen for reconnaissance dating because of their location in an area of low finite strain and the fact that they are stratigraphically the oldest known materials in the South Indian Craton readily amenable to the Rb–Sr method. The sample were all taken from active quarries and are extremely fresh rocks.

The gneisses range from dark dioritic amphibolites through tonalites and granodiorites to very pale trondjhemites. This gives the gneisses a broad banded aspect, each band showing little evidence of strong deformation. In places the compositional banding is emphasised by parallel highly strained zones with isoclinical folds. Late stage epidotic crush zones have developed locally. Analysed samples were collected from the least deformed representative of each phase, and at least 3 km from the post-kinematic Mavinkere Granite (Fig. 1).

The Rb–Sr data set out in Table 1 were determined at IGS by standard methods of mass and X-ray fluorescence spectrometry using an automatic V.G. Micromass 30 and an automatic Philips PW 1450. Data for standards obtained during the course of the sample analyses are also set out in Table 1. The Rb–Sr data are plotted on an isochron diagram in Fig. 2.

Least squares regression of the data points using the method of Williamson[4] yields a slope and intercept corresponding to an age and initial $^{87}Sr/^{86}Sr$ ratio of 3,369±31 Myr and 0.6995±0.0002 (1σ errors). The MSWD, indicating how well the points fit a line, using the 1σ errors estimated from replicate analyses (Table 1) is 15.2. Rejecting two samples, whose thin sections show slight epidotisation, reduces the MSWD to 1.84 and yields an age of 3,358±66 Myr (2σ) and an initial $^{87}Sr/^{86}Sr$ ratio of 0.7000±0.0004 (2σ) from the five-point isochron. Work is in

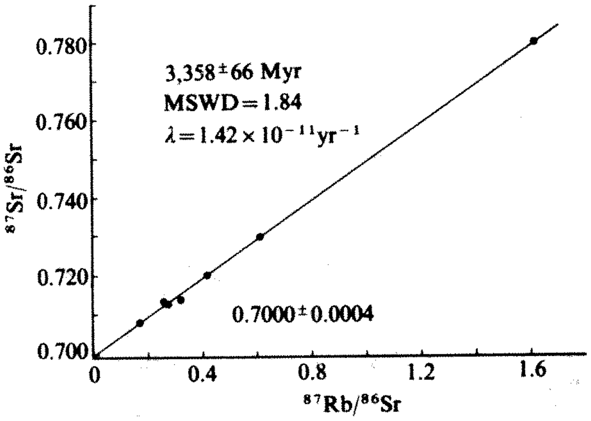

Fig. 2 Rb–Sr whole rock isochron plot for Gorur-Hassan gneisses. Errors are quoted at 2σ level.

progress to document further the Rb–Sr systematics of this crustal segment.

Previous whole rock Rb–Sr isochron ages for the Peninsular Gneisses range from 2,640 (ref. 5) to 3,250 Myr (ref. 6). The latter age was derived from three gneissic clasts in the basal Dharwar conglomerates and consequently has gross errors and little geological significance. However, it does suggest that gneisses of the age we report here may be widespread in the South Indian Craton.

The intial $^{87}Sr/^{86}Sr$ ratio of 0.7000 ± 0.0004 lies slightly below an $^{87}Sr/^{86}Sr$ growth line for the mantle (Rb/Sr = 0.03) and well below most similar Archaean gneisses from elsewhere (Fig. 3). Assuming that the initial ratio of the gneisses grew from a primordial ratio of 0.699 (ref. 7) at 4,560 Myr to their measured value at 3,358 Myr the Rb/Sr ratio during this time must have averaged about 0.020. This implies a source region for the igneous precursors of the gneisses depleted in Rb compared with more typical mantle (Rb/Sr = 0.038). Such a depletion may reflect either: (1) an earlier differentiation of material with high Rb/Sr ratios from the mantle, in other words it is possible that even older crustal rocks may be identified in the South Indian Craton; (2) a mantle source region that was originally anomalously low in initial $^{87}Sr/^{86}Sr$ in comparison with basaltic achondrites or other meteorites (ref. 7); (3) a source region that had been depleted in Rb/Sr by some indeterminate process. It is not possible to choose between these alternatives at present, although possibility (2) appears least probable.

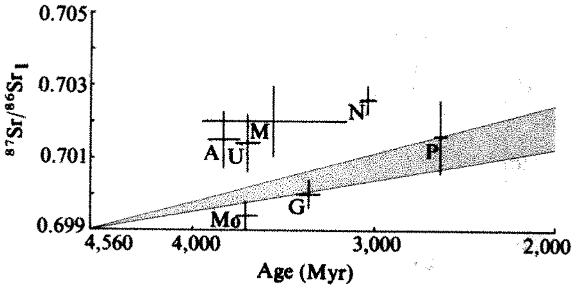

Fig. 3 Graph of initial $^{87}Sr/^{86}Sr$ versus age for Archaean gneisses relative to a range of $^{87}Sr/^{86}Sr$ ratios for igneous rocks derived from the mantle (stipple): A, Amîtsog gneiss, West Greenland[8]; N, Nûk gneiss, West Greenland[9]; M, Mashaba gneisses, Rhodesia[10]; U, Uivak gneisses, Labrador[11]; Mo, Morton gneiss, Minnesota[12]; P, Peninsular gneiss, Mysore[5]; G, Gorur–Hassan gneiss, this paper.

The very low initial $^{87}Sr/^{86}Sr$ ratio virtually rules out any evolution of the gneisses' Sr isotope system before the measured age. We therefore interpret the age of 3,358 ± 66 Myr to represent the age of separation of the gneisses' precursors from a mantle depth source region. The gneisses are the oldest rocks known from the Indian sub-continent. The anomalously low $^{87}Sr/^{86}Sr$ ratio of the gneisses and the reported presence of metapelitic and metabasic enclaves within the gneisses of the low finite strain zone of the Hassan District (B. Chadwick, personal communication) suggest the Hassan District to be potentially the most fruitful area for investigations of the early crustal history of the Indian sub-continent.

S.A.D. and R.W. were introduced to the geology of the Hassan District and persuaded of its importance by Dr S. M. Naqvi and his colleagues from NGRI Hyderabad, India. Field work was supported by NERC grant GR3/3665. R.D.B. thanks the Director Institute of Geological Sciences for permission to publish.

Convergent metamorphism of eclogite and garnet-bearing ultramafic rocks at Lien, West Norway

L. G. Medaris Jr

Department of Geology and Geophysics,
University of Wisconsin, Madison, Wisconsin 53706

Eclogite and garnet peridotite and pyroxenite are important features in the supracrustal sequence of the Basal Gneiss region in West Norway. Three modes of origin have been proposed for these rock types: (1) both eclogite and garnet-bearing ultramafic rocks equilibrated in the upper mantle and subsequently were tectonically emplaced in their present positions[1–3], (2) the eclogites were produced by *in situ* metamorphism of a crustal sequence, but the ultramafic rocks originated in the upper mantle and were tectonically emplaced[4–10], and (3) the ultramafic rocks were derived from the mantle but were emplaced before the eclogite facies metamorphic event and have shared a common metamorphic history, at least in part, with the crustal eclogites[11]. I report here the application of recently developed geothermometers/barometers to garnet-bearing assemblages in the Lien peridotite at Almklovdalen and to adjacent eclogites in surrounding supracrustal gneisses which has documented a retrograde metamorphic trend from 820 °C, 28.1 kbar to 645 °C, 17.6 kbar in the ultramafic rocks and a prograde trend in the eclogites which converges with that of the ultramafic rocks. The Lien peridotite seems to have been derived from the upper mantle in eclogite facies conditions and emplaced into unusually thick continental crust during an eclogite facies metamorphic event.

One of the classic occurrences of garnet peridotite and pyroxenite in west Norway is located within the Lien peridotite[1-2,12-13] (Fig. 1), which is part of a large ultramafic body in Almklovdalen[14]. The Lien peridotite consists predominantly of partly serpentinised, foliated chlorite peridotite containing an equilibrium assemblage of forsterite–enstatite–tremolite–clinochlore ± low Al chromite with a fine- to medium-grained mosaic texture. Four areas of garnet peridotite with locally abundant garnet pyroxenite layers are preserved within the Lien body (Fig. 1) and represent relicts of the earliest discernible mineral assemblage in the ultramafic mass. Garnet peridotite displays an inequigranular texture in which large strained grains of clinopyroxene, orthopyroxene, and garnet occur in a fine- to medium-grained mosaic matrix of strain-free olivine, orthopyroxene, clinopyroxene, pargasitic amphibole, and small amounts of chromiferous spinel. Garnet pyroxenite displays similar texture and mineralogy, except that olivine is subordinate in amount, or absent. In both rock types garnet is commonly surrounded by a kelyphitic rim of finely intergrown amphibole and spinel.

The Lien peridotite has generally concordant contacts with surrounding gneisses of tonalitic to granodioritic composition. Garnet- and muscovite-bearing layers are present in the gneiss, and amphibolite layers and boudins are common. Amphibolite facies mineral assemblages in the gneiss are compatible with the chlorite peridotite assemblage in the ultramafic rocks, which is stable from 700 °C to 780 °C (ref. 15).

The predominant structural style in gneiss and chlorite peridotite is one of tight to isoclinal similar folds with a penetrative axial plane foliation which strikes east-northeast and dips steeply to the south. Linear elements of these folds measured in both rock types over the map area plot along a girdle which coincides with orientation of the axial plane foliation in the area. Thus, not only do gneiss and chlorite peridotite contain compatible mineral assemblages, they also share the same structural elements.

Nine occurrences of eclogite boudins, the largest of which is 20 m by 50 m, have been located in gneiss adjacent to the Lien peridotite (Fig. 1). Eclogite contains a primary mineral assemblage of garnet–omphacite–edenitic amphibole ± zoisite ± biotite–quartz–rutile–apatite–sulphide ± carbonate. Retrograde recrystallisation has been extensive in some samples, largely due to development of amphibole–plagioclase symplectite from omphacite and amphibole kelyphite from garnet.

Electron microprobe analyses were obtained for cores and rims of minerals in five samples of garnet peridotite, seven of

garnet pyroxenite, and four of eclogite (summarised in Table 1). Fe^{3+} was determined by charge balance calculations and by wet chemical analyses of selected mineral separates.

Coarse-grained garnet, clinopyroxene, and orthopyroxene in garnet peridotite and pyroxenite are compositionally zoned; from core to rim there is an increase in Fe and decrease in Mg in garnet, a slight decrease in Al and Cr in orthopyroxene, and a decrease in Al, Cr, and Na in clinopyroxene. Compositional zoning in eclogite garnet is opposite to that in peridotite and pyroxenite, that is, a decrease in Fe and increase in Mg from core to rim. Zoning in eclogite clinopyroxene is slight, there being a small increase in Al and decrease in Ca from core to rim.

Due to compositional zoning $K_{\mathrm{D\,gar/cpx}}^{\mathrm{Fe/Mg}}$ increases from cores to rims in peridotite and pyroxenite, reflecting a decrease in temperature during mineral growth, whereas $K_{\mathrm{D\,gar/cpx}}^{\mathrm{Fe/Mg}}$ decreases from cores to rims in eclogite, indicating an increase in temperature.

Estimates of equilibration temperatures for core and rim compositions of coarse-grained minerals in garnet, peridotite and pyroxenite have been obtained from geothermometers based on Fe-Mg partitioning among garnet, orthopyroxene, clinopyroxene, and olivine[16,17] and on the pyroxene miscibility gap[18]. In Fig. 2 temperatures based on $K_{\mathrm{D\,gar/cpx}}^{\mathrm{Fe/Mg}}$ have been selected because this is the most sensitive of the various geothermometers in the temperature range of interest. Pressures of equilibration have been calculated according to Wood's[19] procedure, based on the Al content of orthopyroxene in equilibrium with garnet and incorporating all corrections for Cr and Fe^{3+}. Calculated values of pressure and temperature are consistently lower for rim compositions compared to core compositions in garnet peridotite and pyroxenite and reveal a clear trend of retrograde metamorphism from 820 °C, 28.1 kbar to 645 °C, 17.6 kbar, which lies within the stability field of garnet peridotite[20,21], but which penetrates the higher *P–T* portion of the prograde metamorphic trend for eclogites in this region established by Krogh[8] (Fig. 2). Although pressure estimates may be in error up to ±5 kbar[18] due to uncertainties in temperature estimates, extrapolation of high temperature experimental results to lower temperature conditions, and the effects of relatively high concentrations of Cr in garnet and pyroxenes, it seems most likely that the Lien garnet peridotite and pyroxenite equilibrated in response to decreasing pressures of the order of 25–20 kbar and certainly <30 kbar. The *P–T* estimates obtained in this study are in close agreement with those reported recently by Carswell and Gibb[11] for Norwegian crustal garnet lherzolites.

Neither orthopyroxene, phengite, nor primary plagioclase occur in eclogites close to the Lien peridotite, and consequently, only minimum estimates of equilibration temperatures and pressures can be made[22]. Core and rim compositions of adjacent garnet and omphacite grains in four eclogite samples define a prograde metamorphic trend (Fig. 2), based on experimental calibration of Fe-Mg partitioning between garnet and clinopyroxene in basic rocks[22,23] and the jadeite content of omphacite[24]. Considering that only minimum pressure estimates can be made for these samples, their metamorphic pattern is consistent with that for other eclogites in the region. Furthermore, values for $K_{\mathrm{D\,gar/cpx}}^{\mathrm{Fe/Mg}}$ in the four eclogite samples (5.2, 8.0, 9.9, and 10.7) are compatible with values (5.5–9.5) which would be expected in basic rocks recrystallised in the same *P–T* conditions as those for the Lien garnet peridotite and pyroxenite.

This investigation supports a dual origin for eclogite and garnet-bearing ultramafic rocks at Lien, eclogite having developed by *in situ* metamorphism of crustal materials and ultramafic rocks having been derived from the upper mantle. Such an interpretation was proposed previously by Bryhni *et al.*[10] and Carswell[9] and subsequently supported by Brueckner's[25] strontium isotope analyses of clinopyroxene from eclogite and garnet-bearing ultramafic rocks. The metamorphic trends for eclogite and ultramafic rocks suggest that eclogite facies metamorphism of the ultramafic rocks may have begun in the upper mantle and then continued at progressively decreasing temperatures and pressures as the ultramafic rocks were emplaced in continental crust at depths of 60–70 km and that eclogite and garnet peridotite and pyroxenite have shared in the same metamorphic episode.

This investigation and published isotopic data indicate the following three-stage evolution of the Lien peridotite: (1) emplacement of mantle-derived garnet-bearing ultramafic rocks into a deep crustal environment and convergent metamorphism with eclogite 1,850 Myr ago[26]; (2) extensive recrystallisation of the Lien peridotite and surrounding gneisses in amphibolite facies conditions 1,150 Myr ago[27]; and (3) isotopic re-equilibration of the gneisses and development of hydrous fracture and contact mineral assemblages in peridotite during the Caledonian Orogeny[27,28].

Financial support for this project was provided by the Graduate School of the University of Wisconsin, and by the G. Unger Vetlesen Foundation, administered by Norges Teknisk-Naturvitenskapelige Forskningsrad. I thank W. L. Griffin and E. J. Krogh for advice and encouragement, the staff at the Mineralogisk-Geologisk Museum in Oslo, where this investigation was carried out, and W. L. Griffin, E. J. Krogh, B. W. Evans and D. A. Carswell for helpful comments.

Size constancy fails below half a degree

John Ross*, B. Jenkins* & J. R. Johnstone†

Department of Psychology* and Department of Physiology†, University of Western Australia, Nedlands, Western Australia, 6009, Australia

Size constancy is a term used to refer to the fact that objects seem to maintain size as their distance from an observer changes, despite change in image size. it is known that size constancy has limits[1,2]. People seen from the top of tall buildings look small. By observing objects, including the Moon, and after-images, we demonstrate here that size constancy holds when image size is above half a degree, and breaks down when it is less. In other words, image size is scaled for distance only when image size is above half a degree.

The primary evidence for size constancy is negative: objects do not seem to change in size with change in their image size. An immediate experimental difficulty is that observers can judge both object size and image size separately. An observer who is asked if an object seems to change size as it moves away from him may reply 'yes', meaning, not that the object changes in apparent size, but that it covers a smaller patch of the visual field. For this reason, measurements obtained from naive subjects are particularly suspect in the field of size constancy. It is safer, therefore, to rely on observations that the reader can make and repeat himself, rather than what was said by experimental subjects, who may well have been confused about what was asked of them.

It may readily be observed, without the aid of instruments, that large objects begin to look small when their image size reduces to half a degree, or less. A convenient reference is the fingernail of the index finger, which subtends about a degree with the arm fully extended. People seen in the distance seem doll-like[2] when their image size is less than half the size of the image of the fingernail. Aeroplanes, after taking off, maintain object size and then, at a certain point, look small. The change occurs when image size shrinks to half a degree. Similarly, motor cars, lorries, trains and houses, seen from the air, look small, like toys, when their images subtend less than half a degree. As a plane comes in to land a passenger may observe the sudden transition from small to large occurring for each object as its image size breaks the half a degree barrier. Many other examples will be noticed by the reader as soon as he is alerted to half a degree as the critical image size, and learns to measure image size with his fingernail. The situation is less clear with smaller objects, although to the authors, household and laboratory objects look to have diminished in size at a distance at which each first subtends less than half a degree.

The proposition that size scaling holds only when image size is above half a degree may be tested by changing apparent distance while holding image size constant. One convenient method of so doing is to form an after-image, and observe it as projected on to surfaces at different distances. Emmert's law[3] states that the apparent size of an after-image varies directly with the perceived distance of the surface on which it is projected. We have observed that Emmert's law breaks down when after-image size is less than half a degree. An after-image does not seem to change size with the distance of the surface on which it is projected when it is below the critical size of half a degree. The reader is urged to verify this observation, which he can do conveniently by observing the after-image formed by a flashgun, from a distance at which it subtends half a degree or less.

An alternative way of demonstrating this to a large group of people, which we have used several times, is as follows. A flashgun is so positioned that it subtends more than half a degree to roughly half the group, and less to the other half. All are asked to observe the after-image on the palm of the hand and then on a side wall of the room. They are then asked to raise their hands if the image seemed to change in size when transferred from the near to the far surface. With high probability, subjects w images above half a degree (those in the front of the room) raise their hands and subjects with images below half a degree (those in the back of the room) do not, despite the fact that they can see raised hands in front of them. Results are well beyond chance levels, so much so that the experiment may be used as a classroom demonstration of Emmert's law and of its boundary condition.

The Moon is of interest in this connection, because it subtends almost exactly half a degree, whatever its position in the sky, and because it seems large at the horizon and small when high in the sky. Variation in apparent distance is the most probable cause[4] of the Moon's variation in apparent size. According to the hypothesis that size scaling occurs at half a degree and above, but not below, the illusion of change in the Moon's size should be abolished by reducing the size of image. This can be done optically. The full Moon was observed in a clear sky at Easter, 1978 (and subsequently) through a positive lens close to the eye, and a negative lens further away (reversed galilean telescope), both contained in a tube and so positioned that the Moon's image was reduced by about one-third, to 20 arc min. The horizon Moon seemed to diminish by much more than a third in diameter, by a factor of two or three. The zenith Moon, when it was observed, seemed to diminish by only the expected one-third, like terrestrial objects whose distance can be judged by eye. Furthermore, the zenith Moon, when reduced, seemed to be of the same size as the horizon Moon, when it was reduced. These effects are not due to observing through a tube. The horizon Moon seemed much larger than the zenith Moon when both were observed through a tube containing no lenses. It may be relevant that, of all Jupiter's moons, only one, Io, subtends a visual angle near half a degree at Jupiter's surface. Thus, only Io should seem to change size to an observer on Jupiter.

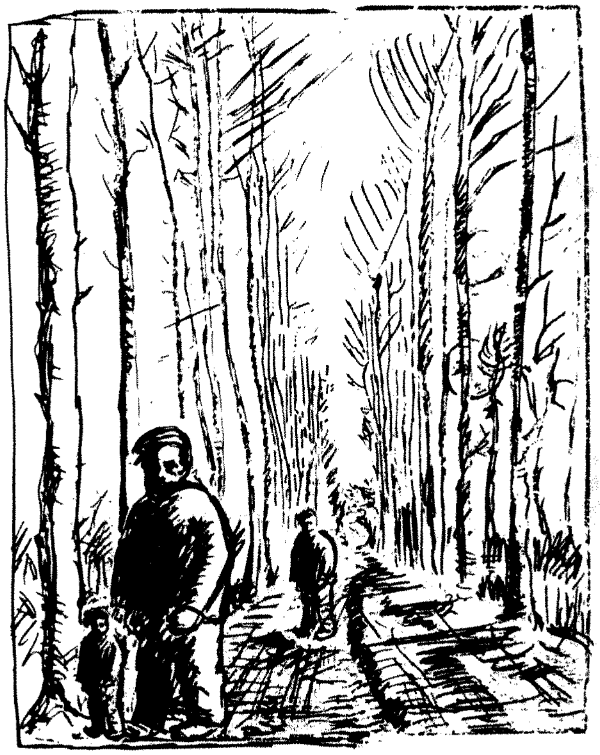

Fig. 1 Because the figure in the background seems more distant than the small figure in the left foreground, its size seems larger when the page is at normal reading distance. At this distance both figures subtend more than 30 arc min in the vertical. At a greater distance, when both subtend less than 30 arc min, the two seem to be the same size. The head of the large figure also looks smaller than the Moon, which can be seen on the right of the picture. The head and Moon also seem the same size when they subtend 30 arc min or less. As the observer moves back from the picture, this critical image size is reached earlier for the Moon and the head than it is for the two smaller figures.

0028–0836/80/050473—02$01.00

xample of the fact that image size is critical is Fig. 1. Three men are depicted (after Van Gogh), the same size. Perspective makes the one in the ground seem further away, and larger at normal reading distance. However, when the page is removed to a distance (about 3 m) at which both figures subtend 20 arc min, they seem the same size.

There may be some significance in the fact that size constancy breaks down at half a degree. It has been proposed[5,6] that there are no size tuned channels in the low frequency range, but instead a single mechanism sensitive to luminance gradients: above the peak of the contrast sensitivity function there is harmonic analysis and below it contrast gradient analysis. The hypothesis may therefore be advanced that large and small retinal images are calibrated in different ways, the large being subject to automatic size correction to take account of distance, and the small giving absolute size information, which is not corrected for distance.

A dorso-ventral shift of embryonic primordia in a new maternal-effect mutant of *Drosophila*

Mutations altering the spatial pattern of embryonic primordia are valuable tools for studying the earliest steps of embryonic pattern formation. As the spatial organisation of the egg cell arises during oogenesis, such mutants are likely to affect the embryo via the maternal genome (maternal effect). In *Drosophila*, most maternal-effect mutants studied so far lead to early developmental arrest. A few others yield pattern defects apparently linked to local failure of blastodermal cellularisation rather than to abnormal arrangement of primordia or ooplasmic determinants[1,2]. A small number of mutants, however, are known in which the embryonic fate map is affected, for example, *bicaudal*[3,4], which profoundly alters the antero-posterior pattern of embryonic organisation. The *bicaudal* phenotypes suggest that the mutation causes a perturbation of a morphogen gradient that defines the antero-posterior coordinate in early embryonic pattern formation[5,6]. A new maternal-effect mutant, *dorsal*, seems to exert a similar influence on the dorso-ventral coordinate for patterning[6]. *Dorsal* (*dl*) has both a recessive and a dominant maternal-effect phenotype. The *dl* recessive phenotype is marked by an apparently complete lack of dorso-ventral polarity from early embryogenesis onward[6]. The *dl* dominant (dl^{D}) phenotype, which we report on here, is temperature sensitive: at 22 °C, *dl*/+ females lay eggs which develop normally while eggs produced at high temperature (29 °C) yield abnormal larvae which fail to hatch. These mutant dl^{D} larvae vary in phenotype but nearly always lack muscles and frequently part of the ventral hypoderm. They are defective in structures that arise from the ventral region of the blastoderm in normal embryogenesis[6,7] (Fig. 1).

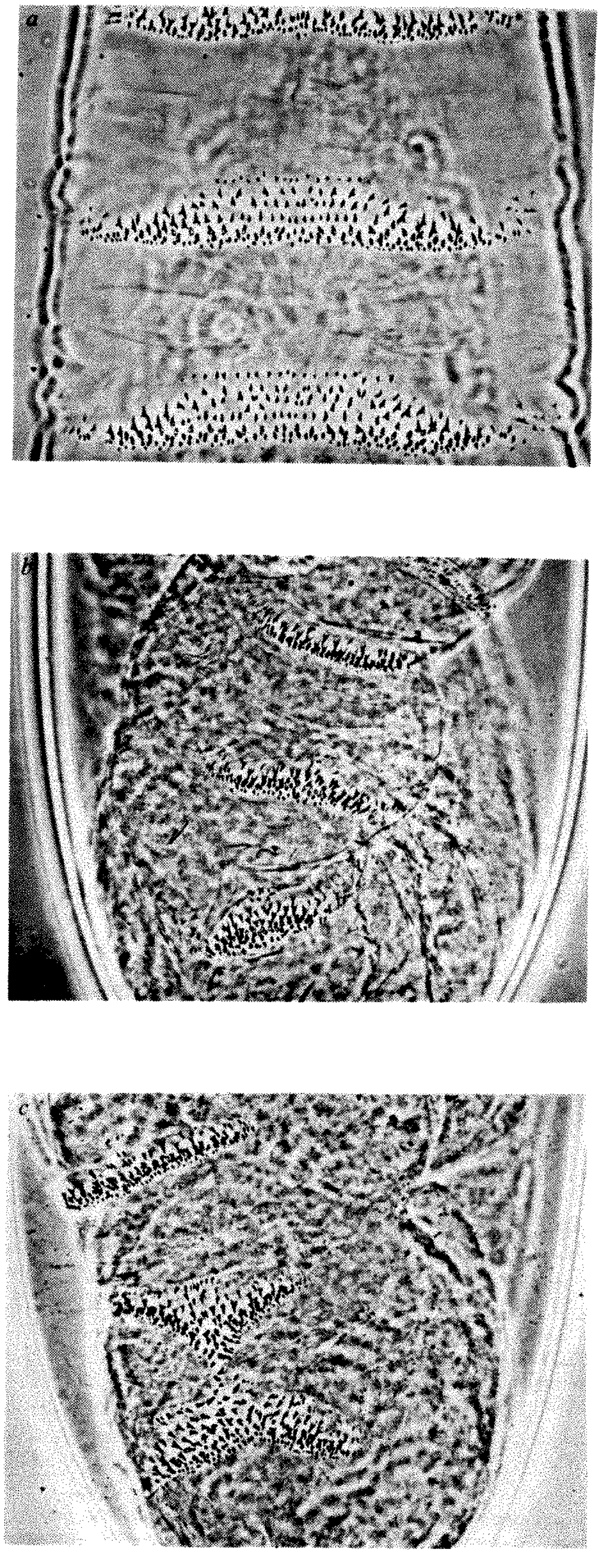

Fig. 1 Ventral hypoderm from the abdomen of wild-type and mutant larvae. *a*, Larva shortly after hatching; *b*, *c*, dl^{D} larvae produced by *dl*/+females at 29 °C. The genotype of the females was *al dp b dl bic sp*/*vg*$^{\mathrm{D}}$ in all experiments. For the descriptions of genes see refs 6, 10. The expressivity of the dl^{D}-phenotype is dependent on the genetic background of the female and this particular genotype was chosen because it happened to produce weak and extreme phenotypes with approximately equal frequency, while less than 1% of the eggs hatch. Larvae were regarded as extreme mutant if they had a notably reduced width of the ventral denticle hook rows (*b*); they also always were twisted or coiled up in the egg case. The larva in *c* has been irradiated mid-ventrally at 40% egg length (0% = posterior pole) at the cellular blastoderm stage.

0028-0836/80/050474—03$01.00

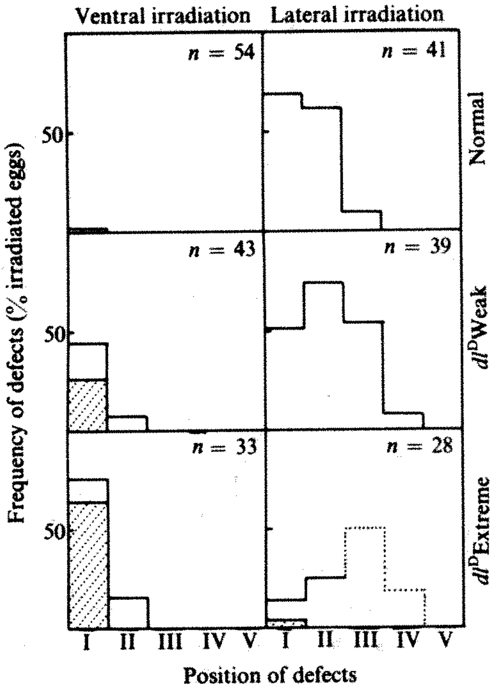

Fig. 2 Distribution of defects in the ventro-dorsal hypoderm pattern following UV-laser irradiation of wild-type and mutant eggs at the blastoderm stage. Eggs were collected from *dl*/+ females (*al dp b dl bic sp*/*vg*$^{\mathrm{D}}$) or +/+ (Oregon K) females at 29 °C or 25 °C respectively in 30-min intervals, aged until briefly before blastoderm formation, partly dechorionated and irradiated with a UV-laser microbeam (257 nm, 20 μm diameters, 7 erg) at the cellular blastoderm stage as described[9]. Ventral irradiations (left panels) were aimed at the ventral midline of eggs orientated with their ventral side facing the UV beam. For lateral irradiations, laterally orientated eggs were irradiated at 30% egg diameter measured from the ventral side (vd4 in ref. 9). These positions correspond to 0% or 36% half-circumference (0% = ventral midline, 100% = dorsal midline). All eggs were irradiated at 30% egg length (0% = posterior pole). This position was chosen because it creates defects predominantly in the posterior abdomen (centre of defect 5th abdominal segment), a region permitting optimal detection of defects also in extreme mutant larvae which often are twisted or coiled in the anterior abdominal and thoracic region. Irradiation at more anterior position (40% and 50% egg length) gave similar results (data not shown). Following irradiation, more than 90% of the eggs survived to the larval stage. The larvae and unhatched eggs were fixed and cleared and the cuticle examined for defects using phase contrast optics at ×400 magnification (Zeiss Neofluar). For quantitative evaluation of the location of the defects the ventro-dorsal cuticular pattern was divided into five sections[9] (I and II, ventral and lateral half of the ventral hypoderm; III, lateral hypoderm; IV and V, lateral and dorsal half of dorsal hypoderm, see ref. 9 for description of markers used). The frequency of defects per section was determined whereby defects spanning more than one section were counted separately for each section. Mutant larvae were regarded as extreme if the width of the ventral denticle belts was markedly reduced. Owing to a severe twisting of the hypoderm in extreme mutant larvae, the lateral and dorsal hypodermal region (sections III to IV) could sometimes not reliably be scored, the values indicated by stippled bars are therefore lower limits of the true defect frequency. The shaded bars indicate the frequency of bilateral defects, in which both right and left sides of the ventral hypoderm were affected simultaneously. No correction was made for spontaneous defects (<5% in both mutant and wild-type larvae), however, larvae with defects outside the abdominal segments A3–A7 (<5%) were disregarded in the calculations.

The absence of ventrally derived structures in dl^{D} embryos is not due to a failure of cell formation in ventral egg regions. The embryos develop an apparently normal cellular blastoderm. At gastrulation, the first deviation from normal development is observed: dl^{D} embryos fail to form the ventral invaginations which lead to the separation of the mesodermal and anterior endodermal anlagen from the ectoderm in normal development[6]. The defect of ventral structures could thus result from inability of the ventral cells to develop beyond blastoderm. Alternatively, the ventral cells could give rise to structures normally derived from more lateral egg regions, which would mean that the dorso-ventral fate map is affected by the mutation. To test this idea, we investigated the developmental fate of blastoderm cells in dl^{D} embryos. As a method for fate mapping, we used UV-laser induced local lesions.

We have previously shown that irradiating wild-type blastoderms with a UV-laser microbeam[8] frequently leads to localised cuticle defects in the ensuing larvae[9]. The position of the defects within the cuticle pattern depends rather strictly on the site of irradiation, indicating that the defects were created by damaging the respective anlage cells. We have used this correlation to construct a detailed fate map of the larval epidermis[9] (Fig. 3). The mid-ventral region (20% of the egg circumference) gives rise to mesoderm[7] and irradiation of this region very rarely induces cuticular defects. The larval hypoderm stems from the larger part of the blastoderm (76%); ventro-lateral and lateral irradiations create defects predominantly in the ventral hypoderm, while the dorsal hypoderm is frequently defective following dorso-lateral and dorsal irradiations.

When dl^{D} embryos are irradiated as blastoderms, the pattern of the ensuing defects is markedly changed (Fig. 2). Following mid-ventral irradiations, 79% (26/33) of the extreme mutant larvae show a defect in their ventral hypoderm while only 2% (1/54) of the control larvae do so. Larvae of a weak mutant phenotype give an intermediate value (20/43). Moreover, the majority of defects are bilateral defects, impairing right and left side of the ventral hypoderm simultaneously, while ventral hypodermal defects created in normal larvae are always restricted to one side, consistent with the separation of the right and left ventral anlagen by the mesodermal anlage. This result

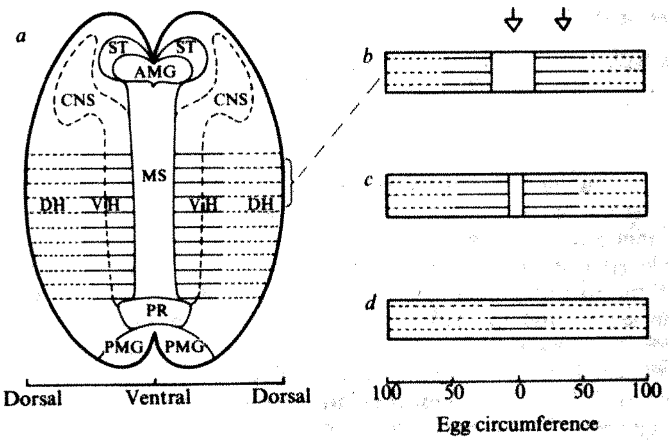

Fig. 3 Alteration of the embryonic fate map in *dl*-dominant embryos. *a*, Poulson's fate map[7] of the *Drosophila* egg cut open along the dorsal midline and spread out. Simplified and slightly modified[9,11]. The location of the segment borders in the larval hypoderm as determined from laser-induced lesions[9] are indicated by the transverse lines, dotted for the dorsal part of the segments. The serosal anlage is not indicated separately because it seems that at least part of it is later incorporated in the dorsal hypoderm. AMG, anterior midgut; PMG, posterior midgut; ST, stomodeum; CNS central nervous system; PR, proctodeum; MS, mesoderm; VH, ventral hypoderm; DH, dorsal hypoderm. *b–d*, Proposed alteration of the fate map in *dl*-dominant embryos; *b*, middle region of fate map in a normal embryo; *c*, in a dl^{D} embryo with weak; and *d*, with extreme mutant phenotype. The left and right anlage for the ventral hypoderm, flanking the mid-ventral mesodermal anlage, are shifted ventrally at the expense of the mesoderm anlage. The absence of anterior midgut and malpighian tubules (part of the posterior midgut[7]), in extreme mutant embryos suggests that the shift of lateral primordia towards the ventral midline also occurs at the anterior and posterior egg regions. The arrows indicate the sites of irradiation with respect to the egg circumference.

ventral cells which form mesoderm in normal instead form ventral hypoderm in dl^D embryos. iations indicate that not only the fate of ventral, lateral cells is affected in mutant embryos. Figure 2 shows that in contrast to the high defect frequency in control embryos (88%) relatively few dl^D embryos with extreme phenotype have defects in their ventral hypoderm (7/28), most of the defects being located in the dorso-lateral part of the hypoderm. This shift of defect location towards more dorsal positions in the hypodermal pattern is less pronounced in weak mutant phenotypes. Note that in both ventral and lateral irradiations, the antero-posterior positions of the defects are very similar in mutant and wild-type embryos and correspond to the site of irradiation.

The results suggest that the absence of ventral structures in dl^D embryos results from a change of the embryonic fate map: ventral cells form ventral hypoderm instead of mesoderm, while lateral cells form hypodermal structures that are normally derived from more dorsal positions. It seems that the lateral and dorsal anlagen are shifted towards the ventral midline at the expense of ventral anlagen. The degree of this shift parallels expressivity of the mutant phenotype. In extreme cases, it may be as much as 30% of the dorso-ventral coordinate as judged from the width of the remaining ventral hypoderm (Fig. 1) and by comparing the distribution of defects following lateral irradiations of extreme mutant larvae to that obtained in normal larvae by more dorsal irradiations[9]. The proposed alteration of the fate map is shown in Fig. 3.

We suggest that *dorsal*, rather than eliminating a localised determinant required for proper ventral development, affects a continuous property, such as a morphogenetic gradient, that defines the entire dorso-ventral coordinate of the developing embryo.

Intrinsic immunosuppressive activity of different trypanosome strains varies with parasite virulence

David L. Sacks*, Murray Selkirk, Bridget M. Ogilvie & Brigitte A. Askonas*

Divisions of Immunology* and Parasitology, National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7, UK

The virulence of African trypanosomes varies greatly with the host and parasite strain combinations used[1]. In mice, infections range from those which are rapidly fatal to those which more closely resemble the chronic disease patterns seen in man and domestic cattle[2]. The basis of trypanosome virulence is assumed to be related to intrinsic parasite replication rate and the effectiveness of the host's immune response to successive waves of parasites which differ in their surface antigens. Continued control of each emergent population requires sustained immune vigilance. Thus, the generalised immunodepression which accompanies African trypanosomiasis in man[3], cattle[4] and experimental animals[5,6] would be expected to determine the fatal outcome of most untreated infections if the secondary immunodeficiency extends to responses against the parasite as well as to unrelated antigens. Virulence, in this view, could be explained by the rapidity and intensity with which a given strain of trypanosomes induces immunodepression in a given host. We have attempted to define the relationship between parasite virulence and generalised immunodepression by examining the intrinsic potential of trypanosome strains of differing virulence to induce immunodepression in the same murine host. Following the observation that kiled trypanosomes or their subcellular membrane fractions mimic the immunological consequences of active infection *in vivo*[7], it has now become possible to compare the immunosuppressive potential of acute and chronic strains by using active fractions derived from identical numbers of killed organisms. We conclude from these comparisons that trypanosome strains can have inherently different immunosuppressive activities, and that the extent to which IgM responses, in particular, are suppressed correlates with and suggests a basis for parasite virulence.

The parasitaemia profiles of four clones from three strains of *Trypanosoma brucei brucei* (see Fig. 1 legend) ranging in virulence from acute (NIM 9) to subacute (NIM 2 and 6) and chronic (NIM 7), are presented in Fig. 1. The association of fluctuating parasitaemias with the emergence of antigenically distinct parasites has already been described for clones NIM 2 and 6 (ref. 2) and for the chronic strain from which clone NIM 7 is derived[8]. Taken as a whole, the greater the level of initial parasitaemia, the shorter the survival time of the infected mice. In addition, the prepatent period, that is, the time from inoculation until first detectable blood parasitaemia, was shortest for clone NIM 9, for which even the initial parasitaemia was uncontrolled. The subacute and chronic clones each had indistinguishable prepatent periods of between 3 and 4 d, suggesting that their intrinsic replication rates were similar. This was confirmed by infection of irradiated mice in which no significant difference was observed between growth rates of NIM 2, 6 or 7 parasites in either blood or tissues (data not shown). Growth of clone NIM 9 was, as expected, significantly more rapid than that of the other clones in irradiated animals.

Membrane fractions derived from carefully determined numbers of organisms of each clone were prepared and injected into mice 4 d before priming with sheep red blood cells (SRBC). A large proportion of trypanosome material is routinely lost during the fractionation procedures. However, the final membrane yield was comparable between each of the four clones; reproducibly, 20–30 μg protein was derived from 10^7 trypanosomes. The comparative suppressive effect of each fraction on the direct and indirect anti-SRBC plaque-forming cell (PFC) response is shown in Fig. 2. IgG response, measured by indirect PFC, seemed to be extremely sensitive to the effects of all four clones. Membrane fractions derived from 10^8 parasites of each of the four clones inhibited up to 98% of the normal 1gG response. Fractions from 10^7 parasites were slightly less immunosuppressive, but the degree of suppression was still the same for all four clones. However, at this same dose, we were able to detect a strict hierarchy with respect to inhibition of IgM responses measured by direct PFC. The pattern of IgM suppression induced by the membrane fractions was directly correlated with the virulence of the trypanosome strains from which they had been derived. At a log higher dose, the acute and subacute clones each had potent suppressive effects (70–80%), whereas the inhibitory activity of the chronic strain remained significantly lower (35%).

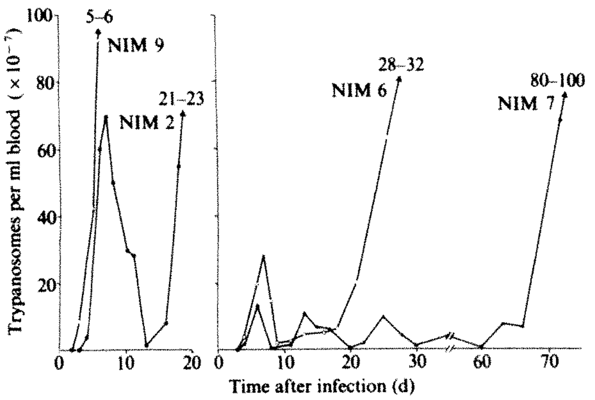

Fig. 1 Course of infection with four clones of *T.b. brucei* in (CBA/H$\times$C57BL/6)F_1 female mice, and survival times. Each point represents the mean parasitaemia of five or six mice, except for NIM 7, which represents the parasitaemia of a representative individual mouse. Trypanosome passage and cloning, and infection of mice with 200 parasites, were as described previously[12]. Clones NIM 2 and NIM 6 are non-cross-reacting variant clones, both derived from primary isolate Serengeti/66/SVRP/42 (ref. 2), previously referred to as strain S42. Clone NIM 7 is derived from primary isolate Uganda/66/EVE/10, and NIM 9 is derived from primary isolate Uganda/60/EATRO/217. The nomenclature follows that recently proposed for the reference of salivarian trypanosomes[13]. Parasitaemias were followed by examination of wet tail blood films under high power and counts converted to trypanosomes per ml as previously described[12].

The comparative suppression induced during active infection is summarised in Table 1. When mice were infected with 200 parasites of clones NIM 2, NIM 6 or NIM 7 and challenged with SRBC 10 d later, the IgG antibody response was completely inhibited regardless of the relative virulence of the infecting clone. The suppression of IgM antibody was virtually complete (background levels) for those clones which led to uncontrolled parasitaemia soon after day 10. Only the IgM response of the chronically infected mice, which continued to control parasitaemia for up to 80 d, survived at least partially intact (17% of normal response).

Although these data are concerned with the effects of trypanosomes on the response to an unrelated antigen, a similar pattern of suppression of the response to the parasite itself is suggested by the findings that the intrinsic differences between *T. brucei* clones in suppressing primary immune responses, particularly IgM responses, correlate well with trypanosome virulence, and the extent of IgM suppression induced during infection correlates with the control of parasitaemia and the pattern of infection in that host.

Whereas IgG responses are readily and comparably eliminated by active fractions of all four clones regardless of virulence, IgM responses are less susceptible to inhibition, and the degree of suppression varies directly with parasite virulence. In infected mice, our results and those of Hudson and Terry[8] essentially reflect these suppression patterns; thus, heterologous IgG responses are rapidly eliminated during both acute and chronic infections, whereas residual IgM responses persist during chronic infections in association with continued control of parasitaemia. These findings suggest that control of circulating trypanosomes can be achieved in the absence of IgG antibody by low levels of IgM. There is direct evidence to support this view. The control of blood parasites by nude mice occurs without detectable levels of IgG antibody[9], and very low concentrations of IgM antibody have been shown to protect mice passively against infection with *Trypanosoma gambiense*[10]. Thus, the residual immunity, however slight, seems to have as great a bearing on the outcome of infection as does the profound immunosuppression. This point may be relevant to the wide spectrum of infectious diseases for which immunodepression has been described.

A relationship between variable antigenic type and panosome virulence was first proposed by McNeillage and Herbert[11]. In the present study, although clones NIM 2 and 6 are antigenic variants or subclones derived from a common strain, they differ slightly with respect to both virulence and immunosuppressive activity. The possibility that the variant antigens are themselves responsible for the suppression is now being investigated.

Apart from the intrinsic suppressor activities of *T. brucei* strains, the level of parasitaemia (suppressor dose) undoubtedly contributes to the overall pattern of secondary immunodeficiency. This and previous studies[2] have generally noted an inverse relationship between the survival time and parasite load during the first peak of parasitaemia. However, the level of initial parasitaemia may itself reflect the degree of suppression induced by trypanosome growth early in infection. This is only true for those clones which have comparable replication rates (for example, NIM 2, 6 and 7), which must therefore establish different levels of growth as a consequence of host immune parameters.

Antigenic variation seems to be the principal mechanism whereby the survival of African trypanosomes is prolonged in the host. Depression of anti-trypanosome responses might be required to prevent rapid, complete elimination of the parasite before antigenic variants are expressed. On the other hand, at least partial responsiveness is required to prevent one variant from growing in an uncontrolled fashion, a condition which would also preclude expression of future variants. If the goal is an overall, non-qualitative depression of responsiveness to a residual level, then IgG responses could be affected first because they are more susceptible to general mechanisms of suppression,

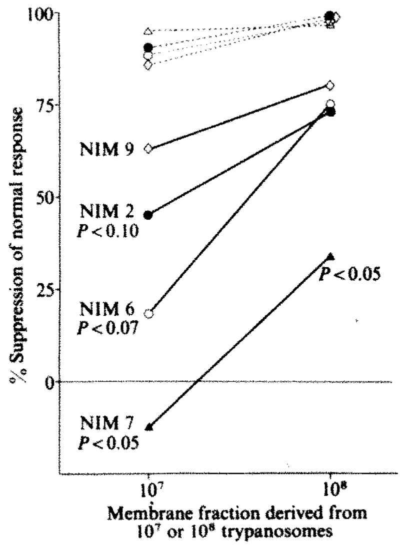

Fig. 2 Comparative suppression of SRBC response by membrane fractions derived from four clones of *T.b. brucei*. Crude membrane fractions from 10^8 or 10^7 trypanosomes were prepared as previously described[8]. Briefly, freeze-thawed homogenates of each clone were spun at 12,000g to remove nuclei, kinetoplasts and large debris. Membrane fractions were collected by high speed centrifugation (150,000g for 90 min), suspended in phosphate-buffered saline and injected intraperitoneally into (CBA/H$\times$C57BL/6)F_1 female mice. Mice were primed 4 d later with 4×10^7 SRBC, and the direct and indirect anti-SRBC response assayed 6 d after priming by the slide modification of the Jerne technique[14]. Each point is the arithmetic mean (five mice per group) of the per cent suppression of the normal response. ——, Direct (IgM) PFC; - - - - - -, indirect PFC developed using a rabbit antiserum specific for mouse IgG. P values were ascertained by Student's t-test for comparison of each mean value with the corresponding next greater mean. Statistic is omitted when no significant difference between the respective mean values was found.

477

n of immune response to SRBC after infection with different clones of *T.b. brucei*

no.	clone	Direct PFC	% Normal	Indirect PFC	% Normal
1	—	53,000 ± 8,400		169,000 ± 25,000	
	NIM 6	1,200 ± 2,100*	2	<500	<1
	NIM 2	900 ± 1,300*	1	< 500	<1
2	—	84,000 ± 10,400		143,000 ± 33,000	
	NIM 7	14,200 ± 5,100	17	600 ± 420	<1

Mice were infected with 200 parasites and primed with 4×10^7 SRBC 10 d later. Assay of direct PFC on day 4 and indirect PFC on day 6 were as in Fig. 2; values represent the arithmetic mean ± s.d.; four to five mice per group.

* Value not significantly different from background PFC of unprimed, infected mice.

including disturbances in lymphoid function at the level of B and T cells and macrophages. Alternatively, selective inhibition of IgG as opposed to IgM responses might be purposeful and advantageous to parasite survival. Terry has suggested that although IgM antibody is effective in the control of circulating trypanosomes, it is less effective than IgG classes in reaching tissue parasites from which antigenic variants are thought to arise[1]. The present data are strikingly consistent with this interpretation. Complete suppression of IgG responses and only partial suppression of IgM seems to ensure chronicity of infection, and the intrinsic differences between *T. brucei* clones in suppressing IgM responses seem to form a basis for parasite virulence.

Biochemical basis for the continuous copulation of female *Schistosoma mansoni*

Kristine H. Atkinson & Burr G. Atkinson

Department of Zoology, University of Western Ontario, London, Ontario, Canada N6A 5B7

Sexual dimorphism in blood flukes of the family Schistosomatidae is marked, and until the male clasps the female in the gynaecophoric canal the female cannot attain sexual maturity[1] or migrate out of the liver[2]. When previously-paired egg-producing females are transferred to a new host without males, the vitelline cells necessary for egg production degenerate[3]. By means of sensitive fluorographic analysis of electrophoresed polypeptides, we have now found molecular evidence of an obligatory continuous relationship between the sexes in *Schistosoma mansoni*. The male worm retains little of the protein it produces in greatest abundance, and this protein is electrophoretically identical to the most abundant protein found in, but not synthesised by, the female.

To detect which proteins were actually produced by the worms, *S. mansoni* of the NIH strain were perfused from C57BL/6B mice at 70 days post-infection, mechanically separated according to sex, and incubated for 24 h in medium HB597 (Connaught) with 10% fetal calf serum and 8 μCi ml^{-1} ^{14}C-leucine (Specific activity 339 mCi mmol^{-1}; NEN). The worms were washed in saline and homogenised in 2% SDS and 5% β-mercaptoethanol in 80 mM Tris-HCl (*p*H 6.8), heated at 100 °C for 1 min, cooled and precipitated with 20% trichloroacetic acid (TCA). After centrifugation at 5,000 *g* for 10 min, the pellets were washed twice with cold 5% TCA, heated in 5% TCA at 90 °C for 15 min, washed with ethanol/ether (2:1) saturated with sodium acetate, washed in ether and dried overnight *in vacuo*. The dried protein precipitates were resolubilised in the homogenising solution, the protein determined by TCA-turbidity[4] and radioactivity measured in a Beckman LS-255 liquid scintillation counter. Vertical SDS-polyacrylamide slab gels were prepared by the method of Laemmli[5], and known amounts of radioactivity or protein were added to each well. Standards of known molecular weight (MW), mouse serum and proteins of the *in vitro* culture medium were co-electrophoresed. After photography of the Coomassie blue staining patterns, the gels were prepared for fluorography[6,7], wherein the dried gel containing isotope-labelled peptides is apposed to pre-flashed Kodak X-Omat R X-ray film and exposed at −70 °C. Only newly synthesised polypeptides having incorporated radioactive leucine from the *in vitro* medium show up as bands in the fluorogram. The procedure was also carried out with a strain of *S. mansoni* inbred in the laboratory of R. B. Short (Florida State University), grown in a white mouse host. The results were virtually identical, with only very minor quantitative differences perceivable in both staining and fluorograms. Protein similarity among *S. mansoni* strains was also found immunoelectrophoretically by Capron *et al.*[8].

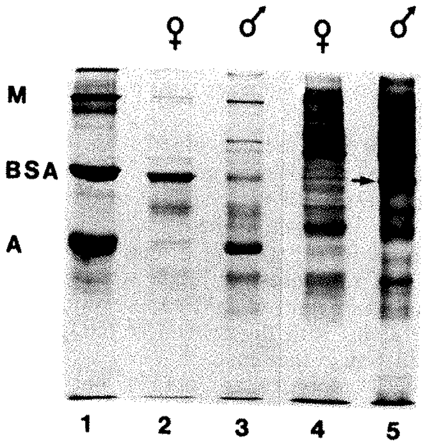

Fig. 1 SDS–8% polyacrylamide gel electrophoretic patterns of the polypeptides of adult male and female *Schistosoma mansoni*. In lane 1 of this composite photograph of a single gel, standard purified polypeptides are stained with Coomassie blue. M = myosin heavy chain, MW 200,000; α = α-actinin, 105,000 MW: BSA = bovine serum albumin, 58,000 MW; A = actin, 43,000 MW; T = tropomyosin, 31,000 MW. The stained patterns of the female (lane 2) and male (lane 3) reveal a high degree of identity, but a prominent band in the female is evident at about 66,000 MW. As equal amounts of protein were placed in these wells, this is evidently a striking quantitative difference in comparison with the faint band in the male. Lanes 4 and 5 are photographs of the fluorograms exposed by the same samples shown stained in lanes 2 and 3. Equal amounts of radioactivity were placed in the wells, and these autoradiographs show which proteins were synthesised by isolated worms *in vitro*. That the females do not produce their most prominent stained band is striking. The males, on the other band, actively produce a polypeptide at this MW of which they have only small quantities, as seen stained in lane 3.

0028–0836/80/050478—02$01.00

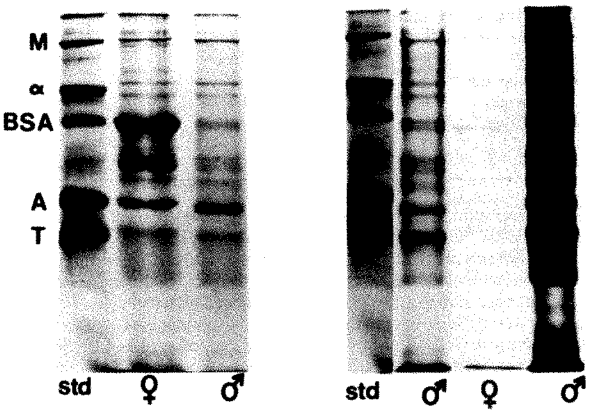

Fig. 2 SDS – 10% polyacrylamide gel electrophoretic patterns of unlabelled female *S. mansoni* after remaining *in copula* with labelled males for 20 h. On the left are the Coomassie blue staining patterns of the samples shown in the three fluorograms of the composite picture on the right (the standards are a stained preparation). The male and female samples on the far right are a comparison exposure to show the low radioactivity profile of the females; the male fluorographic pattern next to the standard was prepared with a shorter exposure. The 66,000-MW protein is picked up by the female in greater amounts than any other. The other proteins supplied to the female by the male mirror his most actively synthesised proteins. Prolonged exposure of the female samples suggested a quantitative synthetic pattern typical of the male. (Abbreviations as in Fig. 1.)

Figure 1 is a composite of the Coomassie blue patterns and fluorograms of the total proteins of male and female *S. mansoni*. In the female, the heavily stained band with a mobility slightly faster than that of bovine serum albumin (BSA) is outstanding. Its absence in the fluorogram of the same gel means that this protein could not have been synthesised by the female. Two-dimensional electrophoretic analysis of this protein indicates that its MW and isoelectric point do not match any of the proteins found in the culture medium or the mouse serum, and so this does not represent a 'captured' protein.

The absence of a major protein synthesised uniquely by mature females was at first disappointing, as it was expected that the commitment to egg and vitelline cell production would be reflected in the proteins produced. However, quantitative differences in the amount of a protein produced by the male (arrow, Fig. 1) but found in relatively low amounts (revealed by the staining pattern) compared with the female pointed to the transport of this substance transtegumentally between the sexes. The fact that the female is almost entirely enveloped by the male tegument and that the male gynaecophoric canal has a modified surface[9] supported this view.

To characterise further the nature of the 66,000-MW protein in question, the experiment was repeated with males labelled for 24 h, then rinsed and mated to unlabelled females for 20 h. Figure 2 depicts the fluorogram developed after electrophoresis of the polypeptides of the females following removal of the males and three washes with fresh medium. Transfer of the labelled polypeptide from the male to the female within 20 h was significant; the females also picked up some minor common polypeptides. No radioactivity was detectable in the TCA-soluble fractions from the homogenised females, indicating the absence of free ^{14}C-leucine. The medium in which the mated worms had been incubated contained negligible amounts of radioactivity (<30 c.p.m. μl^{-1}), so it is very unlikely after the thorough rinsing that the labelled polypeptides revealed in the fluorogram were a result of passive transfer. The concept of direct transtegumental transport between the sexes is supported by the studies of Shaw *et al.*[10], who found that the vitelline cells of immature females were stimulated to develop by extracts of whole male worms, but not by the medium in which the males were cultured. It is unlikely that the protein is transferred with sperm, as in butterflies[11], because the seminal receptacle is o about 0.1% of the female's volume, whereas the 66,000-M band is about one-tenth of her total stained protein.

Our subsequent work with two-dimensional electrophoresis and fluorographic analysis (manuscript in preparation) has shown that this protein represents the major difference between the male and female in terms of their acid-precipitable proteins. Ruppel and Cioli[12] have published a polyacrylamide gel electrophoresis staining pattern with similar results, although they do not discuss this protein with a mobility slightly faster than BSA.

The absence of parthenogenesis in the genus *Schistosoma* (except for *Schistosoma mattheei*[13]) seems predictable in the light of this molecular symbiosis maintained by the sexes for the production of offspring. A cure for schistosomiasis may consist of finding a method of keeping the sexes unpaired.

This research was sponsored by a grant-in-aid from the Society of the Sigma Xi to K.H.A., with matching funds from the Faculty of Science, University of Western Ontario. We thank Dr T. K. R. Bourns for use of the laboratory.

The *in vitro* transmission frequency of the t^6 allele

James McGrath & Nina Hillman

Department of Biology, Temple University, Philadelphia,
Pennsylvania 19122

The *T* region, located on chromosome 17 in the mouse, is a complex genetic locus which includes a series of recessive mutations, t^n (refs 1, 2). These mutations include several alleles (also referred to as *t*-haplotypes[2]) which are embryonic lethals (t^L). An additional phenotypic expression of the recessive lethal mutations is a distorted transmission of the *t* allele by the heterozygous male parent. Most T/t^L and $+/t^L$ males transmit the recessive mutation to over 50% of their offspring. Two conditions are known to modify significantly the transmission frequency of some t^L alleles: the length of time between insemination and fertilisation[3–5] and the genetic background of the female[6]. The present studies were undertaken to determine if the distorted transmission frequency of one of the lethal alleles, t^6, could be reproduced *in vitro*. The data show that the *in vitro* transmission frequency of the t^6 mutation is non-mendelian and is not significantly different from the frequency of transmission of this mutation following *in vivo* delayed matings. The *in vitro* frequency is, however, significantly lower than the normal mating frequency and does not vary as a function of incubation time. These data suggest that the observed delayed and normal mating frequency differences result from time-dependent interactions between the t^6-bearing spermatozoon and the female reproductive tract.

1 Normal and delayed transmission frequencies of the t^6 allele determined by the *in vitro* culture of one-cell embryos fertilised *in vivo*

	Control cross $T/+$♀ × $+/t^6$♂		Experimental cross $+/t^6$♀ × $+/t^6$♂		
	No. of blastocyst outgrowths	No. of outgrowths with t^6/t^6 phenotype	No. of blastocyst outgrowths	No. of outgrowths with t^6/t^6 phenotype	Transmission frequency*
Normal mating	409	0	724	187	0.52
Delayed mating	281	0	481	58	0.24

(C57BL/6J♀ × T/t^6♂) F_1 females were injected intraperitoneally with pregnant mare serum gonadotropin (5 IU) followed 48 h later by an injection of human chorionic gonadotropin (HCG; 5 IU)[25]. The females were caged with $+/t^6$ [(BALB/c♀ × T/t^6♂)F_1] males and on the following day the pregnant females were killed by cervical dislocation. One-cell embryos were flushed from the extirpated oviducts and placed in modified Whitten's medium[8,26] (4 mg ml^{-1} bovine serum albumin, Miles; 75 μM Na_2EDTA) under silicone oil (Dow Corning 200 Fluid, 50 cSt viscosity). The silicone oil (equilibrated with modified Whitten's medium, 7:1 v/v) and modified Whitten's medium were gassed with 5% O_2, 5% CO_2 and 90% N_2 before use. For the first two cleavage divisions the embryos were cultured in a sealed anaerobic jar (Torbal) which had been gassed for 20 min with 5% O_2, 5% CO_2 and 90% N_2. At the four-cell stage the dishes containing the embryos were transferred to an incubator with a continuous gas flow of 5% CO_2 in air. Blastocyst-stage embryos were transferred to a 35 × 10 mm tissue culture dish (Falcon Plastics) containing 2 ml of modified Eagle's medium supplemented with 10% heat-inactivated (56°C, 30 min) fetal calf serum (GIBCO)[9]. The dishes were returned to the continuous gas flow incubator for an additional 4 days. Outgrowths were scored as mutant or non-mutant using a Zeiss inverted microscope equipped with phase contrast optics (×160) on days 8 and 9 post-fertilisation. Preimplantation development at normal mating times from the two-cell stage to the blastocyst stage for the control and experimental crosses was 456/486 (94%) and 814/872 (93%), respectively, and at delayed mating times 311/321 (97%) and 531/546 (97%), respectively. Outgrowth of the blastocysts at normal mating times for the control and experimental crosses was 409/447 (91%) and 724/798 (91%), respectively, and delayed mating times 281/310 (91%) and 481/528 (91%), respectively. Significant differences were computed using a χ^2 contingency test. For normal matings, females were caged with males immediately after the HCG injection. For delayed mating, females were caged with males 12 h after the HCG injection.

* Transmission frequency = 2 × (no. of t^6/t^6 outgrowths/total no. of outgrowths).

These studies were possible because: (1) ova from F_1 hybrid females fertilised either *in vitro*[7] or *in vivo*[8] can develop to the blastocyst stage when incubated in modified Krebs–Ringer medium; (2) these blastocysts will continue to develop ('outgrow') when placed in modified Eagle's medium[9]; (3) the outgrowths from t^6/t^6 uterine blastocyst embryos can be distinguished morphologically from their phenotypically wild-type littermates[10–12]; (4) the number of mutant outgrowths in these genetically mixed embryo populations is equivalent to the expected number based on the tested transmission frequency of the t^6 allele[11]. Mutant outgrowths developing *in vitro* from uterine blastocysts can be distinguished from their normal counterparts by the failure of their trophoblast cells to polyploidise and become giant and by a reduced viability of the inner cell mass cells. However, only the former criterion could be used in the present studies because outgrowths developing from ova fertilised *in vitro* may not contain an inner cell mass.

To ensure the development of embryos in culture following *in vitro* fertilisation, ova from hybrid females were used[13,14]. These females were obtained by crossing C57BL/6J females with T/t^6 males. The offspring from this cross are phenotypically distinguishable: $+/t^6$ females have tails of normal length whereas $T/+$ females are short-tailed. Ova from the $T/+$ females were used as the controls for the *in vitro* fertilisation studies.

Before using spermatozoa from $+/t^6$ males for *in vitro* inseminations, we tested the males for their transmission frequencies in normal and delayed matings with the hybrid $+/t^6$ females. Following normal matings, spermatozoa reside in the uterus for 6–7 h before ovulation and fertilisation. In delayed matings, fertilisation is initiated 1–2 h post-insemination[15]. After both normal and delayed matings, the fertilised one-cell embryos were removed from the female and placed in culture. Blastocyst outgrowths were scored to distinguish the t^6 homozygotes. Table 1 gives the percentage transmission of the t^6 allele from $+/t^6$ males following both normal and delayed matings with hybrid $+/t^6$ females. The data show that in normal

(C57BL/6J♀ × T/t^6♂)F_1 females were injected as described in Table 1 legend. At 12–13 h after the HCG injection the females were killed and their oviducts excised and placed in drops of modified Tyrode's medium[27] under silicone oil. The cumulus masses containing the ova were removed from the ampullary regions of the oviducts and twice transferred to fresh drops of medium (0.2 ml) under silicone oil. Spermatozoa were obtained from the cauda epididymides and vasa deferentia excised from (BALB/c♀ × T/t^6♂)F_1 males. The ducts, placed into 1 ml of modified Tyrode's medium under silicone oil, were minced and the spermatozoa allowed to disperse for 20 min. A 100-μl sample of the spermatozoan suspension was diluted approximately 1:3 with modified Tyrode's medium. A 10-μl aliquot of the diluted suspension was added to the 0.2-ml drops of medium containing the ova. Final spermatozoan concentrations ranged from 1.3 to 2.7 × 10^5 spermatozoa per ml. The insemination dishes were placed in an anaerobic jar and gassed for 20 min with 5% O_2, 5% CO_2 and 90% N_2 at 37 °C. The jar was subsequently sealed and the gametes were allowed to co-incubate for 6 h. After this 6-h period, the ova were removed and washed through four drops of modified Whitten's medium. Preparation of the fertilisation medium, culture medium, silicone oil and the culture of the embryos were as described in Table 1 legend. The procedures for *in vitro* fertilisation followed the protocol of Fraser and Drury[27] except that the sodium chloride concentration in the modified Tyrode's medium was reduced to 85.2 mM. Fertilisation, based on the number of one-cell ova that cleaved to the two-cell stage, averaged 86% (75–96% range). Preimplantation development from the two-cell stage to the blastocyst stage for the control and experimental crosses was 446/511 (87%) and 565/653 (87%), respectively. The number of blastocyst outgrowths/total number of blastocysts from the control and experimental crosses was 367/417 (88%) and 493/554 (89%), respectively.

* Individual males, before being used for the *in vitro* fertilisation experiments, were tested *in vivo* for their transmission frequencies at either normal or delayed mating times. The times at which the animals were mated and the subsequent culture of the one-cell embryos were as described in Table 1 legend.

† Transmission frequency = 2 × (no. of t^6/t^6 outgrowths/total no. of outgrowths).

‡ Number in parentheses refers to the number of outgrowths on which the *in vivo* transmission frequency value is based.

Females were injected so that recently ovulated oocytes were available at 0 and 6 h. The gametes were obtained from (C57BL/6J♀ × T/t^6♂)F_1 females and (BALB/c♀ × T/t^6♂)F_1 males as described in Table 2 legend. The 0-h data list the results from inseminations with diluted spermatozoan suspensions mixed with ova immediately after the 20-min dispersal period. During the 6-h *in vitro* incubation period the spermatozoa were maintained in 1 ml of modified Tyrode's medium at 37 °C in a gas phase of 5% O_2, 5% CO_2 and 90% N_2. An aliquot of the spermatozoan suspension was then freshly diluted and added to the second group of oocytes. Spermatozoan concentrations ranged from 2.1 to 4.3×10^5 spermatozoa per ml.

* Individual males, before being used for the *in vitro* fertilisation experiments, were tested *in vivo* for their transmission frequencies at either normal or delayed mating times. The times at which the animals were mated and the subsequent culture of the one-cell embryos were as described in Table 1 legend.

† Transmission frequency = 2 × (no. of t^6/t^6 outgrowths/total no. of outgrowths).

‡ Number in parentheses refers to the number of outgrowths on which the *in vivo* transmission frequency value is based.

matings the transmission frequency of the t^6 allele is mendelian (0.52) and that the transmission frequency of the t^6 allele is significantly reduced (0.24) if the matings are delayed until the time of ovulation ($\chi^2 = 33.0$; $P < 0.0001$). These findings support not only the earlier observation that the length of time between insemination and fertilisation affects the transmission frequency of the t^6 allele[16], but also the observation that the genotype of the female can modify the transmission frequency of certain t^L alleles. Males which are heterozygous for the t^6 allele typically transmit the allele at a frequency of greater than 70% in matings with BALB/c (ref. 17) and SWR/J (ref. 11) mice. This is significantly higher than the frequency of transmission of this allele in matings with either the hybrid females or C57BL/6J females. In the latter matings ($T/t^6 \times$ C57BL/6J), the transmission frequency (0.46) was determined from the number of normal-tailed offspring among the total number of progeny (1,070/2,333).

For the *in vitro* fertilisation studies, ova from hybrid $T/+$ and $+/t^6$ females were fertilised *in vitro* by spermatozoa from $+/t^6$ males. Aliquots of spermatozoa from the same male were used to fertilise oviducal ova from females of both genotypes. The results (Table 2) show that all the 367 outgrowths developing from fertilised $T/+$ ova developed normally and all exhibited the wild-type phenotype. Of the ova obtained from $+/t^6$ females and fertilised *in vitro*, 54 of the 493 outgrowths were phenotypically abnormal and were scored as homozygous mutant embryos. Thus, the transmission frequency of the t^6 allele *in vitro* is 0.22. This frequency is significantly less than the frequency observed during *in vivo* normal matings ($\chi^2 = 39.9$; $P < 0.0001$). Conversely, the difference between the *in vitro* transmission frequency and the *in vivo* delayed frequency is not significant ($\chi^2 = 0.19$; $P > 0.05$).

In vitro, fertilisation begins 1–2 h after insemination[18–20]. During this period, the spermatozoa undergo capacitation and penetrate the investments surrounding the ovum. In delayed matings the spermatozoa also reside in the female reproductive tract, before fertilisation, for 1–2 h (ref. 15). In normal matings, however, the time between insemination and fertilisation is considerably longer.

Because *in vitro* insemination and *in vivo* delayed insemination result in similar reductions in the transmission frequency of the t^6 allele, and because both procedures are associated with reduced time between insemination and fertilisation, we tested the affect of 'time *in vitro*' on the frequency of t^6-allele transmission. We compared the transmission frequency of this allele by using aliquots of gametes from the same male to inseminate ova following either a 0 or 6 h incubation period of the spermatozoa. The results (Table 3) show that the increased period of incubation does not increase the *in vitro* transmission frequency of the t^6 allele (0.18 versus 0.17; $\chi^2 = 0.018$; $P > 0.05$).

The data from these latter studies disprove the hypotheses that the distorted transmission frequency of a t-allele is caused by either a selective death of the non-t-bearing spermatozoa with time[21,22] or a differential transport of the + - and t-bearing gametes through the uterotubal junction[23,24]. Our findings suggest, rather, that the increase in transmission frequencies between delayed and normal matings is dependent on an interaction between the female reproductive tract and the male gamete, and that this interaction is time dependent. As the transmission frequency of the tested allele can be significantly affected by the genotype of the female, it is probable that the enhancing factor is intrinsic to the uterine and oviducal environments and is variable among the females of different genotypes.

for a role of plasma kallikrein in the activation of prorenin

K. Wolfgang Rumpf, Klaus Becker, Ulrich Kreusch, Sigrid Schmidt, Roland Vetter & Fritz Scheler

Department of Medicine, Division of Nephrology, University of Göttingen, Robert-Koch-Str. 40, 3400 Göttingen, FRG

The proteolytic enzyme renin seems to play an important part in the humoral control of blood pressure by initiating a reaction which finally leads to the production of the vasoconstrictor peptide angiotensin II. However, it has recently been shown that normal human plasma contains a higher molecular weight form of renin (prorenin), which is enzymatically inactive[1–6]. *In vitro*, prorenin is converted to the active renin enzyme by various unphysiological procedures such as cryoactivation[7–9], acid activation[1,6,7,9] or the addition of trypsin[10,11] or pepsin[11,12], the activation by trypsin being equal to that by acidification[13–15]. Although the physiological role of prorenin remains unclear, it has been shown that differences exist in the response to stimuli between prorenin and the active renin enzyme[3,6,7]. Recently, it has been shown that serine protease(s) may be involved in the activation process of prorenin, during both cryoactivation[7,16] and acid activation[7]. Furthermore, human urinary kallikrein added to plasma in low concentrations is able to activate prorenin completely *in vitro*[17]. Therefore, it has been speculated that urinary kallikrein might be the physiological *in vivo* activator of prorenin[17–19]. This also seemed plausible because renal kallikrein is produced in cells adjacent to the renin-producing cells[20]. On the other hand, plasma kallikrein has been implicated in the activation of prorenin[15,21–23]. In the experiments described below we tried to obtain some more direct evidence for the *in vivo* role of kallikrein(s) in the prorenin activation. Our results suggest that plasma kallikrein may indeed be a physiological activator of prorenin, but they do not support a role for urinary (renal) kallikrein in the activation of prorenin.

If kallikrein is the *in vivo* activator of prorenin, a negative correlation between kallikrein (urinary or plasma) and the proportion of prorenin (prorenin/total renin) may be expected. In 13 normal human volunteers, urinary kallikrein excretion and plasma prekallikrein concentration were correlated to the proportion of prorenin in plasma in different states of sodium balance, which is known to have a marked effect on urinary kallikrein excretion. Urinary kallikrein[24] and plasma prekallikrein[24,25] were measured using chromogenic tripeptide substrates (substrates S2266 and S2302, Kabi Diagnostica). Active renin and prorenin were determined by radioimmunoassay of angiotensin I using acid activation and nephrectomised sheep plasma as renin substrate[6].

Whereas sodium excretion was significantly reduced during sodium restriction (diet containing approximately 1.0 g NaCl per day) and, concomitantly, urinary kallikrein excretion increased fourfold, plasma prekallikrein concentration and the proportion of prorenin remained essentially unchanged (Table 1). During sodium loading (*ad libitum* diet plus 7.5 g NaCl per day for 3 days) sodium excretion was significantly higher than during the control period. Urinary kallikrein excretion was still elevated, presumably because of a significantly elevated urinary volume. Plasma prekallikrein and the proportion of prorenin did not change significantly during sodium loading.

Figure 1 shows that during all experimental periods, there was no correlation between urinary kallikrein excretion and the proportion of prorenin. This is in contrast to the results of other authors, who found a weak correlation between these two parameters[19]. In our experiments, in spite of profound alterations in urinary kallikrein excretion, the proportion of prorenin remained unchanged. This certainly does not exclude a role of urinary kallikrein in the activation of prorenin, but does make it rather improbable.

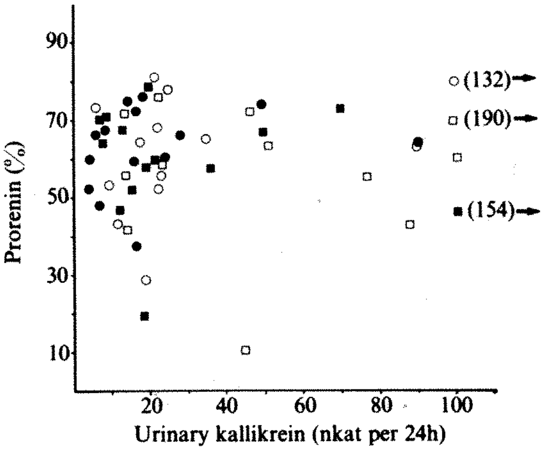

Fig. 1 Urinary kallikrein excretion and proportion of prorenin in different states of sodium balance in 13 normal human volunteers. ●, Normal diet; ○, sodium loading; ■, sodium restriction (2 days); □, sodium restriction (4 days).

Although during the different experimental periods plasma prekallikrein did not change significantly (Table 1), a close relationship between plasma prekallikrein concentration and the proportion of prorenin (Fig. 2) was observed: the higher the plasma prekallikrein, the lower the proportion of prorenin in plasma. The linear correlation coefficients were significant during all periods of the experimental protocol (*ad libitum* diet: $y = 96.8 - 0.64x$; $r = 0.71$; $n = 13$; $P < 0.01$. Sodium restriction: $y = 102.9 - 0.85x$; $r = 0.70$; $n = 22$; $P < 0.001$. Sodium loading: $y = 97.5 - 0.69x$; $r = 0.60$; $n = 13$; $P < 0.05$).

There are two possible explanations for the correlation. First, that this is an *in vitro* effect, which is due to incomplete activation of prorenin by the acidification procedure. However, this seems

Table 1 Urinary volume, sodium excretion, urinary kallikrein excretion, plasma prekallikrein and proportion of prorenin in different states of sodium balance

	ad libitum diet	Days of sodium restriction				Sodium loading
		1	2	3	4	
Urinary volume (ml per 24 h)	1,316 ± 143	1,551 ± 183	1,418 ± 175	1,343 ± 176	1,338 ± 113	1,916 ± 264†
Sodium excretion (mmol per 24 h)	170.0 ± 19.8	124.8 ± 14.8‡	48.9 ± 4.8§	27.7 ± 4.1†	16.4 ± 1.9§	331.7 ± 31.3§
Urinary kallikrein excretion (nkat per 24 h)	16.4 ± 3.4	21.3 ± 4.4‡	22.9 ± 5.1†	50.8 ± 12.1‡	64.6 ± 15.6‡	33.2 ± 10.0*
Plasma prekallikrein (μkat l^{-1})	53.2 ± 3.6		48.6 ± 3.6		52.3 ± 5.0	51.4 ± 3.6

improbable as it has been repeatedly shown that the so-called 'acid'-activation is complete and equivalent to the activation by trypsin[13-15]. Second, the correlation found may be physiologically significant and is applicable to the *in vivo* situation. This, of course, would be a strong argument in favour of an *in vivo* role of plasma kallikrein in the activation of prorenin.

Interestingly, the intercept on the ordinate in all three groups was near 100%, suggesting that in a plasma free of prekallikrein, renin would only be present in the form of prorenin and active renin enzyme would not be formed in these conditions. This, however, would suggest that plasma kallikrein not only is one of several activators of prorenin, but also that it may be the only activator of physiological significance. However, as our results were obtained in normal subjects only, we cannot exclude the possibility that in certain pathological conditions the relationship demonstrated may not apply.

Thus, our results do not support the concept that urinary kallikrein is of importance in the *in vivo* activation of prorenin, as has been proposed[17-19], but they strengthen the view that plasma kallikrein might be the physiological activator of prorenin[15,21,22].

Development of the peripheral nervous system involves an initial overgrowth of synaptic contacts, followed later by the regression of the redundant connections[1-4]. Similarly, in the central nervous system, the adult-type one-to-one relationship between climbing fibres (CFs) and cerebellar Purkinje cells (PCs) is preceded at early developmental stages by a multiple innervation of PCs by CFs[5]. The regression of the supernumerary contacts fails to occur when PCs develop in a cellular environment devoid of granule cells[6-9], suggesting that it may depend on the formation of synapses between parallel fibres and PCs. However, one cannot preclude the possibility that granule cells intervene in the regressive process by a nonsynaptic action, for instance by emitting a chemical signal at the level of their soma, which could act on the CF-PC synapses. In this respect, the recessive *staggerer* (*sg*) mutation[10], is of special interest because one of its major phenotypical expressions in homozygous *sg*/*sg* animals is the selective and almost complete absence of synapse formation between parallel fibres and Purkinje cells, in spite of the presence of an initially important number of granule cells and of parallel fibres during the synaptogenesis period, that is, until about the end of the 3rd post-natal week. Later on, the relay cells progressively die, probably because of the absence of synaptic contacts with PCs[11-13]. This is in marked contrast with the other agranular animals studied so far (X-ray irradiated rats and *weaver* mutant mice[6,7,9]) where granule cells lack from the very beginning[6,9,12]. As the *staggerer* mutation does not prevent the formation of functional synapses between CFs and PCs[14], it was important to establish whether PCs can reach the adult-type monoinnervation in the mutant. We show here that each PC is contacted by several CFs in the adult homozygous *staggerer* mouse, thus supporting the first hypothesis.

Hybrids of C57BL and DBA2J mice originating from the Jackson Laboratory and bearing the mutation were raised at the Laboratory and homozygous mutants *sg*/*sg* were obtained by intercrossing heterozygous animals. Mutant mice were distinguished from their littermates by clinical features[12] and they were kept alive after weaning by the use of appropriate feeding conditions[15]. The organisation of the cerebellar cortex at the ultrastructural level in adult *sg*/*sg* animals was identical to that previously described (C. Sotelo, personal communication) and they were used for electrophysiological studies 5 to 7 months after birth. After initial ether or Nembutal (30 mg per kg intraperitoneally) anaesthesia, animals were paralysed,

0028–0836/80/050483—02$01.00

spired, and the vermis was exposed. Juxtafastigial ion was performed with fine bipolar electrodes and sites were confirmed as previously reported[14]. recordings from PCs were obtained with glass micropipettes (d.c. resistances between 10 and 15 MΩ). An active bridge circuit was used to pass current through the recording microelectrode. The position of the tip of the microelectrode in the cerebellar cortex was determined by iontophoretic injection of methyl blue.

Twenty four PCs identified before cell penetration by their antidromic activation[14,16] elicited by JF stimulation (data not shown) were impaled and their electrical activities were analysed. In all the recorded cells, the orthodromic responses evoked by JF stimulation closely resembled a CF response[16]: they consisted of an initial full spike followed by a prolonged plateau of depolarisation on which partial spikes were or not superimposed (Fig. 1*ai*). Cell deterioration led rapidly to a suppression of spike potentials within the response and the underlying excitatory postsynaptic potential (e.p.s.p.) was revealed (Fig. 1*aii*). It had the typical time course of a CF-e.p.s.p.[16] but it was graded by steps (2 to 4) when increasing stimulation strength as it is usually observed in multiply innervated PCs[6,9] (Fig. 1*aii*). This type of CF-like e.p.s.p. also occurred spontaneously and it fluctuated in size in a stepwise manner (Fig. 1*aiii*), with a firing rate for each component of the response in the range of CF-mediated e.p.s.ps (1–2 s^{-1}). Moreover, harmaline injection (50 mg per kg intraperitoneally) induced a rhythmic bursting (5 to 10 s^{-1}) of these compound e.p.s.ps (Fig. 1*bi*, ii), confirming they were mediated via CF[17]. Finally, these responses were reversed by depolarising currents injected through the microelectrode (Fig. 2), as expected for chemically mediated synaptic potentials[18], and current values for reversal were very similar (10–15 nA) to those found for normal CF-e.p.s.ps[19] and for graded CF-e.p.s.ps in adult X-ray irradiated rats[9].

It seems unlikely that these graded CF-like activities could be mediated through the mossy fibre-granule cell pathway since at the age studied, almost all granule cells have degenerated in the mutant and since maximum stimulation of the residual parallel fibres either evoked no response or evoked only a single spike in the PCs tested (unpublished observations). The rare parallel fibre-PC synapses which still exist in the mutant[13] could nevertheless be responsible for the late and small e.p.s.ps (as compared to the CF-like response) which were sometimes evoked by JF stimulation in the recorded cells (Fig. 1*aii*, arrow) and which spontaneously occurred at a high firing rate (20–50 s^{-1}) during the resting discharge of PCs, thus corresponding to the simple spike spontaneous firing recorded before cell penetration.

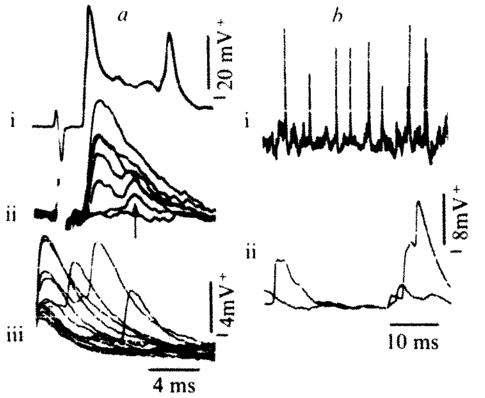

Fig. 1 Intracellular recordings from Purkinje cells. Body temperature was kept constant at 37 °C and the cerebellar vermis was covered with 4% agar in 10% sucrose solution. Resting potentials were −45 mV for the cell illustrated in *a*, and −35 mV for that in *b*. Cells generally remained in a good condition during intracellular recordings for up to 10 min. *ai*, Climbing fibre-like response evoked by JF stimulation; *aii*, same cell as in *ai* after cell deterioration. The underlying e.p.s.p. was graded in a stepwise manner with the intensity of the JF stimulation. *aiii*, Spontaneous climbing fibre-like e.p.s.ps recorded from the same cell as in *ai* and ii. Each sweep was triggered by the rising edge of the response. *bi*, Rhythmical bursting of climbing fibre-like e.p.s.ps at about 5 s^{-1} in another PC after harmaline injection; *bii*, same cell as in *bi* but with a faster sweep speed.

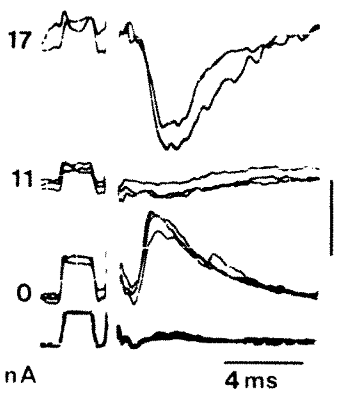

Fig. 2 Reversal properties of a climbing fibre-like e.p.s.p. evoked in a PC by JF stimulation under depolarising d.c. currents. The resting potential of the cell was −42 mV. Current injections were done when the spike generating mechanism of the cell was completely abolished. Ten suprathreshold JF stimulations at 0.5 s^{-1} were applied for each current step (current values are indicated on the left of each record), and the size and polarity of the responses were determined by comparison with the extracellular field potential after withdrawal of the microelectrode (bottom trace). The calibrating pulse on the left of each trace is 2 mV in amplitude and 2 ms in duration.

The present study fully confirms the functional linkage between CFs and PCs in the *staggerer* mouse and establishes that each PC receives several independent CFs in the adult. These results allow the extracellular graded responses evoked in 3-week-old animals by JF stimulation[14] and rhythmically triggered by harmaline injection to be now tentatively re-interpreted as immature CF-responses[20,21] recorded from multiply innervated PCs whose maturation was very delayed[22]. At this early stage a significant number of granule cells is still present and the most striking abnormality is a selective absence of synapses between parallel fibres and PCs[13]. It therefore seems likely that in normal animals, the formation of parallel fibre–PC synapses is responsible for the regression of supernumerary CF-PC synapses which occurs during development. The present study strengthens the view that the *staggerer* mutation does not simply consist of a general reduction in the ability of PCs to form synapses with their afferents (as PCs are multiply innervated by CF) but that the loss of synaptic competence is highly selective.

Imidazole inhibits a temperature-dependent component of mammalian skeletal muscle action potential

D. W. Cheung* & E. E. Daniel

Department of Neurosciences, McMaster University, Hamilton,
Ontario, Canada L8S 4J9

Temperature-dependent transition of conductance in ionic channels has been described in several membrane systems[1–3]. We report here an abrupt change in the maximal rate of rise of the action potentials of the rat extensor digitorum longus (EDL) at 32 °C, indicating alteration in the functional characteristics of the sodium channels. Tetrodotoxin (TTX) and imidazole were used to investigate further the change in properties of the sodium channels with respect to temperature. TTX is known for its specificity in blocking sodium channels[4]. It has been proposed that the guanidinium group of the TTX molecule is essential for its activity. Other guanidinium compounds have also been shown to be effective in blocking the sodium channels[5]. In this study, imidazole, a compound structurally similar to guanidine, was also tested. We find that TTX and imidazole affect the maximal rate of rise of the action potential in a temperature-dependent manner.

Extensor digitorum longus muscles from male Wistar rats were mounted in a muscle bath and perfused with oxygenated Ringer's solution. The temperature of the bath was regulated by water circulating around its jacket. Intracellular recordings were made with microelectrodes filled with 3 M KCl. The muscles were electrically stimulated with a pair of external platinum wire electrodes. The voltage change was recorded through a WPI M4A electrometer and the maximal rate of rise of the action potential was obtained by a differentiating circuit. The maximal rate of rise of the action potential was measured because it gives an indication of the sodium conductance increase during an action potential[6]. The muscles were allowed to soak in the solutions containing the drugs for at least 20 min. before recording. At least 30 min was allowed for equilibration for any change of temperature.

The change in temperature, as well as TTX and imidazole, had no effect on the resting membrane potential of the muscle fibres. However, a dramatic change in the maximal rate of rise of the action potential with temperature was observed (Fig. 1). From a steady level of about 200 V s^{-1} at temperatures below 32 °C, the rate increased to about double its value within a 5 °C temperature rise.

To investigate the effect of imidazole and TTX on the maximal rate of rise of the action potential with respect to temperature change, three representative temperatures (25 °C, 30 °C and 35 °C) were chosen for more detailed studies, although results obtained at other temperatures followed the same pattern. Imidazole reduced the rate of rise in a temperature-dependent manner. Within the lower temperature range from 20 to 30 °C, in which the maximal rate of rise did not change with temperature, imidazole had no effect. At temperatures above 32 °C, 2.5×10^{-5} M imidazole reduced the rate of rise to the same level as that at lower temperatures (Fig. 2*c*). Higher concentrations of imidazole (up to 10^{-3} M) were not effective in further reducing the rate of rise beyond that observed at lower temperatures.

TTX reduced the maximal rate of rise of the action potential at all temperatures (Fig. 2*b*). At 3.1×10^{-9} M TTX, the depression of the rate of rise was more conspicuous at 35 °C. It was only at higher concentrations of TTX (1.55×10^{-7} M) that the rate was reduced to the same level at all temperatures. Pretreatment of the muscle with imidazole (2.5×10^{-5} M) abolished the temperature sensitivity of the rate of rise to TTX. The rate was reduced to the same level at all temperatures (Fig. 2*d*). Increasing the TTX concentration resulted only in a concomitant reduction at the different temperatures.

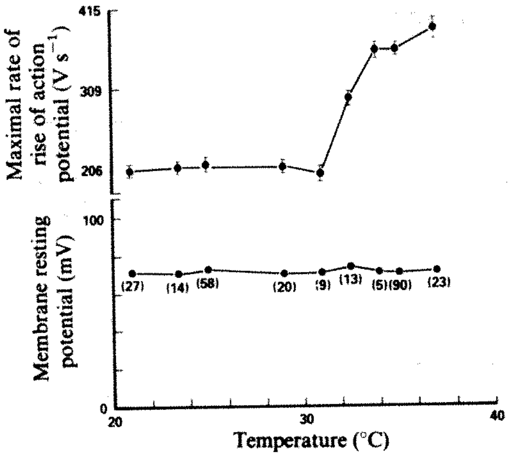

Fig. 1 Effect of temperature change on the maximal rate of rise of the action potential (top) and the resting membrane potential (bottom) of the rat extensor digitorum longus. Although the resting membrane potential was not sensitive to the variation in temperature, the rate of rise became temperature sensitive at around 32 °C, showing a sharp increase with only a small rise in temperature.

The transition of the maximal rate of rise of the action potential at 32 °C indicates a sharp change in the current through the sodium channels of the muscle membrane. Change in membrane fluidity or conformational change of the channel protein has previously been proposed as the underlying cause for the change in properties of other ionic channels[1–3]. It is also

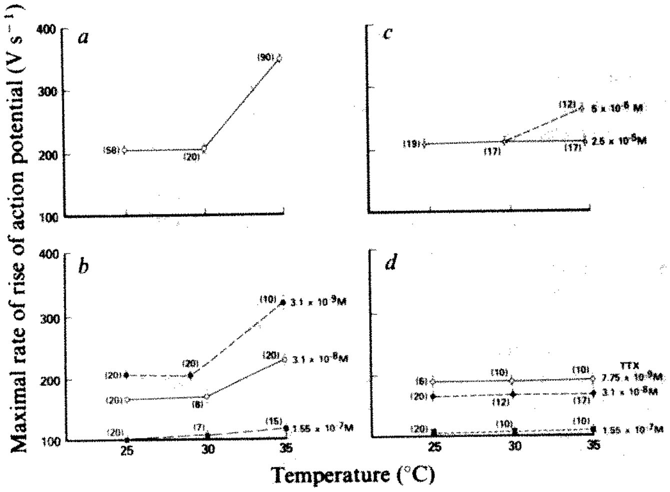

Fig. 2 Effect of imidazole and TTX on the maximal rate of rise of the action potential of the rat extensor digitorum longus at different temperatures. *a*, Control; *b*, effect of TTX. At a low TTX concentration (3.1×10^{-9} M) only the rate at 35 °C showed a significant reduction. At 3.1×10^{-8} M there was in addition a parallel shift of the rate between 25 and 30 °C. At 1.55×10^{-7} M, the difference in rate at different temperatures was completely eliminated. *c*, Effect of imidazole. Note that imidazole was effective in reducing the rate of rise only at 35 °C. The inhibition by imidazole was limited to the level as the rate of rise at low temperature. *d*, Effect of TTX after pretreatment with imidazole (10^{-4} M). Imidazole at 10^{-4} M abolished the difference in the rate of rise with respect to temperature. The effect of TTX in such conditions was to produce an inhibition that was not sensitive to temperature.

possible that there is a separate population of temperature-sensitive channels.

The finding that imidazole only exerts its action at temperatures above 32 °C and reduces the rate of rise to that of the lower temperatures is difficult to explain. Whether imidazole can prevent changes in membrane fluidity or protein conformation has yet to be determined. Alternatively, the results may be interpreted to indicate two components contributing to the maximal rate of rise of the action potential: a temperature-independent component and a temperature-dependent component selectively blocked by imidazole. The latter is also more sensitive to TTX. In such a case, the action of imidazole may be due to its molecular structure, so that it selectively blocks the sodium channels activated at higher temperatures. If this were the correct interpretation, these results then implicate the existence of two types of sodium channel that are pharmacologically distinguishable using imidazole. The possibility that thromboxanes or the adenylate cyclase system may be involved in the regulation of the sodium current may also have to be considered as imidazole is a potent inhibitor of thromboxane synthesis[7] as well as an activator of adenyl cyclase.

Different components of black widow spider venom mediate transmitter release at vertebrate and lobster neuromuscular junctions

L. C. Fritz, M.-C. Tzeng* & A. Mauro

The Rockefeller University, New York, New York 10021

Crude black widow spider venom (BWSV) has profound physiological effects on several neuromuscular preparations, both vertebrate and invertebrate[1]. At frog and mouse neuromuscular junctions (NMJs), BWSV causes a massive increase in the frequency of miniature endplate potentials (m.e.p.ps)[2,3] followed by a reduction in m.e.p.p. frequency and depletion of synaptic vesicles[3–5]. Qualitatively similar physiological and morphological effects are also observed at lobster[6–8] and insect[9,10] NMJs after treatment with BWSV. Apparently, therefore, this venom can cause the release of several transmitters—acetylcholine at vertebrate NMJs and γ-aminobutyric acid (GABA) and glutamate at invertebrate NMJs[11]. BWSV has also been shown to cause the release of acetylcholine, noradrenaline and GABA from slices of mouse cerebral cortex[12,13]. α-Latrotoxin, a protein of molecular weight (MW) 130,000, had previously been shown to be responsible for the venom effects at vertebrate NMJs and in mouse brain slices[12–14]. That finding prompted the question of whether α-latrotoxin was also responsible for transmitter release in the lobster preparation. The present report demonstrates that although the electrophysicological effects of BWSV on lobster and frog NMJs are similar, they are caused by different components of the venom. The effects on the lobster are attributable to fraction E, which contains a major 65,000-MW protein and several lower molecular weight species. It has previously been shown that fraction E causes firing of the crayfish stretch receptor[14]. Some of these results have been published elsewhere[15].

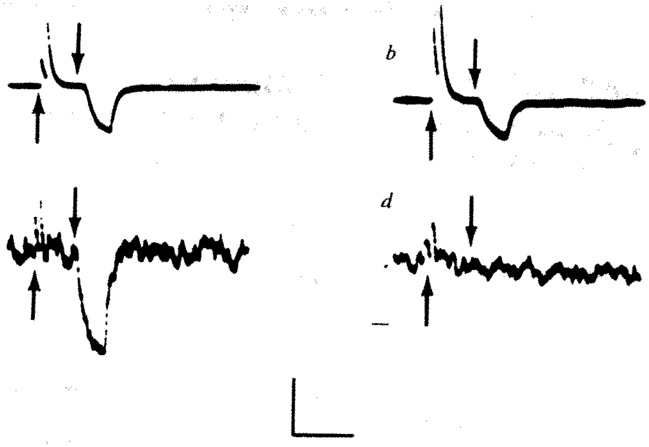

Fig. 1 Effect of fraction E on the lobster neuromuscular junction. In each trace, a pair of stimuli was applied to the excitatory axon (eliciting excitatory postsynaptic potentials) at the upward arrow; a train of stimuli (60 s^{-1}) was applied to the inhibitory axon (eliciting a summated inhibitory postsynaptic potential) at the downward arrow. *a*, Control; *b*, *c*, *d*, 17, 24, 28 min, respectively, after addition of 9 μg of fraction E. The excitatory potentials are potentiated in *b*, and the inhibitory potential is potentiated in *c*. In *d*, both the excitatory and inhibitory potentials are greatly reduced in amplitude. The ragged baseline in *c* and *d* is caused by a high frequency of spontaneous miniature potentials. Calibration: 2 mV, 1 s.

Venom glands were extracted from adult females of the black widow spider, *Latrodectus mactans tredecimguttatus*. Crude venom was prepared by homogenising two glands in 0.25 ml of lobster Ringer; venom was fractionated as previously described[14]. Intracellular recordings from the stretcher muscle of the lobster walking leg and from the frog cutaneous pectoris muscle were made using conventional techniques[16,17]. Superficial fibres from the lobster muscle were exposed by chipping away the overlying shell and removing the connective tissue layers. A small pool (~0.2 ml) was formed around the exposed fibres with Vaseline and toxins were added to the pool. Cutaneous pectoris muscles were pinned out in a chamber (~3 ml) to which toxins were added.

In the lobster, crude BWSV initially causes a potentiation of excitatory and inhibitory postsynaptic potentials, both of which are subsequently abolished, and a great increase in the frequency of miniature excitatory postsynaptic potentials[6]. Figure 1 demonstrates that these physiological effects can be elicited by application of 9 μg of fraction E. In contrast, Fig. 2 shows that at the frog NMJ, even after 2 h of exposure to 12 μg of fraction E, no increase in m.e.p.p. frequency is observed. However, subsequent treatment with 1 μg of α-latrotoxin rapidly causes a large increase in m.e.p.p. frequency (Fig. 2*d*). To test whether the apparent inactivity of fraction E on the frog NMJ in the above experiments was due to the large volume of fluid in the chamber (~3 ml), some additional experiments were carried out in which fraction E was applied to small (~0.2 ml) Vaseline-enclosed pools surrounding endplate regions. Even in these conditions, no rapid increase in m.e.p.p. frequency was observed, although after prolonged exposure (1–2 h) to a large dose (36 μg) of this fraction, high frequency bursts of m.e.p.ps were seen. This low level of activity is most probably attributable to slight contamination of fraction E by α-latrotoxin, as a similar level of activity is observed after prolonged exposure to low doses of α-latrotoxin, and such contamination can be demonstrated by SDS-polyacrylamide gel electrophoresis.

Although the lobster NMJ is sensitive to fraction E, Fig. 3 demonstrates that it is insensitive to α-latrotoxin. Following the addition of 2 μg of α-latrotoxin, no potentiation of evoked responses and no increase in the frequency of spontaneous miniature potentials were observed. Subsequent addition of 50 μl of crude BWSV, however, caused its usual effect, verifying that the preparation was still capable of responding to the crude venom.

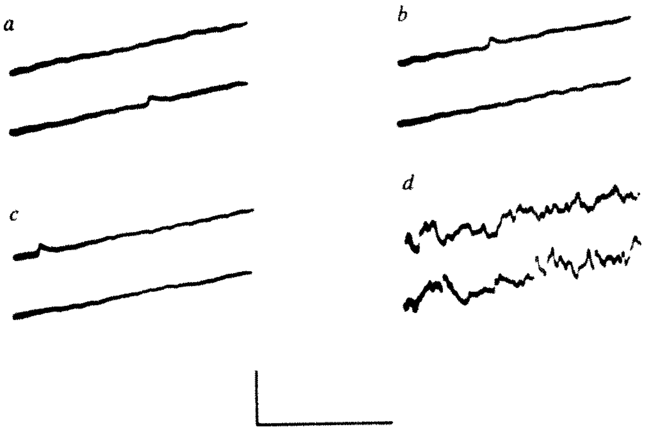

Fig. 2 The absence of an effect of fraction E on the frog neuromuscular junction. *a*, Control; *b* and *c*, 18 and 136 min, respectively, after addition of 12 μg fraction E to the bath. Individual m.e.p.ps can be seen in *a*, *b* and *c*. α-Latrotoxin, 1 μg, was added 168 min after fraction E addition. *d*, 14 min after the α-latrotoxin application. A high m.e.p.p. frequency is evident in *d*. Calibration: 2.5 mV, 50 ms.

These experiments show that fraction E can account for all the physiological effects of BWSV on the lobster NMJ, whereas α-latrotoxin is inactive. In contrast, α-latrotoxin causes the release of every transmitter so far examined in vertebrates[12–14]. The present experiments also confirm that fraction E does not cause the release of transmitter at the frog NMJ[14]. Fraction E has previously been shown to be ineffective in stimulating the release of GABA from mouse brain slices[13].

α-Latrotoxin binds with high affinity to some protein components in neuronal membranes[18], possibly binds also to gangliosides[19], and apparently acts, at least in part, by forming ionic channels[20,21]. It seems possible, then, that the inactivity of α-latrotoxin at the lobster NMJ reflects an absence of toxin receptors on the lobster nerve terminal and/or an inability of the toxin to become incorporated into the lobster nerve terminal membrane. Similarly, membrane components that interact with fraction E may be present on nerve terminals of lobster but not of frog. We cannot rule out the possibility, however, that α-latrotoxin and fraction E do not have equal access to nerve endings of lobster and frog. The calcium ionophore X-537A, on the other hand, seems to interact with both frog and lobster nerve terminals, as it is capable of increasing miniature potential frequency in both these preparations[22].

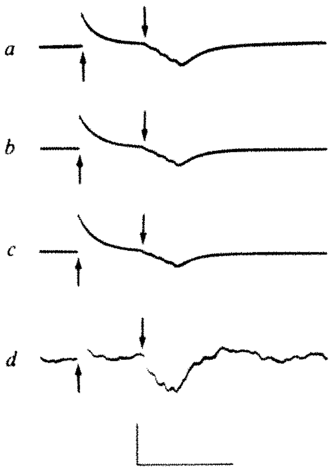

Fig. 3 The absence of an effect of α-latrotoxin on the lobster neuromuscular junction. In each trace, one stimulus was applied to the excitatory axon at the uppward arrow; a train of four stimuli ($10\ s^{-1}$) was applied to the inhibitory axon at the downward arrow. *a*, Control; *b*, and *c*, 10 and 20 min, respectively, after addition of 2 μg α-latrotoxin. 50 μl of crude BWSV was added 25 min after the α-latrotoxin. *d*, 10 min after the addition of the crude BWSV. The ragged baseline in *d* is due to a high frequency of miniature potentials induced by the venom. Calibration: 5 mV, 1 s.

BWSV causes transmitter release from insect NMJs[9,10] and the component which affects the cockroach NMJ has a MW of 125,000 (ref. 10). It seems likely that this component is a constituent of fraction C described by Frontali *et al.*[14], as this fraction is the only one to affect houseflies and cockroaches in their assay. Assuming this is true, the crude venom contains at least three separate protein components, each capable of causing transmitter release, but each demonstrating some degree of species specificity.

We thank Mr B. Capparella, Dr B. Ceccarelli, Dr N. Frontali and Dr W. P. Hurlbut for providing the spiders and Dr D. C. Gadsby for helpful discussion. L.C.F. was supported in part by a graduate fellowship from the US NSF.

Dopamine stimulates the degradation of gonadotropin releasing hormone by rat synaptosomes

Immunohistochemical studies have shown the existence of synapses between nerve endings containing dopamine and gonadotropin releasing hormone (LH-RH) respectively in the hypothalamic median eminence[1]. It is generally accepted that this transmitter is involved in the regulation of gonadotropin secretion as a modulator of LH-RH release, although the evidence is conflicting and both inhibitory and excitatory actions of dopamine have been reported[2,3]. *In vitro* studies support the excitatory effect and low doses of dopamine have been shown to release LH-RH from incubated hypothalamic fragments[4,5] and synaptosomes[6]. This report describes studies with nerve endings isolated from the rat hypothalamus in which dopamine at higher concentrations than those used previously has been found to stimulate the degradation of LH-RH but not thyrotropin releasing hormone (TRH). This mechanism seems to be physiological in that it is calcium-dependent, requires the structural integrity of the nerve endings and fluctuates with the reproductive state of the animal.

Effect of 10^{-4} M dopamine (DA) on the release of oreactive LH-RH from synaptosomes isolated from male and female (*b*) rat hypothalamus. Adult male and female Wistar rats (200–300 g) were housed in a temperature-controlled animal room with lights on from 6.00 to 18.00 h. The animals were stunned and decapitated. The entire hypothalamus was rapidly removed and synaptosomes were isolated and suspended in Krebs–Ringer bicarbonate medium containing glucose, at a tissue concentration equivalent to 1 hypothalamus per ml, using methods described previously[13]. The synaptosomes were incubated at 37 °C in capped plastic vials for a preincubation period of 15 min before the addition of dopamine, added in 20 µl of 1 mM ascorbic acid, to give a final concentration of 10^{-4} M. An equal volume of the ascorbic acid was added to control incubations. After incubation the synaptosomes were deposited by centrifugation (1,000*g* for 10 min) at room temperature and both the supernatant medium and synaptosomal pellets stored at −40 °C. Pellets were extracted with 0.5% Triton-X100 (ref. 14) and both LH-RH[15] and TRH[16] measured by immunoassay. Details of the specificity of the antibody used to measure LH-RH have been described elsewhere[17]. The antiserum does not recognise the peptide fragments produced after cleavage at the Gly^6-Leu^7 bond, the major mechanism for inactivation[10], but it does cross-react with LH-RH after removal of the COOH-terminal glycinamide, the other major point of endogenous peptidase activity[10]. The antiserum against TRH does not cross-react with pyroGlu-His-Pro-OH, pyroGlu-His or pyroGlu-Met-ProNH$_2$ and in studies on endogenous TRH-like material separated by HPLC using several different solvent systems, cross-reaction occurs only against a single fraction with properties identical to synthetic TRH. Dopamine at the concentrations used in the experiments did not interfere with the immunoassays. This aspect was rigorously tested. Small differences in the standard curve for LH-RH were obtained in the presence of 0.5% Triton and two assays were run systematically, one including Triton which was used to estimate the LH-RH content of the extracted pellets. Curves show levels of immunoreactive LH-RH present in the incubation medium (M), and Triton extracts of the synaptosomal pellets (P). In preparations from both sexes approximately two thirds of the total tissue content of LH-RH was released after 30 min control incubation, a finding which we have discussed elsewhere[18]. In *b* the levels of LH-RH released in the presence of bacitracin alone were similar to those obtained with bacitracin plus dopamine, and have not been shown for the sake of clarity. Values are expressed as mean ± s.e.m. in 9 to 31 determinations. The statistical significance of differences was determined with a two-tailed *t*-test. Different from control groups at: $*P<0.05$; $**P<0.001$.

Preliminary studies were carried out with hypothalamus from female rats at random stages of the oestrous cycle and from male animals. Figure 1 shows the basal release of immunoreactive LH-RH from synaptosomes, during a 30-min incubation period. Levels of LH-RH in the incubation medium were relatively high to begin with, because of release during the preincubation period, and increased only slightly during the next 30 min. The content of LH-RH in the synaptosomal pellet obtained after centrifugation showed a decline with time, indicating depletion of a releasable pool of the neuropeptide. In the presence of dopamine (10^{-4} M) there was a significant reduction in the level of LH-RH in the medium from female hypothalamic synaptosomes. This was maximal after 5 min, when almost all of the LH-RH released during the period of preincubation had disappeared. The disappearance of immunoreactive LH-RH from the medium after dopamine treatment is unlikely to be due to re-uptake or inhibition of release as the LH-RH content of the pellet was unchanged at this time, although the possibility of re-uptake coupled with intracellular degradation cannot be excluded. After 15 and 30 min of incubation the concentration of LH-RH in the synaptosomal pellets in the presence of dopamine was raised, but the preparation still showed a significant net loss of LH-RH ($P<0.005$). Furthermore, the action of dopamine was blocked in the presence of bacitracin (5×10^{-4} M), an antibiotic peptide which competitively inhibits the degradation of LH-RH by peptidases[7]. In contrast to this effect of dopamine on LH-RH in synaptosomes isolated from female hypothalamus, dopamine did not reduce the LH-RH level in the medium from synaptosomes isolated from the male rat hypothalamus.

Subsequent experiments were carried out with synaptosomes from female rats at defined stages of the oestrous cycle and incubations with dopamine were carried out for 5-min periods. Figure 2 shows that although a significant effect of dopamine was obtained at every stage of the reproductive cycle, the degradation of LH-RH was most marked in the pro-oestrous preparation. Although the values are not shown, the concentrations of LH-RH in the synaptosomal pellets did not vary with different stages of the oestrous cycle and were not affected by the addition of dopamine. Figure 2 also shows that in the same preparations there was a significant increase in the release of immunoreactive TRH in the presence of dopamine, an effect which we have also observed with nerve endings from sheep hypothalamus[5]. Dopamine did not alter the synaptosomal content of TRH.

The effect of dopamine on the degradation of exogenous LH-RH was also studied using synaptosomes isolated from

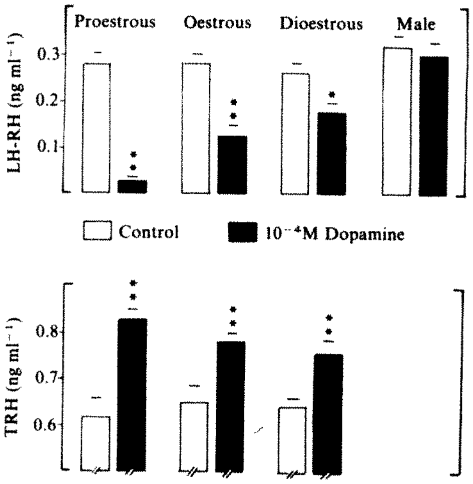

Fig. 2 Levels of immunoreactive LH-RH and TRH in the supernatant medium from synaptosomes isolated from female rat hypothalamus at different stages of the oestrous cycle. Daily vaginal smears were taken in the morning and only rats showing at least 2 or 3 successive regular 4-d cycles were used. Experimental conditions were identical to those described for Fig. 1. Values show levels of peptide present after 15 min preincubation followed by 5 min incubation in the presence of dopamine or ascorbic acid control vehicle, and represent the mean ± s.e.m. in 13 to 18 determinations. The statistical significance of differences was determined by the two-tailed *t*-test. Different from control groups at: $*P<0.025$; $**P<0.001$.

female rats at random stages of the oestrous cycle. After preincubation, 10 ng of synthetic LH-RH was added, an amount almost 30-fold greater than endogenous levels released by the synaptosomes. Dopamine (10^{-4} M) stimulated the disappearance of exogenous LH-RH from the medium and bacitracin completely inhibited this effect (Fig. 3). Exogenous LH-RH was also added to suspensions of cerebral cortex synaptosomes incubated at a tissue concentration equivalent to 1/3 cortex per ml. Substantial degradation of LH-RH occurred in these conditions but dopamine did not have any significant effect on the rate of breakdown. The effect of removal of free calcium on dopamine-induced disposal of both endogenous and exogenous LH-RH by hypothalamic synaptosomes was also studied. When calcium was omitted from the Krebs–Ringer bicarbonate buffer, the degradation of LH-RH in the presence of dopamine was not observed (Fig. 3).

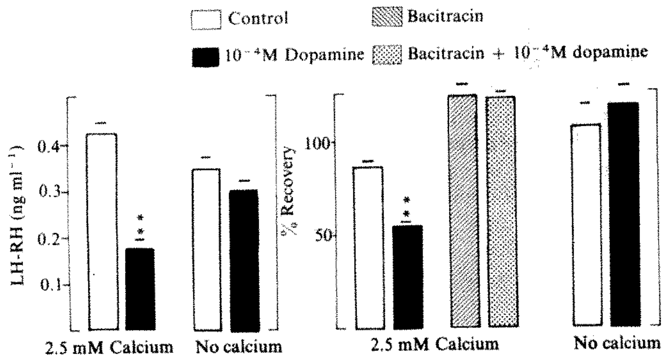

Fig. 3 Effect of calcium on the dopamine-induced degradation of endogenous (left) and exogenous (right) LH-RH. Percentage of recovery was calculated with each experiment from controls consisting of the various media incubated with 10 ng synthetic LH-RH. Values greater than 100% obtained when bacitracin was present or calcium was omitted, are presumably due to the decreased breakdown of endogenously released LH-RH in the medium. The synaptosomes were incubated for 30 min in the presence of LH-RH and other agents. The LH-RH content of the synaptosomal pellets was not significantly altered in the presence of dopamine. Values are expressed as mean±s.e.m. in 9 to 32 determinations. The statistical significance of differences was determined by the two-tailed *t*-test. ** Different from control groups at $P < 0.001$.

The concentration of dopamine (10^{-4} M) required to stimulate the degradation of LH-RH by synaptosomes is relatively high. However, recently it has been reported that concentrations of dopamine in plasma from hypophysial portal blood are between 10^{-8} and 10^{-7} M (ref. 8). If this measurement is correct it is likely that much higher concentrations of dopamine occur in synaptic clefts or extracellular space surrounding dopaminergic nerve terminals. The concentration of acetylcholine in the neuro-muscular junction exceeds 10^{-4} M during stimulation[9] and there is no reason to suppose that such levels of neurotransmitters are not found in synaptic clefts elsewhere.

When synaptosomes were ruptured by sonication, dopamine did not stimulate the degradation of 10 ng synthetic LH-RH added to the preparations, indicating that the mechanism of this effect does not involve a direct action on the enzyme. Also, the supernatant medium from incubated synaptosomes did not significantly degrade LH-RH. Together, these results suggest an extremely complex mechanism which requires the structural integrity of the nerve ending and in which dopamine, ovarian steroids and calcium are all involved. The existence of such a system for the degradation of LH-RH may partly explain the apparent lack of correlation between the distribution of LH-RH and the peptidases which degrade it. Previous studies[10] have reported that less than 5% of LH-RH degrading activity is associated with the synaptosomal fraction, which contains most of the peptide. However, the membrane or cytosol preparations used in such studies lack the cellular organisation that the dopamine-sensitive, synaptosomal mechanism requires.

That dopamine-induced breakdown of LH-RH observed in this study may reflect a physiological mechanism is suggested by: (1) the differential effect of dopamine in rats at different stages of the oestrous cycle; (2) the lack of effect of dopamine on LH-RH degradation on male hypothalamic synaptosomes; (3) the inability of dopamine to enhance LH-RH disposal in a calcium-free medium; (4) the absence of any action on TRH breakdown; and (5) the finding that dopamine did not stimulate the disposal of exogenous LH-RH by synaptosomes from cerebral cortex. We suggest, therefore, that in addition to controlling the release of hypothalamic LH-RH dopamine may acutely regulate the disposal of this hormone by controlling peptidase activity at the nerve terminal. Such a mechanism could be important with relation to both the endocrine functions of LH-RH in control of gonadotropin secretion and its reported actions on neuronal activity[11] and sexual behaviour[12]. It could also have more general significance for the functional relationships between aminergic and peptidergic neurones in the central nervous system.

We thank Mrs J. Pennington for technical assistance, Ayerst Laboratories for LH-RH, and Dr S. L. Jeffcoate for antisera to LH-RH. This work was supported by an MRC Programme Grant to J.A.E. Modulation of nicotinic receptors by opiate receptor agonists in cultured adrenal chromaffin cells

K. Kumakura, F. Karoum*, A. Guidotti & E. Costa

Laboratory of Preclinical Pharmacology and * Laboratory of Clinical Psychopharmacology, National Institute of Mental Health, Saint Elizabeths Hospital, Washington, DC 20032

Morphological, physiological and pharmacological evidence indicates that opioid peptides, which in the brain are located intraneurally[1], may function as neurotransmitters. Similar evidence is not yet available for the opioid peptides that are stored in chromaffin cells of adrenal medulla[2–5] and in axon terminals located in adrenal medulla and sympathetic ganglia[3–5]. The present report contributes evidence suggesting that the opioid peptides which are stored in the axon terminals of the splanchnic nerves located in adrenal medulla[4] may function as

0028-0836/80/050489—04$01.00

neuromodulators of the acetylcholine receptors located on chromaffin cells that are involved in catecholamine release. We support this functional role of the opioid peptides by showing that primary cultures of chromaffin cells of bovine medulla contain opiate receptors. When these receptors are occupied by specific agonists, the number of nicotinic receptors and the amount of catecholamine released by maximal doses of nicotine are reduced. Thus, like in other neuronal systems[6–8] also in adrenal medulla, the action of opioid peptides is inhibitory. The specificity of this action is in part supported by the inability of opiate receptor agonists to reduce the Ca^{2+}-dependent release of catecholamines elicited by K^+ ions.

A highly purified primary culture of chromaffin cells was obtained from bovine adrenal medullae by a modification of the method described by Waymire *et al.*[9]. Approximately 10^8 chromaffin cells were obtained from a single bovine adrenal (for further details see Table 1 legend). These chromaffin cells can be kept in culture, without significant morphological or biochemical changes, for at least 2 weeks[10]. The chromaffin cells in culture retain the ability to release endogenous catecholamines in response to nicotinic receptor stimulation[10,11]. The nicotine-induced release of catecholamines is Ca^{2+} dependent[10].

Nicotinic receptor antagonists such as hexamethonium abolish this response[10,11], which is unaffected by pretreatment with blockers of muscarinic receptors[10]. This finding agrees with reports that in these primary cultures of chromaffin cells the number of high-affinity binding sites for ligands (^{3}H-quinuclidinyl benzilate) of muscarinic receptor sites[10] is very small.

The experiments reported here were carried out in cells maintained in culture for 1 week. To study catecholamine release, 10^6 cells were washed once with phosphate-buffered saline and suspended in 1 ml of Krebs–Ringer bicarbonate–glucose buffer (*p*H 7.2–7.4) and 0.5% bovine serum albumin at 37 °C. The content of catecholamines and their metabolites in the cells was measured by mass-fragmentography as previously reported[12,13], with minor modifications. The cells were homogenised in 100 µl of 1 M HCl solution containing 25 ng each of deuterated adrenaline, noradrenaline and dopamine. These internal deuterated amines were used to quantify the endogenous amines by direct comparison. Adrenaline (15 ± 0.8 nmol per 10^6 cells; $n = 3$) represents approximately 75%, noradrenaline (3.4 ± 0.2 nmol per 10^6 cells; $n = 3$) 17% and dopamine (1.3 ± 0.06 nmol per 10^6 cells) 7%, of the total catecholamine content. Only trace amounts of dihydroxyphenyl acetic acid (DOPAC) and homovanillic acid (HVA) were detected. A rapid spontaneous release of catecholamines was observed during the first 5 min of incubation in Krebs buffer. During this period approximately 1–2% (0.2–0.4 nmol per 10^6 cells) of the total catecholamine stores was released. The spontaneous release of catecholamines decreased to 0.5% of the total cell content in the following 5-min period. During a 3-min exposure to nicotine (10^{-5} M) or a high potassium concentration

Table 1 Effect of morphine and other opiate receptor agonists on the release of endogenous catecholamines from cultured adrenal chromaffin cells

Secretory stimulus	Opiate receptor agonist		Catecholamine secretion (nmol per 10^6 cells)	%

Adrenal chromaffin cells were isolated from fresh bovine adrenal glands as described by Waymire *et al.*[9]. Briefly, the procedure consists of: dissection of the adrenal medulla from the cortex, digestion of the interstitial tissue of adrenal medulla by retrograde perfusion with 0.25% collagenase, differential centrifugation and filtration, and differential plating to remove non-chromaffin cells. The chromaffin cells were cultured in F-12-10% fetal calf serum medium. The purity of the chromaffin cell preparation was established microscopically with the specific method for catecholamine fluorescence and Giemsa staining[23]. The contaminant cells were always less than 5%. The chromaffin cells were able to maintain a constant level of catecholamines (20 nmol per 10^6 cells) and related enzymes for 1–2 weeks[10,11]. Large numbers of cells could be purified with this procedure. Approximately 10^8 cells were obtained from a single bovine adrenal medulla. For the release studies approximately 10^6 cells per sample were used. The release of endogenous catecholamines from cultured chromaffin cells was measured by incubating the cell suspension at 37 °C for 2.5 min in Krebs–Ringer bicarbonate–glucose buffer (*p*H 7.2–7.4) and 0.5% bovine serum albumin with 2.2 mM $CaCl_2$. The cell suspension was filtered through a Millipore filter after the incubation. The released catecholamines (adrenaline + noradrenaline) were extracted from the filtrate with 0.4 M perchloric acid and assayed fluorimetrically after Al_2O_3 adsorption[14]. 'Catecholamine secretion' represents the amount of catecholamines released (in 2.5 min) by nicotine or K^+ ions after subtracting the baseline release of catecholamines. The baseline release accounts for 20–30% of the total catecholamines present in the medium after nicotine or KCl stimulation. Each value is the mean ± s.e. of two or three separate experiments. In each experiment the effect of drugs (added 15 min before 10^{-5} M nicotine) was tested in groups of three separate samples. There was no significant release of the endogenous catecholamines by the opiate substances themselves at the doses used. Regression analysis of the dose–response curve for different opiate receptor agonists give the following coefficient of correlation (r^2) values: morphine, 0.99 ($P < 0.01$); β-endorphin, 0.88 ($P < 0.01$).

* Statistically significant ($P < 0.05$) when the treated groups are compared with the control group, using the *t*-test pair analysis.

† Statistically significant ($P < 0.05$) when morphine-treated groups are compared with the corresponding groups treated with morphine + naltrexone (NTL).

(56 mM), there was a large linear increase in the rate of catecholamine release which was 10 to 15 times greater than the spontaneous release rate.

During the 3-min stimulation period, 10–15% of the total catecholamine cell content was released. After this very high release there was a 3-min period of much slower release during continuous nicotine or potassium stimulation. We measured the relative proportion of adrenaline, noradrenaline and dopamine released before and after nicotine stimulation with or without opiate treatment by mass-fragmentography and found that the medium contained, in all the conditions studied, approximately 55% adrenaline, 45% noradrenaline and 1% dopamine. Only trace amounts of DOPAC and HVA were present. The catecholamine content remaining in the cells after the release experiments and the relative proportions of catecholamines present were mostly the same as those measured in control preparations. Due to the large amounts of catecholamines available in each sample (approximately 2–4 nmol in the supernatant and 20 nmol in the cells) and based on the mass-fragmentographic data indicating that practically only adrenaline and noradrenaline were released, we found it convenient in the experiments reported in Table 1 and Fig. 1 to assay the catecholamines (adrenaline + noradrenaline) with the spectrofluorimetric method[14].

Table 1 shows that morphine reduces the release of catecholamines elicited by the addition of a maximally active dose (10^{-5} M) of nicotine. This inhibitory action of morphine is dose related and is abolished by the presence of naltrexone, a potent opiate receptor antagonist. The peptides β-endorphin and FK33-824 (a stable analogue of enkephalin[15]; Sandoz) also produced a statistically significant dose-related inhibition of the nicotine-stimulated catecholamine release (Table 1). These peptides are several orders of magnitude more potent than morphine or Met-enkephalin (Table 1). The action of opiate receptor agonists cannot be due to an increase in the degradation rate of catecholamines because when ^{3}H-noradrenaline and ^{3}H-adrenaline were incubated for 3 min with the incubation media obtained from cells treated with opiate receptor agonists in the presence or absence of 10^{-5} M nicotine, no loss of ^{3}H-labelled catecholamines was measured. In addition, the effect of opiates cannot be due to changes in the cell catecholamine content because the cell content failed to change with the addition of opiate receptor agonists (20 ± 1.8 nmol per 10^6 cells in controls; 19 ± 1.5 nmol after 10^{-4} M morphine; 21 ± 2.0 after 10^{-7} M β-endorphin). These experiments suggest that opiate receptor agonists inhibit the release of catecholamines elicited by the stimulation of nicotinic receptors and that this action requires the availability of those receptor sites which are blocked by naltrexone. We then studied whether crude P_2 preparations of membranes obtained from chromaffin cell cultures contain specific sites for high-affinity binding of ^{3}H-Met-enkephalinamide and ^{3}H-naloxone (Fig. 1). The K_D values calculated from Scatchard plots of the saturation curves are 0.9 nM for Met-enkephalinamide and 3.2 nM for naloxone. These values are close to those calculated for opiate receptors present in brain membrane preparations[16].

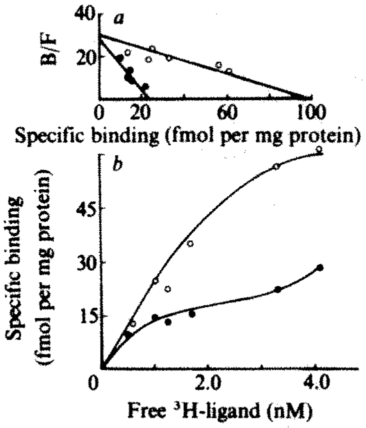

Fig. 1 Scatchard plots (*a*) and saturation curves (*b*) of ^{3}H-(D-Ala^2-L-Met^5)enkephalinamide (●) (37.7 Ci mmol^{-1}), and ^{3}H-naloxone (○) (14.6 Ci mmol^{-1}, both NEN) binding to cell membranes. The cells were homogenised in 50 mM Tris-HCl (*p*H 7.0) and the homogenate was centrifuged at 12,000*g* for 15 min. The pellet was resuspended in 50 mM Tris-HCl (*p*H 7.0) and preincubated at 25 °C for 1 h[16]. After the second centrifugation at 12,000*g* for 15 min, the pellet was resuspended in 50 mM Tris-HCl (*p*H 7.0). Specific binding was calculated by subtracting from the binding which occurred by incubating the pellet (approximately 100 μg protein) at 25 °C for 1 h with ^{3}H-labelled ligand, the binding which occurred by incubating with ^{3}H-labelled ligand plus 10^{-3} M morphine in a total volume of 600 μl. After incubation the reaction was terminated by centrifugation at 12,000*g* for 15 min. The supernatant was discarded and the pellet was rapidly rinsed with 1 ml of ice-cold 50 mM Tris-HCl (*p*H 7.0). The pellet was dissolved in 50 μl of NCS (Amersham tissue solubiliser) before counting the radioactivity with a liquid-scintillation counter. Proteins were determined with the method of Lowry[24]. B/F = [bound ^{3}H-ligand (fmol per mg protein)]/[free ^{3}H-ligand (nM)].

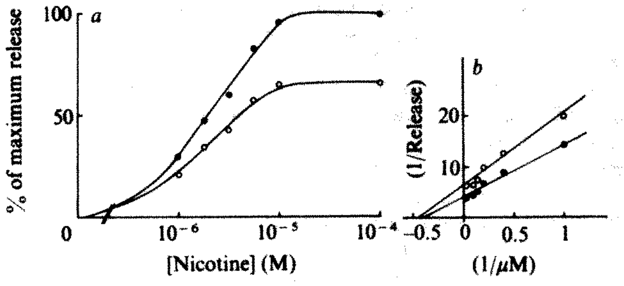

Fig. 2 Effect of morphine on the nicotine-induced release of endogenous catecholamines from cultured adrenal chromaffin cells. *a*, Release of endogenous catecholamines by various concentrations of nicotine in the absence (●) and presence (○) of 10^{-4} M morphine. *b*, Double-reciprocal plot of the data in *a*. The release of the endogenous catecholamines from cultured adrenal chromaffin cells was measured as described in Table 1. Morphine was added to the incubation medium 15 min before nicotine. Each point is the mean of two separate experiments in which triplicate samples were assayed. The error was less than 10% of the mean.

The release of catecholamines elicited by the stimulation of nicotinic receptors is inhibited by opiate receptor agonists (see Table 1) and by hexamethonium[11], but the mechanisms involved are different. Opiate receptor agonists act non-competitively (Fig. 2) whereas hexamethonium acts competitively[11,17]. Figure 2*a* shows that the nicotine-induced catecholamine release is decreased by about 45% in cells preincubated with 10^{-4} M morphine (Fig. 2*a*). The double-reciprocal plot (Fig. 2*b*) of the dose–response curve indicates that the extent of the maximal response decreases, but that the concentration of nicotinic agonist which gives half-maximal response fails to change.

Morphine (10^{-4} M) does not inhibit the release of catecholamines induced by the depolarisation of the cells with KCl (Table 1). Thus, it seems that in the chromaffin cell membranes, the stimulation of opiate receptor changes the function of nicotinic receptors by a specific mechanism. To characterise this mechanism further, we have investigated whether the stimulation of opiate receptors located in the chromaffin cell membranes can influence the number of available nicotinic receptors. In these studies, ^{125}I-α-bungarotoxin was used as the ligand for nicotinic receptors[18,19]. This ligand in a concentration of 10^{-8} M causes a 50% reduction of the release of catecholamine induced by 10^{-5} M nicotine. When morphine

(10^{-4} M) was added to the primary cultures of chromaffin cells it reduced the number of ^{125}I-α-bungarotoxin binding sites by approximately 80%. In untreated cells, the B_{max} for α-bungarotoxin binding was 3.1 fmol per mg protein; this value decreased to 0.65 in cells treated with morphine (10^{-4} M). The decrease in the B_{max} was not associated with a significant change in the affinity constant; the K_D values were 2.8 and 3.1 nM in normal and morphine-treated chromaffin cells, respectively. Similar results were obtained when the chromaffin cells were treated with FK33-824.

In conclusion, opiate receptors are present in the membrane of adrenal chromaffin cells. The activation of these receptors causes a non-competitive inhibition of catecholamine release elicited by the stimulation of nicotinic receptors. Our data indicate that β-endorphin, FK33-824 and Met-enkephalin reduce the action of nicotine by decreasing the number of available nicotinic receptors. This action is probably indirect and may involve an allosteric modulation of the recognition sites for ligands of nicotinic receptors. Based on these data, it is tempting to speculate that when the Met-enkephalin-like material present in terminals of splanchnic nerves[3-5] is released by nerve impulses, it modulates the release of catecholamines induced by nicotinic receptor stimulation elicited by the concomitant release of acetylcholine. A recept report[20] indicates that substance P inhibits nicotinic activation of the chromaffin cells. However, the physiological significance of the latter experiment is difficult to establish because evidence was not provided for the presence of substance P or a substance P-like material in splanchnic nerve terminals. The presence of opiate receptors on chromaffin cell membranes may also suggest a role for opiate peptides released into the circulation from the pituitary[21] or the adrenal cells[1,22]. Although these cells respond to several opiate peptides, including β-endorphin, this sensitivity is very low relative to their actual concentration in blood.

The precise mechanisms whereby the endogenous ligands of opiate receptors modulate the number of functional nicotinic receptor sites present in chromaffin cell membranes is unclear. It seems, however, that in chromaffin cells the opiate peptides that probably co-exist with acetylcholine in splanchnic nerves can disable the function of nicotinic receptors. Hence, it may be interesting to consider the possibility that 'co-transmitters' function as 'enablers' of the receptor function for the primary transmitter.

Amino acids evoke short-latency membrane conductance increase in pancreatic acinar cells

N. Iwatsuki & O. H. Petersen

Department of Physiology, The University, Dundee, UK

Sodium-gradient-driven amino acid transport is regarded as an important mechanism for cellular uptake in general as well as in pancreatic acini[1-6]. Electrophysiological experiments in kidney tubules and intestine have revealed that amino acids can cause sodium-dependent membrane depolarisation[7-11]. The mechanism of this depolarisation is unknown[10] as it is uncertain whether the depolarisation is accompanied by a membrane conductance increase[9,11]. The pancreatic acinar tissue would seem to be an ideal system for investigating the electrophysiological mechanism of action of amino acids because (1) the pancreas is the most active amino acid-accumulating tissue[12], (2) the basic electrophysiology of the pancreatic acinar cells is well characterised[13] and (3) a direct comparison can be made in the same cells between the electrical actions of the pancreatic secretagogues and the amino acids. We now show that L-alanine evokes a stereospecific membrane depolarisation accompanied by an increase in membrane conductance and that this membrane effect has a much shorter latency than the secretagogue response. The null (equilibrium) potential for the amino acid-evoked potential change corresponds to the sodium equilibrium potential.

Two separate KCl-filled microelectrodes were inserted into neighbouring cells in the same acinus of mouse pancreas (under visual control using a Zeiss (Jena) phase contrast microscope (×400) with long working distance) *in vitro* as previously described[14,15]. Up to two extracellular micropipettes were used for local application of acetylcholine (ACh), L- or D-isomers of alanine, L-proline, L-valine or L-glutamate. The substances were ejected from the pipettes by ionophoresis using a similar procedure to that used for local application of peptide secretagogues[16]. The composition of the physiological saline solution, prewarmed to 37 °C, flowing through the bath, was (mM): NaCl, 139; KCl, 4.7; $CaCl_2$, 2.56; $MgCl_2$, 1.13; D-glucose, 2.8; Tris, 3. *p*H was adjusted to 7.4 with HCl and the solution was gassed with 100% O_2.

Figure 1*a* shows membrane depolarisations evoked by microionophoretic application of L- and D-alanine. Although the same amino acid concentrations, stimulus parameters and relative positions of the micropipettes were used, the effect of D-alanine was small and inconspicuous compared with that of L-alanine. This was consistently found in 10 different experiments. The L-alanine-induced depolarisation resembled the depolarisation induced by secretagogues such as ACh, cholecystokinin-like peptides and bombesin-like peptides[13-16]. However, a close examination of the time course of the potential changes (Fig. 1*b*) revealed that the L-alanine-evoked membrane effect had a much shorter latency than the ACh-induced depolarisation. The minimum latency for muscarinic receptor activation of pancreatic acinar[17] as well as other cells[18] is about 0.3–0.5 s. Similar values have been found with peptide secretagogue-evoked effects[16]. In contrast, the latency for the action of L-alanine was <50 ms (the latency may well have been much shorter, but the artefact caused by the onset of the ejecting ionophoretic current unfortunately obscured the initial 50 ms of the potential recording). Also, in spite of the shorter delay of the amino acid effect (Fig. 1*b*) the rise-time was much longer than for ACh. These short-latency responses to L-alanine stimulation were observed in all 14 experiments of this kind carried out. The short-latency responses to L-alanine application show that there is no substantial diffusional barrier to close ionophoretic drug

0028-0836/80/050492—03$01.00

application and that therefore the relatively long latency for the action of ACh is genuine. The long latencies for secretagogue actions in the pancreas may be related to the time taken for an intracellular messenger, calcium, to reach a sufficient concentration to initiate the response[19]. Although the effect of ACh was blocked by atropine (1 μM), this had no effect on the L-alanine-evoked depolarisations (three experiments). Other amino acids were also tested, and L-valine (Fig. 2), L-proline, L-leucine and L-serine had effects similar to that of L-alanine. The latencies of the effects of L-valine and L-proline were determined in five experiments. In all these cases, short latencies of the same order of magnitude as found for L-alanine were observed. L-glutamate, however, had no effect on the bioelectrical properties in the five experiments in which it was tested.

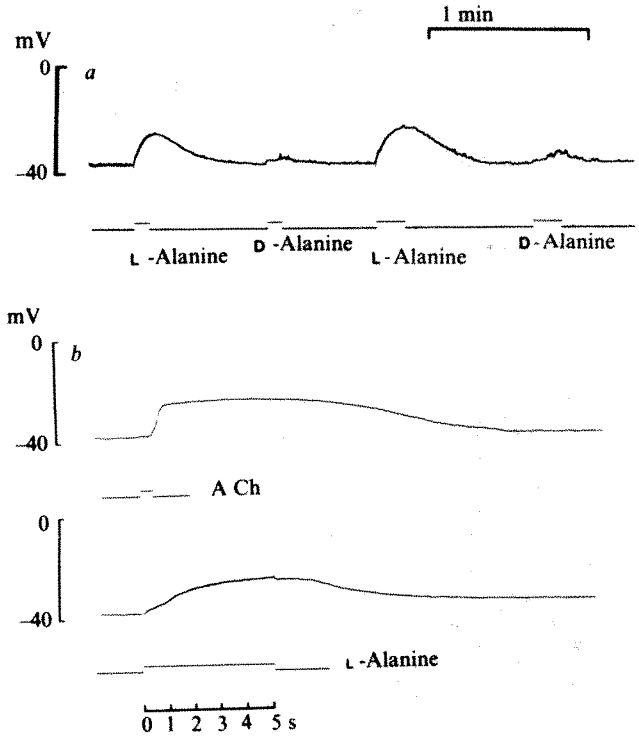

Fig. 1 *a*, Effects of ionophoretic L-alanine and D-alanine applications on the membrane potential in the same acinar cell (atropine (10^{-6} M) present). Micropipettes were filled with either 1 M L- or D-alanine (Sigma) dissolved in 0.9% NaCl (*p*H 4.0). The marker signals in the bottom trace indicate periods of L- or D-alanine ejection near to the surface of the impaled acinar cell, using positive ejecting currents of 100 nA and 5 s (short marker signals) or 10 s (longer marker signals) duration. No retaining current was used. *b*, Measurement of latency of responses to ionophoretic application of acetylcholine (ACh) and L-alanine from the same pancreatic acinar cell. Two extracellular micropipettes, filled with 2 M AChCl and 1 M L-alanine, respectively, were placed very close to the acinus impaled by the KCl-filled recording electrode. Upper trace: ACh stimulation was applied by a positive current of 80 nA (retaining current 20 nA) for 500 ms. Lower trace: L-alanine ionophoresis was applied by a positive current of 800 nA (no retaining current) for 5 s. The latency was taken as the interval between the start of the stimulus artefact and the take-off point arising from the depolarisation of the impaled acinar cell. A latency of 300 ms was found in the upper trace. The lower trace (L-alanine) shows the beginning of cell depolarisation less than 50 ms after the start of L-alanine ejection. The two traces are excerpts from a single continuous membrane potential recording from one cell.

We then tested the effect of superfusing the pancreatic acinar tissue with solutions containing known concentrations of L-alanine. At 0.1 mM, L-alanine caused a depolarisation of 3.3 mV ± 0.3 (s.e.)($n=7$), a 1-mM concentration depolarised the acinar membrane by 7.3 mV ± 0.2 ($n=6$), and at 10 mM, L-alanine evoked a reduction in membrane potential of 17.6 mV ± 1.0 ($n=7$). The effect of 20 mM L-alanine was not significantly different from that obtained at 10 mM (18.5 mV ± 0.5 ($n=5$)).

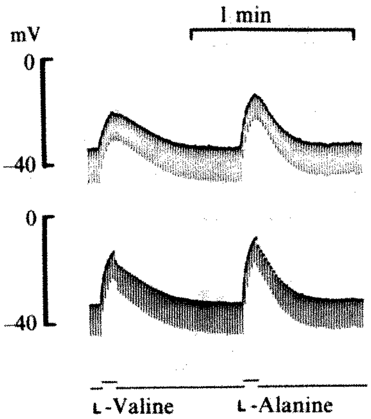

Fig. 2 Effects of microionophoretic application of L-valine and L-alanine on membrane potential and resistance in two electrically coupled neighbouring acinar cells. Current pulses (1 nA, 100 ms duration) were injected through the microelectrode recording the membrane potential represented by the lower of the two potential traces. Current pulses (500 nA and 5 s duration) were passed through the two extracellular micropipettes filled with 0.5 M L-valine or 1 M L-alanine, respectively, at marker signals in the bottom trace. The sudden small potential change corresponding to the end of ejecting current pulses seen in the lower potential trace represents the current artefact. (It is not seen in the upper trace, because that membrane potential was recorded using a differential amplifier.) Resting input resistance was 12 MΩ in this case. During the ionophoretic applications of L-valine and L-alanine the resistance was reduced to 10 and 8.5 MΩ, respectively.

The depolarisation evoked by L-alanine or L-valine was accompanied by a reduction in membrane resistance (Fig. 2). This was a consistent finding in the several hundred experiments carried out with L-alanine and the eight experiments with L-valine. Dose–response curves for L-alanine-evoked depolarisation and resistance reduction followed each other closely. The maximal reductions in input resistance obtained were to about 50% of the pre-stimulation value.

Replacing all the superfusion fluid Na by Tris (16 experiments) or Li (6 experiments) in all cases resulted in an immediate reduction in the amplitude of the L-alanine-evoked depolarisation. This effect was immediately reversible on re-admission of Na to the bath.

Figure 3 shows an attempt to determine the null (reversal) potential for the L-alanine-evoked potential change. In all seven experiments of the kind shown in Fig. 3, an approximately linear relationship between membrane potential and amplitude of L-alanine-evoked depolarisation was observed. An actual reversal of the potential change could not, however, be obtained because it proved impossible to attain membrane potentials

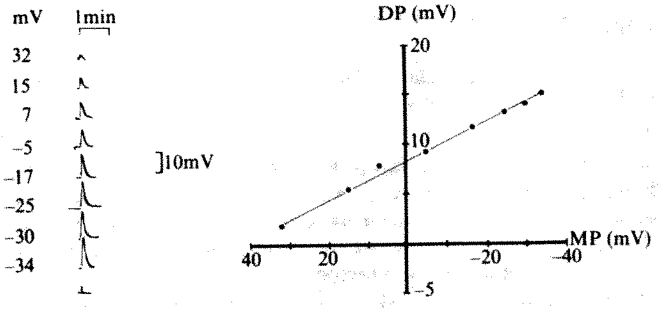

Fig. 3 To the left is shown the effect of L-alanine ionophoresis (1,000 nA ejecting 2 s duration) on the membrane potential of an acinar cell at different levels of resting potential (figures written to the left of individual records) in the same cell. Higher and lower resting potentials were obtained by passing direct hyper- or depolarising current, respectively, through a microelectrode inserted into an electrically coupled neighbouring cell. The L-alanine-evoked potential changes, plotted as a function of resting potential, are shown to the right. DP, depolarisation; MP, membrane potential.

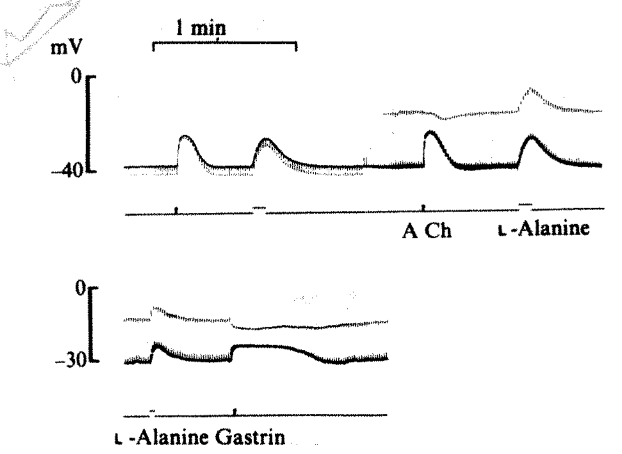

Fig. 4 Comparison of the membrane effects of L-alanine with ACh or gastrin in the same cells. In the upper trace ACh and L-alanine applied from two separate micropipettes by ionophoresis (80 nA, 0.5 s and 800 nA, 5 s, respectively) evoked depolarisations of similar size. During the first ACh and L-alanine stimulation, small hyperpolarising current pulses were repetitively injected through a microelectrode inserted into a neighbouring cell. Thereafter, the polarity of the injected current pulses was switched and the intensity increased (to 7 nA, 100 ms). In this way, the action of ACh and L-alanine could be simultaneously assessed at the spontaneous resting potential (heavy trace) (about −40 mV) and the artificially lowered potential (interrupted trace) (about −14 mV). The reduction in resting potential from −40 to −14 mV just reversed the polarity of the ACh-evoked membrane change, whereas the L-alanine-evoked depolarisation was only slightly reduced. The lower trace shows a similar comparison between L-alanine and gastrin actions in another cell. Gastrin was added directly (3.5 nmol) to the bath. At −30 mV, both substances evoked depolarisation. At −13 mV, the gastrin response was reversed but the L-alanine response was only slightly reduced in amplitude.

beyond +40 mV by direct current injection. Extrapolation of the linear curve in Fig. 3 to the intersection with the membrane potential axis (x-axis) revealed a null (reversal) potential of +40 mV. Values ranging from +20 to +60 mV were found in the other six experiments. These values are vastly different from the reversal potential of −10 to −20 mV repeatedly observed for the potential changes evoked by several different pancreatic secretagogues[14,16]. The null potential for the secretagogue action of about −15 mV has previously been shown to be due to increases in both chloride and sodium conductance, with some contribution also from potassium[14]. Figure 4 shows that current-evoked membrane depolarisations just sufficient to cause reversal of the effects of ACh or gastrin fail, in the same cells, to reverse the L-alanine-evoked depolarisation. In mouse pancreatic segments superfused *in vitro*, the intracellular sodium concentration, $[\mathrm{Na}]_i$, is about 42 mM (ref. 20), therefore, the Na equilibrium potential (E_{Na}) at 37 °C is about +33 mV. The null (reversal) potential for the action of L-alanine seems to be very close to this value. Null potentials (extrapolated) of +20 to +40 mV were estimated for L-valine and L-proline in four experiments similar in nature to that shown in Fig. 3.

Several L-amino acids are able to evoke marked membrane depolarisation of pancreatic acinar cells. This phenomenon is very different from the previously demonstrated electrophysiological effects of pancreatic secretagogues[13-16] in that the latency is much shorter and the null (reversal) potential much more positive (+40, rather than −15 mV). The clear resistance reduction (Fig. 2), together with the finding that the null potential has a value close to the calculated Na equilibrium potential, indicates that L-alanine, and several other amino acids, open up conductance pathways in the plasma membrane mainly permeable to Na.

Induction of interferon in AKR mice by murine leukaemia viruses

Kenneth J. Blank

Department of Pathology, University of Pennsylvania, School of Medicine, Philadelphia, Pennsylvania 19104

Donna Marie Murasko

Department of Microbiology, The Medical College of Pennsylvania, Philadelphia, Pennsylvania 19129

A high percentage of AKR mice develop spontaneous leukaemia which has been shown to be associated with the early expression of ecotropic murine leukaemia virus (MuLV)[1] and the subsequent expression of xenotropic[2] as well as polytropic[3] MuLVs. Generally, mice infected with any one of several groups of viruses, including MuLVs, have been shown to produce interferon (IF)[4]. However, we report here that AKR mice produce no IF, despite that fact that infectious, endogenous MuLV is expressed in these mice from birth[5].

Three possible reasons for the lack of IF in AKR mice can be considered: (1) a genetic deficiency in their ability to produce IF in response to MuLV; (2) the particular MuLV produced by AKR mice is not an inducer of IF; (3) the chronic production of MuLV in AKR mice interferes in some way with the induction or production of IF. The last possibility is suggested by previous studies demonstrating that mice chronically infected with lymphocytic choriomeningitis virus produce substantially less IF in response to inoculation of Newcastle disease virus than do uninfected controls[6].

These three possibilities were examined in the experiments described in Table 1 legend. AKR, B10.K, BALB/c and NFS mice were infected with virus derived from preleukaemic AKR mice (AKR-P) or with other MuLVs. Sera were collected from these mice 6 and 24 h later and IF titres in the sera were measured by a modification[7] of the microplate method described by Havell and Vilček[8]. Mice from strains other than AKR were included in this study because, unlike AKR, they do not chronically produce endogenous, infectious ecotropic MuLV. In addition, NFS ($Fv\text{-}1^n/Fv\text{-}1^n$) mice were included to eliminate any possible effect of *Fv-1* (ref. 9), as N-tropic AKR-P virus does not replicate well in cells from B10.K or BALB/c mice because of their $Fv\text{-}1^b/Fv\text{-}1^b$ genotypes. The Gross virus (GV) and Friend virus (FV) used in these studies were N→NB tropic, and thus replicate equally well in mice from strains homozygous for $Fv\text{-}1^n$ or $Fv\text{-}1^b$.

The results shown in Table 1 indicate that there is no genetic deficiency in AKR mice to prevent production of IF and that chronic expression of AKR-P does not interfere with IF production in AKR mice, as these mice produce IF after inoculation with GV or FV. It seems, however, that AKR-P virus does

Table 1 Induction of interferon in different mouse strains by various murine leukaemia viruses

Virus	Time (h)	Titre of interferon in: AKR	B10.K	BALB/c	NFS
—	0	<15	<15	<15	<15
GV	6	<15	<15	<15	<15
AKR-P	6	<15	<15	<15	<15
FV	6	20	30	20	<15
BALB/c ext.	6	<15	<15	<15	<15
GV	24	720	180	120	360
AKR-P	24	<15	<15	<15	<15
FV	24	420	600	240	260
BALB/c ext.	24	<15	20	<15	<15

AKR/J mice (Jackson Laboratory), aged 2–3 months, and C57BL/10-H-2^k (B10.K), BALB/c or NFS (bred in our colony) were inoculated intraperitoneally with 0.2 ml of various virus preparations. Virus preparations were 10% cell-free extracts of spleen from: leukaemic BALB/c mice infected with N → NB tropic Gross virus (GV) or N → NB tropic Friend virus (FV); preleukaemic AKR mice (AKR-P); or normal BALB/c. Virus titres (plaque-forming units per ml) determined in the XC assay[9] were: FV, 2.2×10^6; GV, 4×10^4; AKR-P, 6×10^4; BALB/c, 2×10^0. Mice were bled at 6 and 24 h after inoculation of virus. Sera of two or three mice per group were pooled and assayed for the presence of IF by the microplate method of Havell and Vilček[7], as modified by Armstrong[8]. Briefly, 50,000 L cells were added to wells containing serial twofold dilutions of sera. The cells were challenged 24 h later with encephalomyocarditis virus at a multiplicity of 0.2. Changes in cytopathology were recorded 24 h later. Titres were expressed as the highest dilution which protected half of the cells against virus-induced cytopathology. This was expressed as 1-ml volumes and corrected against mouse IF reference standard G002-904-511 distributed by the Reference Reagents Board of the National Institute of Allergy and Infectious Diseases, Bethesda, Maryland. The values given are the average of results from two sets of assays. Neutralisation of IF activity of the samples was as described by Paucker *et al.*[13]. The IF induced by GV and FV in all strains of mice was totally neutralised by sheep anti-type 1 mouse fibroblast IF antiserum.

not induce IF, because none of the strains of mice studied produced detectable amounts of IF after inoculation with this virus. As the titre of AKR-P virus was similar to that of the GV preparation as measured in the XC assay[10] (see Table 1 legend), the lack of IF induction by AKR-P virus cannot have been caused by differences in the amount of virus inoculated.

One possibly relevant distinction between the non-IF-inducing AKR-P virus and the IF-inducing GV is that the latter was derived from leukaemic AKR mice. It was therefore necessary to determine whether a recent virus isolate from leukaemic AKR mice (AKR-L) was capable of inducing the production of IF. The results shown in Table 2 indicate that the AKR-L virus preparation, similar to the AKR-P preparation, does not induce IF production in AKR (*Fv-l*^{n}/*Fv-l*^{n}) or DBA/2 (*Fv-l*^{n}/*FV-l*^{n}) mice. The difference in abilities of GV and FV on the one hand, and of the AKR-P and AKR-L viruses on the other, to induce IF, may reflect a change in the GV and FV during laboratory passage. It is interesting that, although live AKR viruses do not induce IF, a previous study has demonstrated that exogenous IF is effective in inhibiting endogenous MuLV production in AKR mice[11].

Table 2 Induction of interferon by virus from leukaemic and pre-leukaemic AKR mice

Virus	Time (h)	Titre of interferon in AKR	DBA/2
—	0	<15	<15
AKR-P	24	<15	<15
AKR-L*	24	<15	<15
GV	24	80	135
FV	24	150	90

For techniques, see Table 1 legend. Titres are the average of the results from two sets of assays.

* 10% Cell-free extract of spleen from leukaemic AKR mouse (AKR-L). Virus titre as determined in the XC assay: 3×10^4 ml^{-1}.

It is thought that during gestation of AKR mice a small number of cells begin to express virus spontaneously[12]. Virus produced by these cells then infects other cells which in turn produce virus, and a cascade effect results. If AKR virus did induce IF production by infected cells, the progression of the infection might be aborted because of the protective effect of IF. Thus, it is interesting to speculate that in selecting for a strain of mice with a high incidence of spontaneous leukaemia, Furth may have selected for a strain (AK) which produces an MuLV that, although sensitive to IF, does not induce IF.

D.M.M. is the recipient of a Junior Faculty Research Award from the American Cancer Society. Anti-IF antiserum was provided by Dr Kurt Paucker. We thank Barbara Dalton and Marilyn Paucker for technical assistance.

Induction of secondary cytotoxic T lymphocytes by liposomes containing HLA-DR antigens

Steven J. Burakoff*, Victor H. Engelhard† James Kaufman† & Jack L. Strominger†

* Department of Pathology, Harvard Medical School, Boston, Massachusetts 02115
† The Biological Laboratories, Harvard University, Cambridge, Massachusetts 02138

It is evident that the gene products of the major histocompatibility complex (MHC) have a crucial role in the induction of cytotoxic T lymphocytes (CTLs) and as target antigens for CTLs[1–6]. Assessment of the precise molecular requirements for CTL induction and recognition, however, is difficult when intact cells are used as targets. Recently, in several model systems, it has been demonstrated that, after detergent solubilisation, cell-surface antigens can be isolated that retain the ability to stimulate a secondary CTL response. CTL stimulating activity has been isolated by detergent solubilisation from murine tumour cell plasma membranes[7,8] which co-purified with H-2 antigens through lentil lectin affinity chromatography and gel filtration[9,10]. Highly purified HLA-A and HLA-B antigens, from the human lymphoblastoid cell line JY, have been isolated and incorporated into well characterised liposomes[11]. Spleen cells from mice primed to JY cells developed cytolytic activity, specific for JY targets, after co-culture with these HLA-liposomes[12]. In these experiments it was observed that membranes which had been solubilised with deoxycholate and then dialysed to remove the detergent (reconstituted membranes) always stimulated greater cytolytic activity than did HLA-liposomes. At the time it was suggested that this disparity might reflect the loss of other antigens involved in CTL stimulation as a consequence of HLA-A and HLA-B purification. Data are presented here which demonstrate that other antigens are indeed able to induce secondary CTLs, independently of the HLA-A and HLA-B antigens. The results suggest that this activity is present on HLA-DR-associated molecules.

0028-0836/80/050495—03$01.00

L/6 mice were primed intraperitoneally with 2×10^7 Y cells 1–2 months and again 1 week before *in vitro* culture [12]. Spleen cells were then isolated and co-cultured for 5 days with various liposome preparations. Cytolytic activity was assessed by incubation of the effector cells with ^{51}Cr-labelled target cells. Reconstituted membranes were prepared by solubilisation of JY membranes in 0.5% deoxycholate, centrifugation at 100,000*g* for 1 h, and dialysis of the supernatant[11]. The 100,000*g* supernatant contained 80% of the membrane protein and 90% of the membrane phospholipid. Reconstituted membranes were selectively depleted of certain proteins by passage of the detergent-solubilised supernatant through anti-β_2-microglobulin–Sepharose or lentil lectin–Sepharose columns before dialysis. Material specifically eluted from the columns was reconstituted by dialysis after addition of JY lipid. Liposomes containing purified HLA-A and HLA-B antigens were prepared as previously described[11]. Briefly, the dried lipid was dispersed together with the purified protein in 0.5% deoxycholate, and the detergent was then removed by dialysis. Data indicate that the material eluted from the lentil lectin column also becomes associated with phospholipid vesicles (K. Parker, V.H.E. and J.K., unpublished). Equivalent amounts of dialysed material (based on A_{280} and phospholipid content) were centrifuged at 100,000*g* for 1 h and resuspended in a volume corrected for the amount of dilution which occurred on the columns. The pellets generally contained 80–90% of the detergent-solubilised phospholipid and protein[13].

The CTL-stimulating activity of these various preparations was assessed on JY targets at an effector: target ratio of 100:1 (Table 1). Reconstituted membranes stimulated far greater cytolytic activity than did liposomes containing only purified HLA-A and HLA-B antigens (compare samples 1 and 5). In addition, the flowthrough from the anti-β_2 column (sample 3) demonstrated CTL-stimulating activity. As assessed by inhibition of complement-dependent cytotoxicity, this preparation contained less than 0.005% of the original amount of the HLA-A and HLA-B antigens. However, passage of solubilised membranes over a lentil lectin column was sufficient to remove stimulating activity entirely.

Table 1 Only a portion of CTL-stimulating activity is removed by anti-β_2-microglobulin

Sample	HLA (μg ml^{-1})	% Lysis of JY
1. Reconstituted membranes	20	52
2. One pass over anti-β_2 column	0.5 (0.2%)	20
3. Two passes over anti-β_2 column	0.001 (0.005%)	16
4. One pass over lentil lectin column	0.9 (4.4%)	0
5. HLA-A and HLA-B liposomes	20	26

Fractions were prepared by solubilisation of 2.5 mg of JY membranes in 2 ml 10 mM Tris, 0.14 M NaCl and 0.5% deoxycholate, *p*H 8.0, followed by centrifugation at 100,000*g* for 1 h. The supernatant was either dialysed immediately against 10 mM Tris, 0.14 M NaCl and 5 mM $CaCl_2$, *p*H 7.8, or passed through anti-β_2-microglobulin–Sepharose or lentil lectin–Sepharose columns (0.5 ml each). The anti-β_2-microglobulin column had been equilibrated in solubilisation buffer, and the lentil lectin column was equilibrated in 10 mM Tris, 0.14 M NaCl, 0.1% deoxycholate, 75 μM $CaCl_2$ and 75 μM $MnCl_2$, *p*H 8.0. The flowthrough fractions were monitored by A_{280}, and fractions representing at least 85% of the recovered A_{280} were pooled. The extent of dilution of this material compared with the starting material was assessed by phospholipid analysis according to Ames[26]. The pooled material was then dialysed as described above. After dialysis all fractions were centrifuged at 100,000*g* for 1 h and resuspended in 1 ml 10 mM Tris, 0.14 M NaCl and 5 mM $CaCl_2$, *p*H 7.8, per ml of original detergent-solubilised supernatant. Aliquots of 50 μl was added to each 2-ml culture well. Lysis is expressed as per cent specific release of ^{51}Cr (ref. 2).

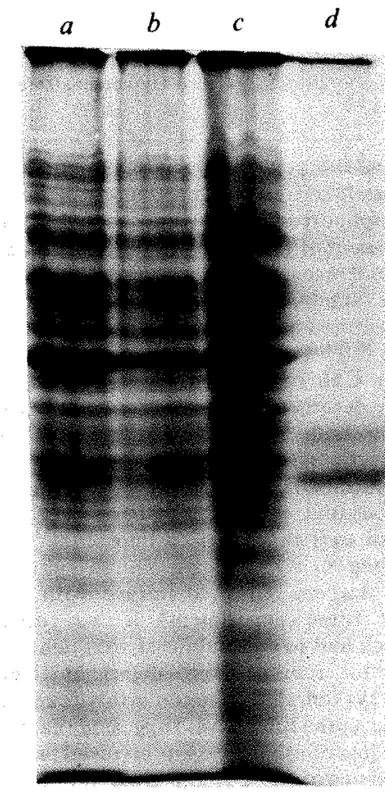

Fig. 1 12% SDS-polyacrylamide gel electrophoresis patterns of fractions from Table 2. Lane *a*, detergent-solubilised membrane supernatant; lane *b*, anti-β_2-microglobulin flowthrough; lane *c*, lentil lectin flowthrough; lane *d*, lentil lectin eluate.

SCIENCE COLLEGE
92, Upper Circular Road
CALCUTTA

Table 2 presents evidence that solubilised membrane proteins which flow through the anti-β_2 column and specifically bind to lentil lectin can stimulate CTL activity when incorporated into liposomes. SDS-polyacrylamide gel electrophoresis of fractions from Table 2 shows that although the flowthrough material from the anti-β_2-microglobulin and lentil lectin columns contained most of the protein bands present in the reconstituted membranes, the lentil lectin eluate consisted primarily of two polypeptide chains of molecular weights 29,000 and 34,000, with no detectable HLA-A and HLA-B band (Fig. 1). These polypeptides have previously been shown by various immunological and protein chemical criteria to correspond to the HLA-DR alloantigens, which are the human analogues of the murine Ia antigens[14,15]. Although other minor protein bands are present in the lentil lectin eluate, the presence of HLA-DR antigens as the major component of this material, coupled with previous reports of Ia- or HLA-DR-specific allogeneic CTL, suggest that these antigens represent the non-HLA-A and -B CTL-stimulating activity seen here.

We are currently investigating the specificity of the CTLs induced by these HLA-DR-containing liposomes. It is possible that CTLs are induced with specificity to HLA-A and HLA-B antigens or that these liposomes induce CTLs with specificity for HLA-DR antigens. These possibilities were tested as follows:

Table 2 The CTL-stimulating material which flows through the anti-β_2-microglobulin column can be specifically bound to and eluted from lentil lectin

Sample	% Lysis of JY
1. Reconstituted membranes	54
2. Two passes over anti-β_2 column	38
3. Above passed through lentil lectin column	4
4. 2% α-methyl mannoside eluate of lectin column	31
5. HLA-A and HLA-B liposomes	24

The procedure was the same as that described in Table 1 legend, except that the detergent-solubilised material was passed through the lentil lectin column only after passage through the anti-β_2-microglobulin column. In addition, the lentil lectin eluate was reconstituted after addition of 1 mg ml^{-1} JY lipid.

CTLs were induced with liposomes containing either HLA-A and HLA-B or HLA-DR. These CTLs were assayed on Daudi target cells, which are HLA-A and HLA-B negative but HLA-DR positive[16]. Only CTLs induced with HLA-DR liposomes lysed Daudi, suggesting that these CTLs have specificity for HLA-DR antigens (Table 3). We confirmed that the cytolytic activity observed on Daudi targets resided in the T-cell population by two criteria: cytolytic activity was eliminated by treatment of cells with anti-Thy 1.2 serum plus complement, and the effluent cells from nylon wool column passage (which removed ≥95% Ig$^+$ cells) retained cytolytic activity (data not shown). Preliminary experiments indicate that an antiserum raised against the highly purified HLA-DR complex (anti-p 29, 34)[17] and which recognises only these two chains by immunoprecipitation[14] blocks target cell lysis by CTLs stimulated with HLA-DR-containing liposomes.

Table 3 CTL induced with HLA-DR containing liposomes lyse Daudi target cells

Stimulator	Target JY	Target Daudi
HLA-A and HLA-B liposomes	66	5
HLA-DR liposomes	78	55

Spleen cells from C57BL/6 mice primed with JY were stimulated with either HLA-A and HLA-B or HLA-DR liposomes. These CTL were then assayed after 5 days on either JY or Daudi targets.

There have been several reports that CTLs can be generated to mouse allogenic Ia antigens[18-20]. It has also been observed that these Ia antigens are recognised by CTLs independently of H-2K and H-2D antigens[21,22]. Recently, several studies have shown that CTLs were generated in human mixed lymphocyte cultures between donors differing at the HLA-D/DR but not HLA-A and HLA-B loci[23-25]. These CTLs only lysed targets bearing HLA-DR region antigens (monocytes and Epstein-Barr virus-transformed peripheral blood lymphocytes).

In conclusion, non-HLA-A and -B cell surface antigens have been isolated from JY cells that are able to stimulate primed xenogeneic mouse spleen cells to exhibit cytolytic activity. These antigens seem to be HLA-DR antigens, the human equivalent of the mouse Ia antigens, and preliminary data suggest that the CTLs induced are specific for HLA-DR antigens. Further studies are in progress to define the specificity of the CTLs induced and to determine whether other biological functions are associated with these isolated HLA-DR antigens.

We thank Dr Baruj Benacerraf for his sustained encouragement and review of this manuscript, Mr John Riccio for technical assistance and Ms Teresa Greenberg for secretarial assistance. This work was supported by USPHS grants CA-14723 and AI-10736.

The joining of V and J gene segments creates antibody diversity

Martin Weigert, Robert Perry & Dawn Kelley

The Institute for Cancer Research, Fox Chase Cancer Center,
Philadelphia, Pennsylvania 19111

Tim Hunkapiller, James Schilling & Leroy Hood

California Institute of Technology, Division of Biology, Pasadena,
California 91125

The variable regions of mouse kappa (κ) chains are coded for by multiple variable (V) gene segments and multiple joining (J) gene segments. The V_κ gene segments code for residues 1 to 95; the J_κ gene segments code for residues 96 to 108 (refs 1–3). This gene organisation is similar to that encoding the V_λ regions[4]. Diversity in V_κ regions arises from several sources: (1) there are multiple germ-line V_κ gene segments and J_κ gene segments; (2) combinatorial joining of V_κ gene segments with different germ-line J_κ gene segments; and possibly, (3) somatic point mutation, as postulated for V_λ gene segments[5]. Also, from a comparison of the number of germ-line J_κ gene segments and amino acid sequences, it has been suggested that J_κ region sequences may be determined by the way V_κ and J_κ gene segments are joined[2,3]. This report supports this model by directly associating various J_κ sequences with given J_κ gene segments.

The number of germ-line J_κ gene segments has been estimated in two ways. A region of DNA containing J_κ gene segments has been characterised by DNA sequence analysis and was found to include five J_κ (or J_κ-like) gene segments, only four of which have been found to be expressed as J segments[2,3]. Additional J_κ gene segments have not been found, although their presence cannot be excluded rigorously. Alternatively, the number of J_κ gene segments may be determined by counting the number of distinctive RNA precursor patterns associated with different κ chain mRNAs[6]. Since the κ-mRNA precursors contain the intervening sequence between the J_κ and C_κ segments, they have a characteristic size depending on which J segment is used, the largest precursor corresponding to the J_κ segment most distal to the C_κ gene and the smallest to the most proximal J_κ segment. On this basis the RNA precursor patterns for 20 different myeloma tumours were classified into four different categories, corresponding to the four different J_κ gene segments that these chains use. The distances between the C_κ gene and the various J_κ gene segments deduced from the analysis of precursor patterns in NZB plasmacytomas agree with the distances determined by restriction mapping and DNA sequence analysis of BALB/c germ-line DNA. A previously suspected discrepancy[6] has been resolved by a more accurate calibration of the mobility data.

We have analysed κ chains of the V_κ 21 group from the NZB mouse strain. To date ten different J_κ amino acid sequences have been observed in twenty V_κ 21 examples (Fig. 1). Thus the

0028-0836/80/050497—03$01.00

Fig. 1 J segments associated with V_κ21 chains from NZB myeloma antibodies. J segments are numbered according to their processing category[6]. This is based on the relative sizes of the κ-mRNA precursors, as determined by gel-electrophoretic analysis of poly(A)$^+$ nuclear RNA. These precursors are approximately 5.3, 5.0, 4.4 and 4.1 kilobases for categories I, II, III and IV, respectively. The amino-terminal sequences (40 residues) of PC8701, PC8982 and PC10916 were determined on a modified Beckman sequenator as described previously[11] and were found to be representatives of the V_κ21 subgroups, D, C and C, respectively. The J segment sequence of these κ chains were determined as follows: each κ chain was subjected to mild acid cleavage[12] of the aspartylproline between residues 94 and 95. The peptide mixture was sequenced without separation after the amino-terminal peptide was blocked by addition of fluorescamine[13]. The rest of the sequences are taken from ref. 1. The germ-line J segments are defined as described in the text. J_1, J_2, J_3 and J_4 are coded for by the BALB/c embryo J gene segments termed J_1, J_2, J_4 and J_5 in ref. 2 or those termed J_5, J_4, J_2 and J_1 in ref. 3. The PC2413 J segment may be coded for by a germ-line J gene (or variant of a J gene) unique to the NZB mouse.

number of J_κ sequences appears to be greater than the number of germ-line J_κ gene segments. There are three types of J_κ sequence. First, four distinct types (J_1, J_2, J_3 and J_4) correspond to those coded for by four of the germ-line J_κ gene segments in BALB/c DNA. Each of these J_κ sequences has been observed two or more times in the NZB V_κ21 regions (Fig. 1). These J_κ sequences also have been observed in BALB/c κ chains[7] indicating that NZB and BALB/c germ-line J_κ gene segments code for the same J_κ regions. A second type of J_κ sequence differs by a single residue from those of the germ-line J_κ gene segments; these are termed variant J_κ sequences. There are five J_κ sequences of this type and each has been observed only once.

There are two possible explanations for the variant J_κ sequences: (1) they arise from somatic diversification which occurs at the junctional region during the joining of V_κ and J_κ gene segments or (2) they are encoded by additional germ-line J_κ gene segments that are absent from or have not yet been detected in the BALB/c genome. The former model predicts that the precursors of the mRNAs coding for these variant J_κ segments would belong to a category typical of one of the four germ-line examples; the latter model predicts a unique mRNA precursor for each variant. A third type of J sequence which occurs in the exceptional PC2413, differs from the other germ-line J_κ gene segments by at least two nucleotide substitutions.

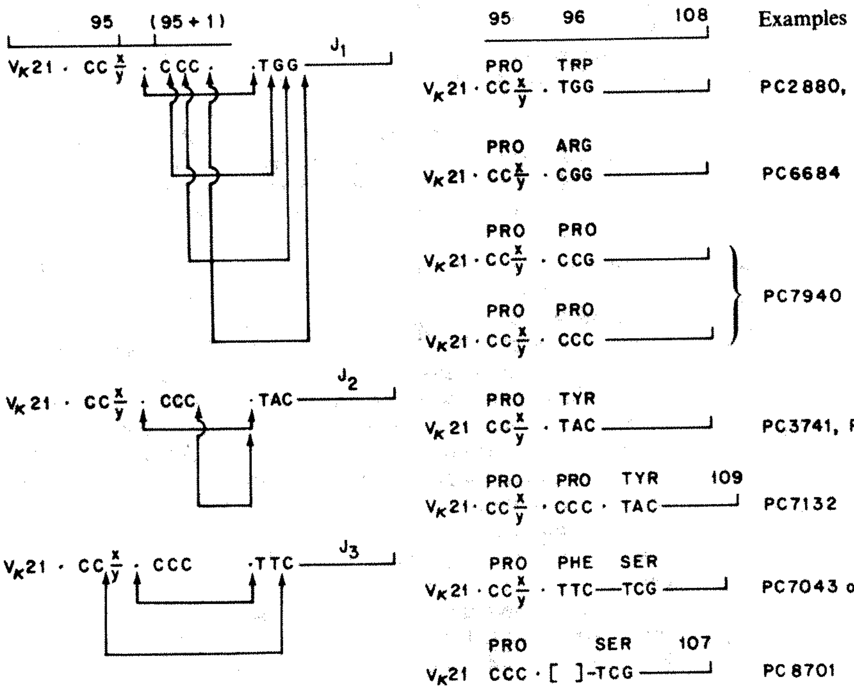

Fig. 2 Fusion of V_κ21 genes and J gene segments. The fusion can occur to join V and J gene segments exactly to form a contiguous V–J gene. Such genes will have germ-line J region sequences as in the case of PC2880, PC3741 or PC7043 and other examples[1]. Fusion to J genes might include nucleotides in the intervening sequence (95+1). If this codon is CCC for all V_κ21, then the variant sequences, PC6684, PC7940 and PC7132 can be explained by fusion to a J gene (PC7132), within a J gene (PC6684 and PC7940) or within a V gene (PC8701).

Differences of this extent raise the issue of whether the PC2413 J_κ sequence might be encoded by a fifth germ-line J_κ gene segment in the NZB mouse.

An analysis of the RNA processing patterns for the tumours producing κ chains with variant J_κ sequences indicates that each pattern belongs to one of the four categories characteristic of germ-line J_κ gene segments (Fig. 1). Thus it appears that these variant J sequences arise during the process of V_κ–J_κ joining.

Knowing the size of the mRNA precursor for a J_κ variant allows us to infer the kind of somatic mutation that could have produced the variant sequence. For example, both PC6684 and PC7940 mRNAs exhibit the J_1 type prescursor. Their J segments differ from the germ-line J_1 segment at position 96, presumably due to modifications of the tryptophan codon 96. PC7132 arose from the insertion of a proline codon before the J_2 gene segment. PC8701 resulted from a deletion of the phenylalanine codon at the beginning of J_3 gene segment. In addition to this junctional diversity, random point mutations either in the germ line or during somatic differentiation may occasionally occur (for example, PC8982).

The κ-mRNA precursor in PC2413 appears to belong to the category characteristic of the germ-line J_1 segment. Thus, if the J sequence of this tumour is actually encoded by a unique NZB germ-line J_κ segment, thus segment would have to be located very close to the J_1 segment, or alternatively, be associated with a second, as yet unidentified, C_κ gene.

The nature of most J_κ variants suggests that they may be due to variations arising from the V–J joining process because the substitutions, mutations, insertions or deletions generally occur at the beginning of J_κ segments. These variations may be explained by two base substitutions (for example, tryptophan to proline) as well as the insertion or deletion of codons. Thus this variation does not appear to arise merely by single-base somatic mutation. Leder and Tonegawa and their coworkers have recently observed identical inverted repeat sequences at the 3′ end of the V gene segment and at the 5′ end of the J gene segment. They have hypothesised that these inverted repeats may form paired stem structures that juxtapose the V and J gene segments and that recombination may occur across the base of this stem at slightly different points to generate V–J junctional diversity (refs 2 and 3 and Fig. 2). This site-specific recombinational model appears to explain the V–J junctional diversity that we have noted in the $V_\kappa 21$ chains.

By whatever mechanism V gene segments are translocated to J gene segments, a continuous DNA sequence coding for the entire V region must be generated[4]. Since all mouse κ chains studied to date have proline at residue 95 (CC_y^x), a V_κ gene segment translocation to the J_1 gene segment (tryptophan (TGG) at residue 96) will result in the contiguous DNA sequence, CC_y^x TGG at the V–J joining site (Fig. 2). Such a translocation will create a V_κ gene segment that is associated with the J_1 germ-line gene segment. This type of translocation explains five out of the twenty $V_\kappa 21$ regions observed (Fig. 1). Likewise, similar translocations between $V_\kappa 21$ gene segments and the J_2, J_3 and J_4 gene segments can explain the nine additional examples of germ-line J segments (Fig. 1).

The variant J segments may arise by recombination within rather than between the V gene segment codons for positions 95 or 95 + 1 and their counterparts in the J gene segments (Fig. 2). Codon 95 + 1 is CCC in several V_κ gene segments[2,8]. If the (95 + 1) codon is CCC for all $V_\kappa 21$ gene segments, the type of variation that may occur at the V–J joining site is limited. Amino acid substitutions at residue 96 for a $V_\kappa 21$–J_1 translocation can only be arginine (CGG) or proline (CCG) (Fig. 2). An amino acid insertion would result in an extra proline codon before the J gene segment. In addition, deletions of residue 96 could occur. As shown in Fig. 2, the variants observed so far fit the predictions of this model. If there is variation at the (95 + 1) codon, a greater variety of substitutions could occur at residue 96[3]. Obviously similar variation could occur in the (96 − 1) codon of the J gene segment. Additional analyses of $V_\kappa 21$ chains are under way to define more completely the amino acid sequence variability at the V–J junctional site.

In our survey of $V_\kappa 21$ chains, the frequency of κ chains expressing variant J segments relative to those expressing germ-line J segments is high (5 out of 20). This frequency could be high because the N-terminus of the J_κ segment is important for combining-site size and shape[9] and antigen selection of specific antibodies amplifies mutations that occur at a low frequency. (The uniformity of J_λ segments[10] may mean that variation in this region does not affect the complementarity of antibodies with λ chains.) Alternatively, this frequency may be a true reflection of the rate of variation by this mechanism.

Translation of globin messenger RNA by the mouse ovum

R. L. Brinster, H. Y. Chen, M. E. Trumbauer & M. R. Avarbock

Laboratory of Reproductive Physiology, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania 19104

It has been demonstrated that the *Xenopus* oocyte can translate rabbit haemoglobin messenger RNA (mRNA) following microinjection of the message into the cell[1]. The *Xenopus* oocyte has since been shown to be capable of translating a variety of messenger RNAs from different species[2–4]. This system has proved useful in understanding the mechanism of message translation and has also provided information about the translation capability of the *Xenopus* oocyte[5,6]. Several other cell types, including HeLa cells and fibroblasts, can also translate exogenous message injected into the cell[7,8]. However, there have been no reports of injection of mRNA into oocytes or fertilised one-cell ova of mammalian species. Nevertheless, the latter system could be of considerable use in studying the processing of exogenous messages in a mammalian system undergoing development, as well as providing insight into the way the early embryo processes injected messages and the protein products of such messages. We report here the results of injecting message into the fertilised one-cell mouse ovum and show that both mouse and rabbit globin mRNA are translated in this system.

Fertilised one-cell mouse ova were collected following superovulation from hybrid C57 × SJL females on the day of the vaginal plug by techniques described previously[9]. The ova were collected in Brinster's medium for ovum culture (BMOC-2, see ref. 9) and the cumulus cells removed with hyaluronidase (300

0028-0836/80/050499—03$01.00

$^{-1}$) in phosphate-buffered saline[9]. After washing to remove cumulus cell debris, the ova were maintained in BMOC-2. Purified mRNA for these experiments was prepared by the method of Gorski *et al.*[10] except that polysomes were dissociated with SDS and applied directly to oligo(dT)-cellulose as described by Krystosek *et al.*[11]. For injection, the ova were placed on a depression slide and held with a blunt pipette as shown in Fig. 1. The tip of the injector pipette was filled with a solution of mRNA in water (1 mg ml^{-1}) and a small amount of solution was injected into each ovum. The average volume injected was determined by injecting ^{3}H-inulin into several groups of ova and measuring the radioactivity found in each ovum. On the basis of these measurements, the average volume injected into each ovum was estimated to be 13 pl. Some of the ova underwent lysis during the 15–30 min after removal of the injector pipette and release of the ovum from the holder. The survival rate was 30–40%, and it was found that injection of the ova in medium containing cytochalasin B (5–10 μg ml^{-1}) approximately doubled the chance of survival. Each group of 20–40 injected ova was placed in BMOC-2 containing a mixture of five ^{3}H-labelled amino acids (leucine, lysine, phenylalanine, proline, tyrosine; specific activities 75–120 Ci mmol^{-1}; Amersham Searle) for 15–17 h, during which time approximately one third of the one-cell ova divided into two cells. Generally, about 80% of one-cell ova will cleave during this period, but the high level of radioactivity necessary for labelling decreased the number of ova undergoing cleavage. After labelling, the ova were washed three times in media containing non-radioactive amino acids, placed in a 6 × 60 mm tube and stored at −70 °C. To determine whether globin had been synthesised from the injected message, non-radioactive globin marker was added to the tube, and the proteins were separated by two-dimensional high-resolution electrophoresis[12].

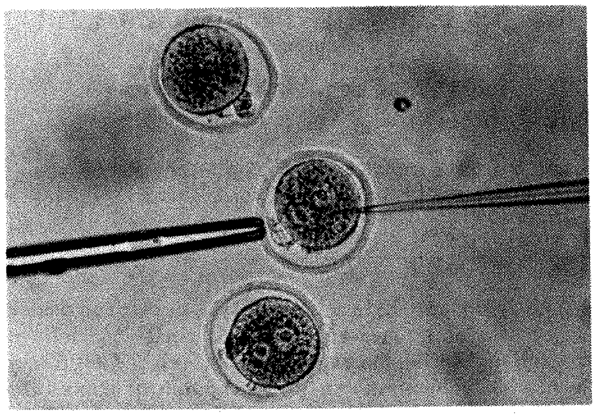

Fig. 1 Injection of one-cell mouse ovum with mRNA. The ovum was held with a blunt suction pipette (5 μm i.d., 20 μm o.d.). The o.d. of the injector pipette was 2–3 μm, and the tip was sharpened either by chipping or grinding. The ova were maintained on a depression slide in culture medium under silicone oil. The injection solution drop, from which the injector pipette was filled, was adjacent to the medium containing the ova. The technique was similar to that used for injecting cells into blastocysts[15].

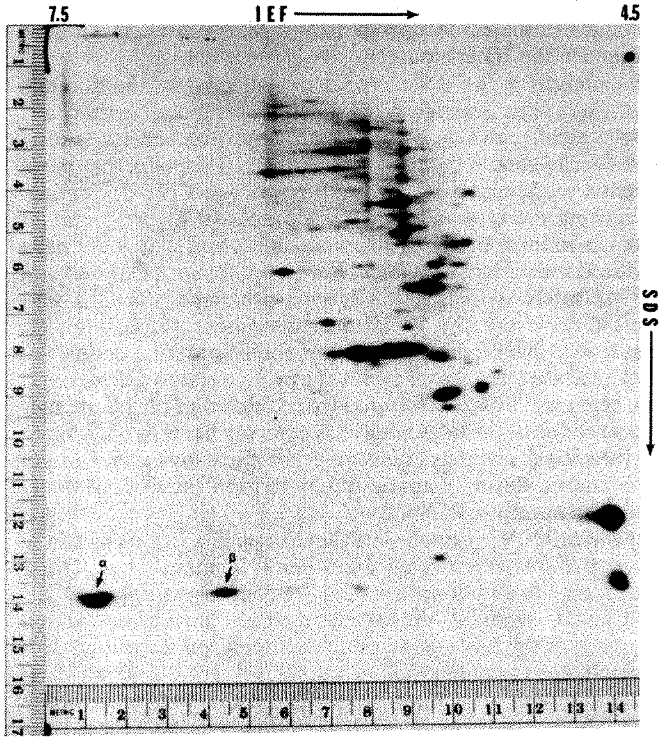

Fig. 2 Fluorograph of two-dimensional electrophoretic separation of proteins from 20 one-cell fertilised mouse ova injected with mouse globin mRNA and incubated in ^{3}H-labelled amino acids. Isoelectric focusing (IEF) was from left (*p*H 7.5) to right (*p*H 4.5) and SDS-polyacrylamide electrophoresis was from top to bottom. The technique used was basically that of O'Farrell, as previously described[12,16]. The IEF was carried out with *p*H 3–10 ampholines. Marker proteins on the right margin are lactoglobulin (top, MW = 18,400) and methaemoglobin (bottom, MW = 16,000). The two radioactive spots indicated by the arrows coincide with the position of the non-radioactive globin marker protein prepared from mouse blood. α and β indicate the positions of α- and β-chains of globin.

Figure 2 shows a typical fluorograph of the electrophoretic separation of synthesised proteins following injection of ova with mouse globin mRNA. Two major radioactive spots, indicated by arrows, co-migrated with non-radioactive globin marker prepared from mouse blood. Injection of message into mouse oocytes yields a similar pattern (unpublished). The other spots on the fluorograph are endogenous proteins. On control gels from ova not injected with mRNA there are no radioactive spots in the area of globin migration, indicating the absence of endogenous labelled protein in this area that might confuse the interpretation of the fluorographs (Fig. 3). When the non-radioactive markers are separated on isoelectric focusing (IEF) gels and stained for protein, each of the major spots is composed of two closely migrating but clearly distinct bands. This separation, although less apparent in the second dimension, can sometimes be seen in the radioactive spots such as the most basic of those in Fig. 2. No globin marker bands are present in the IEF gel at a more basic position than those shown in Fig. 2. The absence of such bands was confirmed by non-equilibrium *p*H gradient electrophoresis (unpublished observations); in this procedure the migration is from the acidic end and can be stopped at various positions before reaching the basic end[13]. Thus, the technique used for the egg proteins is capable of identifying the location of all the globin chains synthesised from the injected message.

When rabbit mRNA is injected into the ova, the pattern is slightly different. As shown in Fig. 4, only one major globin spot is present. This major spot seems to be composed of two sub-bands, similar to the situation for the mouse globin. However, because of the high level of radioactivity, it generally appears as one spot in the photographs of the fluorograph. By reference to purified globin markers for mouse α- and β-chain and for rabbit α- and β-chain, the large basic spot in Figs 2 and 4 was identified as α-globin for both the mouse and rabbit mRNA. The more acidic spot from the mouse globin mRNA is β-globin. No β-globin spot, which would be located in approximately the same position as the mouse β-globin, can be detected in Fig. 4.

However, other studies suggest that a low level of rabbit β-globin synthesis does occur (unpublished observations).

When ova were injected with either mouse or rabbit message at the one-cell stage, cultivated *in vitro* to the blastocyst stage (5 days) and then labelled with ^{3}H-amino acids, fluorographs showed no indication of globin synthesis. In fact, preliminary studies suggest that globin synthesis is not detectable 48 h after message injection. However, some globin is synthesised when labelling begins 24 h after message injection. A precise half life of the injected message can only be determined following more detailed investigation to identify the saturating level of message and the lag time before the message is active. However, it is clear that the mRNA half life in mouse ova is considerably shorter than that in *Xenopus* oocytes, where globin message has been shown to retain its activity for 2 weeks or longer[14]. Clearly, the cell type containing the message profoundly influences its stability. These studies do not indicate whether the message is degraded or is converted to a non-translatable form. Although the former possibility seems the more likely, the presence of masked message in the embryo makes the latter an intriguing possibility.

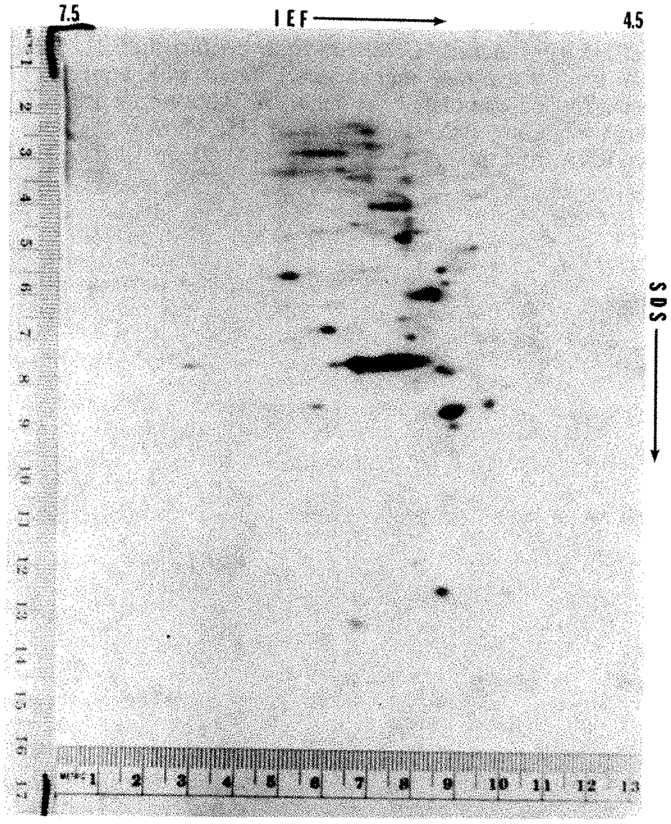

Fig. 3 Fluorograph of two-dimensional electrophoretic separation of proteins from 20 one-cell fertilised mouse ova injected with water. Techniques used were similar to those for Fig. 2. No radioactivity appears in the area of globin migration.

These observations on the translation of globin message by the mouse ovum identify an important new system in which to study the activity of mRNA and the synthetic products of the message. Although having some similarities to the *Xenopus* oocyte, the system shows several differences. For instance, the mouse cells are mammalian rather than amphibian and are actively dividing rather than dormant or static as is the *Xenopus* oocyte. The unique characteristics of each system may provide different answers to the same question. The large difference found between the two cell types in the stability of injected globin message is one example. Another is the preponderance of synthesis of α- relative to β-chains in the mouse ovum; the relative synthesis is just the opposite in the *Xenopus* oocyte. The injection of exogenous messages into the mouse ovum should help in understanding message stability and activity in the developing mammalian embryo, as well as providing a means of studying translational activity and specific protein stability in the embryo.

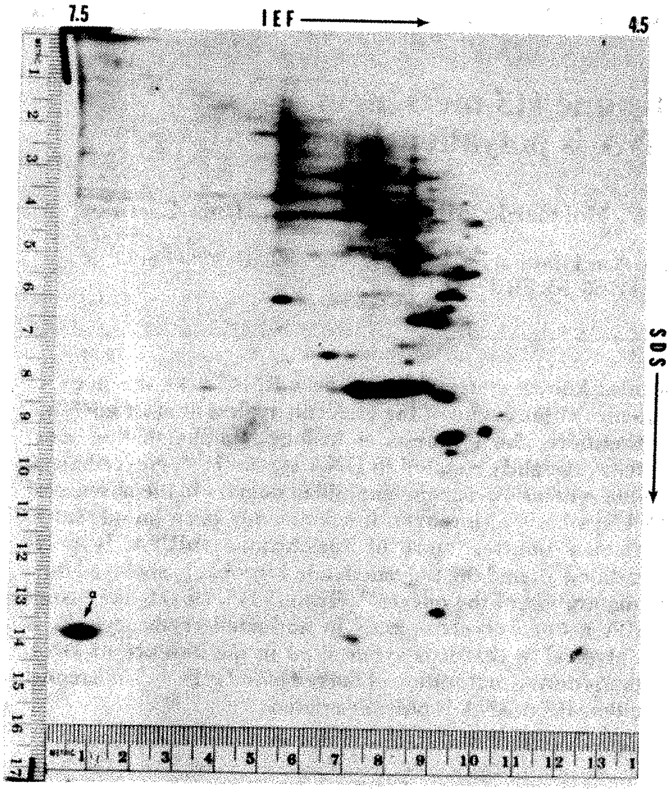

Fig. 4 Fluorograph of two-dimensional electrophoretic separation of proteins from 20 one-cell fertilised mouse ova injected with rabbit globin mRNA. Techniques used were similar to those for Fig. 2. The single radioactive spot indicated by the arrow coincides with the position of the non-radioactive globin marker protein prepared from rabbit blood. α Indicates the position of the α-chain of globin. No β-chain was detected on the fluorograph.

Messenger RNA was supplied by Dr J. B. Lingrel, and purified globin markers by Dr Raymond Popp. This work was supported by NIH grants HD 08539, HD 12384 and NSF grant PCM 78-22931. H.Y.C. is a trainee on HD 00239.

Histone H5 messenger RNA is polyadenylated

H. V. Molgaard*, M. Perucho† & A. Ruiz-Carrillo‡

Max-Planck-Institut für Molekulare Genetik, D-1000 Berlin 33,
Ihnestr. 63–73, FRG

In most known systems[1,2], histone mRNA lacks the poly(A) sequence at the 3′ end of the molecule typical of most mRNAs. Furthermore, the synthesis of histones, unlike that of most proteins, is tightly coupled to DNA synthesis[3–5]. Nevertheless, histone synthesis occurs in amphibian oocytes in the absence of DNA synthesis[6]. Moreover, it has recently been found that in amphibian oocytes most of the histone mRNA is polyadenylated[7–9], and the polyadenylate is probably removed during maturation of the oocyte[10]. Histone H5, an H1-like tissue-specific histone occurring only in nucleated erythrocytes[11], is also atypical in that it is synthesised in the absence of DNA synthesis during maturation of the red blood cells[12,13]. We report here that H5 mRNA is polyadenylated.

RNA from anaemic chicken blood was enriched in H5 mRNA by immunoprecipitation of isolated polysomes[14], essentially as described by Groner *et al.*[15]. In one experiment polysomes were isolated and immunoprecipitated as described by Scott & Wells[16]. The result of passing total polysomal RNA, enriched for H5 mRNA, over poly(U)-Sepharose is shown in Fig. 1*a*. In this sample there is little evidence of translatable H5 mRNA in the unbound material (lane 4) and only a trace in the 5% formamide eluate (lane 5). The bulk of the translation product, which migrates at the same mobility as *in vitro*-labelled H5, occurs in the translation product of the fraction eluted by 90% formamide (lane 6). In Fig 1*b* a similar result is shown with a different sample of RNA which had been further purified by size fractionation on a sucrose gradient, and subjected to oligo(dT) cellulose chromatography. Although a small fraction of the H5 mRNA activity does not bind to oligo(dT) cellulose (lane 3) most of the translatable activity appears in the bound fraction eluted with distilled water (lane 5). To ensure that the binding of H5 mRNA was not due to an interaction with the cellulose support we passed the RNA over oligo(dA) cellulose (Fig. 1*b* lanes 6–8). The H5 mRNA showed no affinity for this support (compare lanes 6 and 8).

In all these experiments the H5 mRNA behaved in much the same way as the contaminating poly(A)-containing globin mRNA. That the translation products migrating with the mobility of H5 were indeed H5 follows from the fact that: (1) only RNA from polysomes immunoprecipitated with antibodies specific for H5 stimulated the rabbit reticulocyte to produce protein migrating with the mobility of H5, which was absent when RNA from total polysomes was used; (2) the cell-free H5

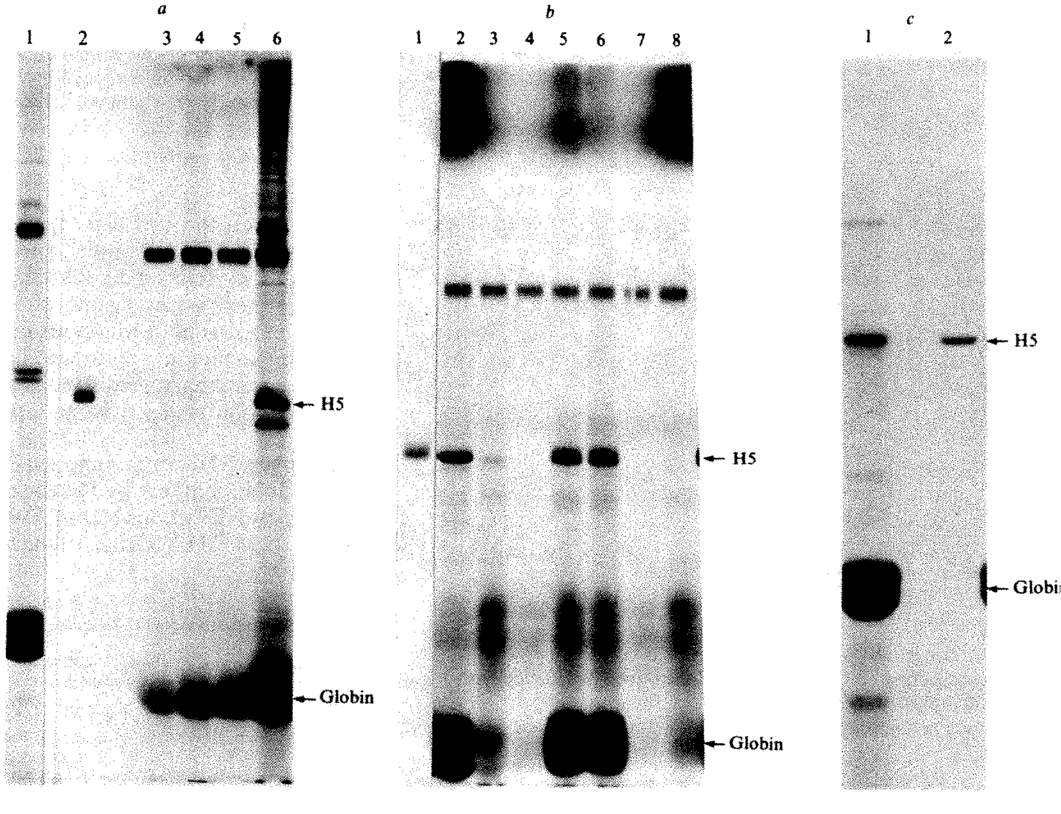

Fig. 1 H5 mRNA binding to poly(U)-Sepharose and oligo(dT)-cellulose. *a*, 7.5 μg of immature chicken erythrocyte polysomal RNA, phenol extracted[21] from polysomes enriched for H5 message by immunoprecipitation[16] was fractionated by poly(U)-Sepharose chromatography[22]. The unbound material, the 5% and 90% formamide eluates were, after ethanol precipitation, dissolved in 10 μl water. Aliquots (2 μl) of each of these fractions were analysed by translation in a rabbit reticulocyte cell-free translation system (NEN) using ^{35}S-L-methionine as label. Aliquots of the lysate were analysed on 15%–19% SDS polyacrylamide gels[23] and exposed by fluorography[24] on presensitised film[25]. *Lane 1*, total enriched polysomal RNA translated in the cell free system; *lane 2*, H5, labelled *in vitro*, by reductive methylation[26]; *lane 3*, no RNA added to the lysate; *lane 4*, polysomal RNA not bound in 0.2 M NaCl in ETS buffer (0.01 M Tris–HCl *p*H 7.5, 0.01 M EDTA, 0.2% SDS); *lane 5*, polysomal RNA eluted by 5% formamide in ETS; *lane 6*, RNA eluted by 90% formamide in ETS. *b*, immature chicken erythrocyte polysomal RNA was phenol extracted as above from polysomes[14] and immunoprecipitated as described by Groner *et al.*[15]. The RNA was purified by size fractionation on a sucrose gradient before being chromatographed on oligo(dT)-cellulose (T 3 Collaborative Research) and oligo(dA)-cellulose (T 6 Collaborative Research). The RNA was analysed by translation as above. The 0.4 M NaCl and 0.1 M NaCl solutions referred to below included 0.01 M Tris–HCl *p*H 7.4, 0.001 M EDTA, 0.5%, SDS. *Lane 1*, *in vitro* labelled H5; *lane 2*, RNA before oligo(dT)-cellulose chromatography; *lane 3*, RNA unbound in 0.4 M NaCl; *lanes 4 and 7*, RNA eluted with 0.1 M NaCl; *lanes 5 and 8*, RNA eluted with sterile water; *lane 6*, RNA not bound to oligo(dA)-cellulose in 0.4 M NaCl. *c*, Part of the RNA used in *b* was translated as described and the PCA-soluble translation products were precipitated by rabbit antibodies directed against H5 (manuscript in preparation). The labelled proteins were analysed as in *a*. *Lane 1*, an aliquot of the total translation assay; *lane 2*, the translation products precipitated by anti-H5.

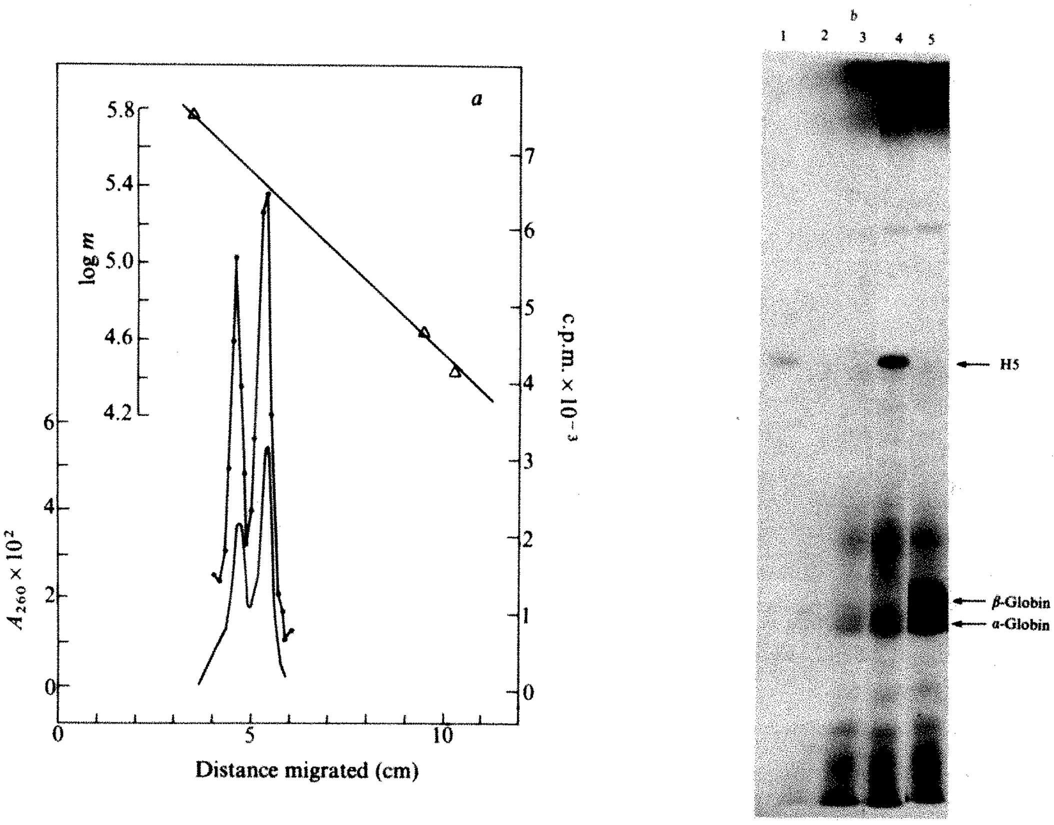

Fig. 2 Preparative electrophoresis of poly(A)$^+$RNA. RNA prepared as in Fig. 1*b* and size-fractionated by two cycles of sucrose gradient centrifugation was separated into poly(A)$^+$ and poly(A)$^-$ RNA by poly(U)-Sepharose chromatography. Both fractions were further analysed on 3.5% polyacrylamide, 99% formamide gels[27]. Labelled 16S and 5S *E. coli* rRNA (extracted from *E. coli* subunits provided by Dr R. Brimacombe) were included as size markers, and calf liver tRNA (Boehringer) as carrier and marker. After electrophoresis, the gels were washed for about 3 h in sterile water and scanned at 260 nm in a Gilford spectrophotometer. The gel was then frozen and sliced into 0.5-mm slices in a Mickle gel slicer. The slices were eluted in pairs in 0.5 ml of 0.6 M lithium acetate, 0.2% SDS[28], 5 μg ml^{-1} calf liver tRNA for about 18 h. After phenol extraction and ethanol precipitation, the eluates were dissolved in 10 μl sterile water. Aliquots (1 μl) were used for translation assays as described under Fig. 1*a* and for poly(U) hybridisation[29] with tritiated poly(U) (NEN). *a*, Absorbance at 260 nm (——); poly(U) hybridisation (—·—); 16S, 5S and 4S RNA markers (△). *b*, RNA samples separated by electrophoresis as in *a* were analysed by cell-free translation as in Fig. 1*a*. *Lane 1*, *in vitro* labelled H5 (ref. 26); *lane 2*, lysate without RNA added; *lanes 3–5*, translation products from RNA samples that migrated 4.1, 4.5 and 5.4 cm along the gel shown in *a*. The arrows mark the distances migrated by the respective marker proteins.

product was specifically solubilised by 5% perchloric acid which is known to selectively extract very lysine rich-histones[17]; and (3) all the protein-bound ^{35}S-methionine radioactivity extracted with 5% perchloric acid from cell-free assays was immunoprecipitated by purified rabbit anti-H5 antibodies, and comigrated with H5 on SDS electrophoresis of the immunoprecipitate (Fig. 1*c*, and manuscript in preparation).

To characterise further the H5 mRNA, total RNA from immunoprecipitated polysomes was fractionated by size by two sucrose gradient cycles and the poly(A)$^+$ RNA was separated by poly(U)-Sepharose chromatography and analysed by electrophoresis in polyacrylamide gels containing 99% formamide. Only two significant peaks were observed when the RNA gel was scanned at 260 nm (Fig. 2*a*). Translation of fractions eluted from the gel showed a peak of H5 mRNA activity in the more slowly migrating zone (Fig. 2*b*, lane 4) and mainly β-globin in the faster zone (Fig. 2*b*, lane 5). No other prominent translation products were observed.

For additional confirmation of polyadenylation of the H5 mRNA, peak fractions of the eluted RNA were hybridised with tritiated poly(U) (Fig. 2*a*). The more slowly migrating zone showed a degree of hybridisation similar to or greater than that of the globin component. The optical density, the poly(U) hybridisation and the translational activity coincided closely in both peaks. This result (Fig. 2*a*) leads to an estimated molecular weight of 3.38 (±0.15) × 10^5 for the polyadenylated H5 mRNA, that is, a length of about 1,000 nucleotides. A parallel electrophoresis of chicken globin mRNA gave two partly resolved peaks of molecular weights 2.34 × 10^5 and 2.14 × 10^5 for the β- and α-chains respectively, in good agreement with the data of Crawford *et al.*[18], but significantly higher than the molecular weights found by Longacre & Rutter[19].

If the H5 mRNA is polyadenylated then it should be possible to isolate and measure the length of the poly(A) since this sequence is relatively insensitive to RNase A and RNase T1.

Aliquots of fractions eluted from near the peaks of both the H5 and globin zones in the preparative gel were digested with RNase A and RNase T1 essentially as described by Brownlee *et al.*[20]. Parallel RNase digestion in these conditions rendered *Escherichia coli* rRNA soluble in 5% trichloroacetic acid and did not effect the acid solubility of poly(A). The digested samples were electrophoresed in 10% polyacrylamide gels containing 99% formamide, together with 5S and 4S RNA markers. Two parallel gels included oligo(dT) 17 as an additional marker. The gels were scanned, sliced and the RNA eluted and hybridised with labelled poly(U)[29]. The results (Fig. 3*a*, *b*) showed a peak of hybridisation activity for H5 at a mobility corresponding to 150 ±50 nucleotides and for globin at about 110±40 nucleotides.

The results presented above suggest that a significant proportion of the H5-coding mRNA of chicken red blood cells is polyadenylated.

In the sample analysed, the lengths of the polyadenylate and of the H5 mRNA, together with the protein coding sequence[30], lead to the conclusion that in addition to the poly(A) sequence there are about 260 non-translated nucleotides. The relative amounts of poly(A)$^+$ and poly(A)$^-$ H5 mRNA varied from sample to sample but most of the translatable activity was always found in the polyadenylated material. The binding of H5 mRNA to oligo(dT)-cellulose and poly(U) sepharose is not an artifact due to the high lysine content of H5 (lysine may be coded by AAA or AAG) because, as is clear from Fig. 3*b*, a long fragment of poly(A) is present in the H5 mRNA, and, in addition, short stretches of oligo(A) do not contribute to the poly(U)

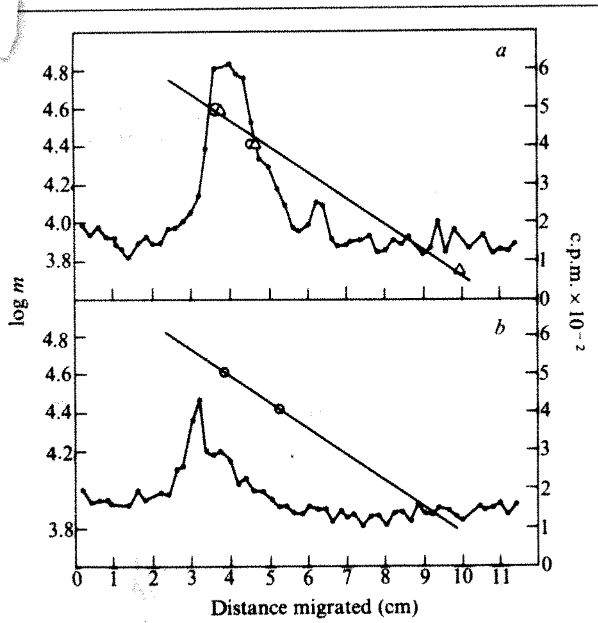

Fig. 3 Poly(A) length measurement. Aliquots of approximately 1 µl of the RNA eluted from slices at 4.5 and 5.4 cm from the origin of the gel shown in Fig. 2*a* were digested with RNase A (RNase to substrate ratio 1:100) and RNase T_1 (RNAse to substrate ratio 1:10) as described[20], in the presence of carrier (0.2 µg) calf liver tRNA. The digests were made 80% in formamide, mixed with 5S *E. coli* rRNA (from Dr V. Erdman) and calf liver tRNA markers and electrophoresed on 10% polyacrylamide, 99% formamide gels made and electrophoresed as described by Pinder *et al.*[27] except that the bis-acrylamide concentration was lowered to 5%. After electrophoresis, the gels were washed, scanned and sliced as described in the legend to Fig. 2. The eluates were analysed by hybridisation with tritiated poly(U)[29]. *a*, Sample from 5.4 cm (globin); *b*, sample from 4.5 cm (H5); △, 5S, 4S RNA, and oligo(dT) 17 markers run on a parallel gel; ○, markers co-electrophoresed. The slope of log *M* versus mobility curve from the two parallel gels was used to draw the lines through the positions to which the markers migrated.

hybridisation. Another possibility is that the H5 mRNA comigrates with significant amounts of polyadenylated mRNA which translates poorly or not at all under the conditions used. Although we cannot rule this possibility out, we consider it to be very unlikely.

The results presented here conflict with the data of Scott & Wells[16] who isolated H5 mRNA from an oligo(dT)-cellulose run-through fraction. They do not, however, make clear whether any H5 mRNA did bind to oligo(dT) nor did they characterise the putative H5 mRNA activity as we have done. We also find, by *in vivo* labelling and from the yields of the specific immunoprecipitated polysomes, that the H5 mRNA activity does not exceed 0.6% of total messenger activity in anaemic red blood cells (manuscript in preparation), a figure much lower than that estimated by Scott & Wells[31].

The translation of H5 in the absence of DNA synthesis suggests that the H5 gene or the mechanisms that regulate its expression differ intrinsically from those for the other histones. The polyadenylation of H5 may be part of the mechanism allowing this histone's unique expression. The genomic location of the H5 gene and the timing of its transcription are among the questions now being examined.

We thank Mr. A. Shevack for technical assistance.

In vitro simulation of senescence-related membrane damage by ozone-induced lipid peroxidation

K. P. Pauls & J. E. Thompson

Department of Biology, University of Waterloo, Waterloo, Ontario, Canada N2L 3GL

Recent evidence indicates that as cells deteriorate, increasing proportions of the membrane lipids become crystalline (gel phase) at physiological temperature. Microsomal as well as chloroplast membranes from ageing bean (*Phaseolus vulgaris*) cotyledon and leaf tissue acquire regions of gel-phase lipid as senescence advances[1–5]. Gel-phase lipid has also been detected in microsomal membranes from aged batch cultures of green algae (*Scenedesmus quadricauda*)[6], microsomal membranes from regressing corpus luteum of rat[7] and plasma membranes of chick intestinal cells infected with an intracellular coccidial parasite[8]. These observations suggest that the presence of gel-phase lipid in membranes at physiological temperature may be a generalised feature of cell deterioration whether it is attributable to natural ageing or to some kind of infection. Moreover, the resulting mixture of liquid-crystalline-(fluid) and gel-phase lipid in the bilayer is likely to render the membranes leaky[9,10], and could thus readily account for the loss of cellular compartmentalisation that accompanies tissue senescence. The present study reports that phase changes occurring naturally during senescence of bean cotyledons[1,2] can be simulated by exposing isolated membranes from young cotyledon tissue to ozone, a treatment that induces lipid peroxidation[11]. This finding has considerable bearing on previous observations which implicate atmospheric ozone as a source of crop damage by reason of its ability to induce premature plant senescence[12], and lipid peroxidation as a major cause of membrane deterioration in ageing systems[13,14].

Smooth microsomes and cytosol were isolated from cotyledons of 3-day-old etiolated seedlings of *Phaseolus vulgaris* (Kinghorn) grown at 29 °C (refs 15, 16). The isolates were exposed either separately or as a mixture to three 2-min pulses of ozone administered at prescribed intervals over a period of 1 h (Fig. 1). Levels of malondialdehyde (MDA) were measured to determine the degree of lipid peroxidation, and phase changes in the membrane lipid were monitored by wide-angle X-ray diffraction. This technique allows unambiguous detection of gel-phase lipid in membranes and can thus be used to determine liquid-crystalline- to gel-phase transitions[4].

0028–0836/80/050504—03$01.00

Figure 1*a* shows ozone concentration fluctuations in the reaction mixture over the 60-min incubation period. These measurements were obtained by bubbling ozone into buffer; corresponding measurements for the full incubation mixture could not be made because the turbidity of the mixture interferes with the spectrophotometric assay for ozone. The buffer was given 2-min pulses of ozone at 0-, 20- and 40-min intervals. Immediately following each pulse the concentration of ozone in the buffer was about 24 p.p.m.; it then decreased over a 20-min period to about 4 p.p.m. (Fig. 1*a*).

Samples of the incubation mixtures were removed for MDA assays immediately after each pulse of ozone. This 3-carbon dialdehyde is produced during oxidation of polyunsaturated fatty acids[17,18], and it is clear that progressively less MDA was produced with each successive exposure to ozone when membrane lipids were the sole source of polyunsaturated fatty acids (Fig. 1*b*, incubation mixture *A*). By contrast, the mixture of membrane and cytosol yielded increasing levels of MDA with each ozone treatment (Fig. 1*b*, incubation mixture *B*). However, treatment of cytosol alone revealed that the extra MDA production could be attributed to peroxidation of cytosol lipids (Fig. 1*b*, incubation mixture *C*). Indeed, when the cytosol values were subtracted, cumulative levels of MDA produced over the 60-min period indicated that membrane treated in the absence of cytosol sustained more oxidative damage than that treated in its presence (Fig. 1*b*).

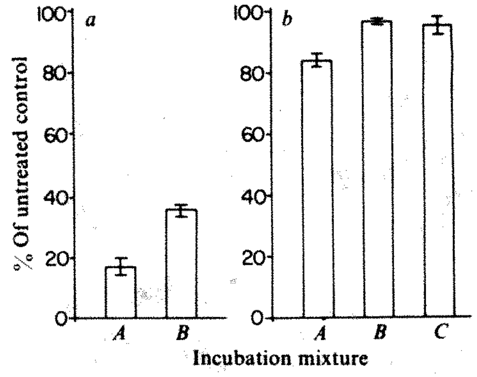

Fig. 2 Levels of phospholipid (*a*) and protein (*b*) remaining in the ozone-treated reaction mixtures after 60 min of incubation. Values are expressed as a % of corresponding controls that were not treated with ozone. Reaction mixtures (the same as described in Fig. 1*b*) were extracted with chloroform/methanol (2 : 1) and levels of organic phosphate in the extracts were determined[34]. Protein in the reaction mixtures was measured by the Lowry method.[35] S.e.m. values are indicated; *n* = 3–6.

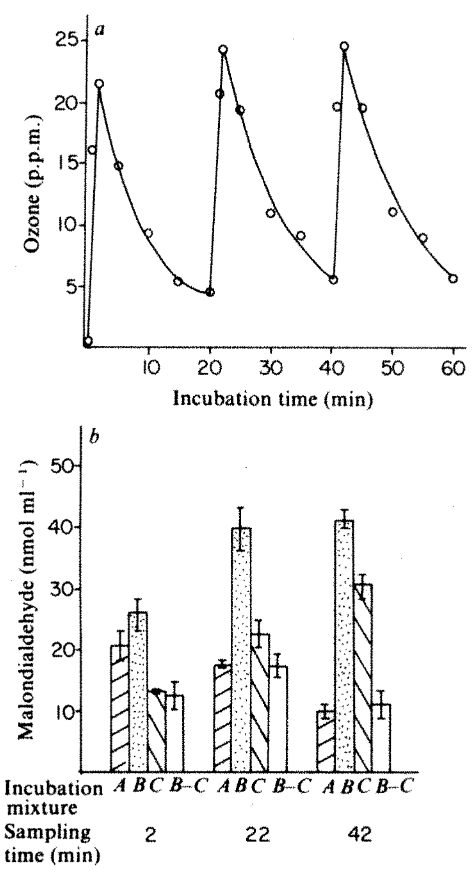

Fig. 1 *a*, Measurements of ozone delivered to the experimental system. Ozone was generated by passing oxygen at 44 ml min^{-1} through an electrical discharge ozoniser, and bubbled with a gas dispersion tube through 30 ml of 0.05 M phosphate buffer, *p*H 7.0, in a 100-ml graduated cylinder placed in a shaking water bath set at 29 °C and 130 c.p.m. A 2-min pulse of ozone was delivered at 0, 20 and 40 min of the incubation period, and the total incubation period was 60 min. Samples of buffer (0.2 ml) were taken at intervals shown and assayed for ozone as described[32]. *b*, Ozone-induced lipid peroxidation. Ozone was delivered as described above to three reaction mixtures containing: *A*, smooth microsomes from 3-day-old cotyledons[15] (0.5 mg protein ml^{-1}) and bovine serum albumin (BSA; 2.5 mg ml^{-1}) in 30 ml of 0.05 M phosphate buffer, *p*H 7.0; *B*, smooth microsomes from 3-day-old cotyledons[15] (0.5 mg protein ml^{-1}) and cytosol from the same tissue[16] (2.5 mg protein ml^{-1}) in the same buffer; *C*, cytosol from 3-day-old cotyledons (2.5 mg protein ml^{-1}) and BSA (0.5 mg ml^{-1}) in the same buffer. All the reaction mixtures and a set of identical control reaction mixtures not exposed to ozone were incubated for 60 min at 29 °C and agitated at 130 c.p.m. Samples (0.2 ml) of each reaction mixture were taken immediately after each 2-min ozone pulse and assayed for malondialdehyde (MDA) using a modified[36,37] thiobarbituric acid test[33]. The values obtained for the experimental reaction mixtures were corrected for levels of MDA found in the corresponding control reaction mixtures. S.e.m. values are shown; *n* = 3.

This was confirmed by measurements of phospholipid at the end of the 60-min incubation period. Incubation mixtures containing membrane and cytosol retained twice as much phospholipid as did those containing membrane alone (Fig. 2*a*). Moreover, lipid seems to sustain much more damage during ozone treatment than protein. For example, the reaction mixture containing membrane in the absence of cytosol retained less than 20% of the original phospholipid after ozone treatment, whereas greater than 80% of the original protein was still present (Fig. 2). The values recorded in Fig. 2*b* are for total protein and do not reflect the relative fates of membrane protein, cytosol protein and serum albumin on ozone treatment, but the proportions of these three sources of protein were very different in the three types of reaction mixture tested, and in each case there was little decrease in protein resulting from the ozone treatment (Fig. 2*b*). In addition, the size of the membrane pellet obtained by centrifuging the incubation mixture containing membrane in the absence of cytosol was consistently smaller than that obtained from the membrane–cytosol mixture, and both these membrane pellets were smaller than those obtained from identical control incubation mixtures that were not exposed to ozone. These observations collectively suggest that cytosol partially protects the membrane from ozone damage by sustaining peroxidation itself. Phospholipid and other organophosphorus compounds were not detectable in the cytosol fractions although lipid (presumably triglycerides) could be seen suspended at the tops of the centrifuge tubes in which cytosol was isolated. This is presumably the source of the MDA produced during exposure of cytosol to ozone.

Wide-angle X-ray diffraction of the membrane pellets from control and experimental incubation mixtures revealed that ozone treatment raises the lipid transition temperature (T_c). As might be expected from the results of the chemical assays, the T_c of membrane treated in the absence of cytosol was raised to a higher temperature than that of membrane treated in its presence. The difference between experimental and control transition temperatures was 18 °C in the former and only 6 °C in the latter (Fig. 3 legend). The diffraction patterns in Fig. 3 demonstrate that the proportion of gel-phase lipid formed is greater in the absence of cytosol than in its presence, and that the amount of gel-phase lipid increases as the ozone treatment is intensified. Indeed, when eight 2-min pulses of ozone rather than three were administered over a 60-min period, virtually all the membrane lipid was in the gel phase at 16 °C (Fig. 3*e*, *g*).

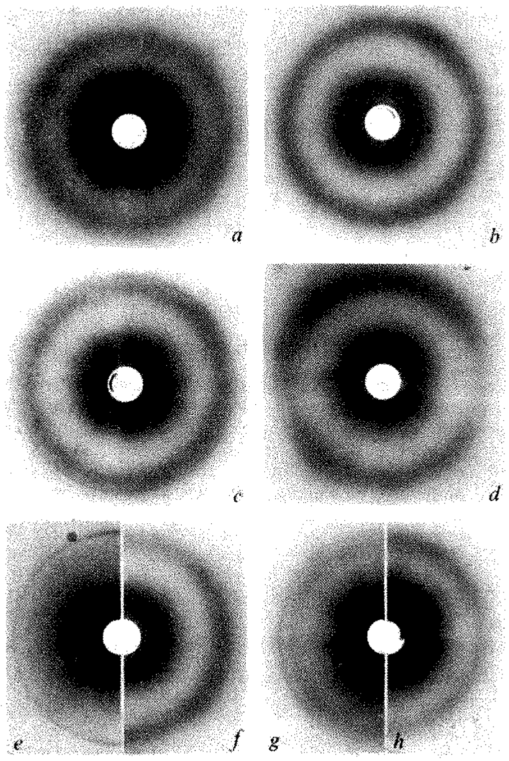

Fig. 3 Wide-angle X-ray diffraction patterns recorded from ozone-treated and untreated smooth microsomes from 3-day-old cotyledons. Reaction mixtures containing membrane and membrane plus cytosol were set up as described for Fig. 1*b*. Control reaction mixtures were given no ozone; one set of experimental reaction mixtures was given three 2-min pulses of ozone at 0, 20, and 40 min, and another set (in 15 ml rather than 30 ml final volume) was given eight 2-min pulses of ozone at 0-min and at 5-min intervals (up to 35 min) thereafter. After 60 min of incubation at 29 °C the membranes were pelleted from the reaction mixtures by centrifugation at 150,000*g* for 1 h. Wide-angle diffraction patterns were recorded from the packed membranes as previously described[1,2]. Patterns recorded at 16 °C for untreated membrane (*a*) and untreated membrane plus cytosol (*b*) show (from outside to inside) a diffuse band at a Bragg spacing of 4.6 Å representing liquid-crystalline lipid and a diffuse band at a Bragg spacing of about 10 Å which probably derives from protein but is not well characterised[1]. Patterns recorded at 16 °C for membrane (*c*) and membrane plus cytosol (*d*) treated with three 2-min pulses of ozone show (from outside to inside) a sharp band at a Bragg spacing of 4.15 Å representing gel phase lipid[1] and a diffuse band at 4.6 Å representing liquid-crystalline lipid[1]. Patterns recorded at 16 °C (*e*) and 55 °C (*f*) for membrane treated with eight 2-min pulses of ozone show (from outside to inside) a sharp band at 4.15 Å in *e* and the diffuse liquid-crystalline band at 4.6 Å in *f*. Patterns recorded at 16 °C (*h*) and 55 °C (*h*) for membrane plus cytosol treated with eight 2-min pulses of ozone show (from outside to inside) a sharp band at 4.15 Å and a diffuse band at 4.6 Å in *g* and only the diffuse band at 4.6 Å in *h*. Transition temperatures (defined as the point at which gel phase lipid first appears as the temperature is lowered) for the experiments illustrated were: *a*, 12 ± 1 °C, $n = 7$; *b*, 15 ± 1 °C, $n = 6$; *c*, 30 ± 2 °C, $n = 5$; *d*, 21 ± 1 °C, $n = 6$; *e*, *f*, 52 °C, $n = 1$; *g*, *h*, 47 °C, $n = 1$.

Moreover, T_c values for membranes receiving this higher ozone dose were 52 °C in the absence of cytosol and 47 °C in its presence. These values for T_c are comparable to those reported previously for the same membranes isolated from extensively senescent 9-day-old cotyledons. Thus, during natural senescence of this tissue, T_c for smooth microsomes rises from 3 °C for 2-day-old cotyledons to 56 °C by day 9 (refs 2, 4, 5).

The specific mechanism by which ozone causes injury to plant tissue is not understood. However, there is considerable evidence that membranes are primary targets. Leaves exposed to ozone display water-soaked spots and become chlorotic and necrotic, symptoms which are thought to reflect loss of membrane selective permeability[12]. Exposure to ozone has been shown to cause leakiness in leaf cells[19], potato tubers[20], unicellular algae[21] and isolated organelles[22,23]. Several observations support the proposal that ozone damage accrues in part from oxidation of unsaturated fatty acids in membranes. Malondialdehyde accumulates[24–26], and there are small decreases in the levels of polyunsaturated fatty acids following exposure of plant tissue to ozone[26]. Lipid peroxidation also renders liposomes leaky[27,28] and increases their viscosity[29]. Our observation that exposure to ozone induces the formation of gel-phase lipid offers an explanation for this increased leakiness, for it has been previously demonstrated that the co-existence of liquid-crystalline- and gel-phase lipid greatly increases the permeability of bilayers[9,10]. The finding that the formation of crystalline lipid during senescence can be simulated by treating membranes from young tissue with ozone supports the contention that lipid peroxidation plays an integral role in senescence, and complements previous observations that anti-senescence compounds such as cytokinins confer resistance to ozone damage on leaves[30] and lower the endogenous level of lipoxygenase[31].

Erratum

In the letter 'Do sponges help hold coral reefs together?' by J. L. Wulff and L. W. Buss, *Nature* **281,** 474–475, in the footnote to Table 1, in line 6 'does assist with the' should read 'does not provide any'. The last two sentences of the penultimate paragraph should read 'Although the influence of bioerosion should not be underestimated, neither should the binding capacities of other reef sponges. Demosponges clearly require several terms in the reef carbonate balance equation.'

BOOK REVIEWS

Biological oceanography

J.H.S. Blaxter

Developments in Deep-Sea Biology. By N.B. Marshall. Pp. 566. (Blandford: Poole, UK, 1979.) £15.

SEVENTY per cent of the Earth's surface is covered by sea; the *average* depth of the ocean is 3800 metres; its maximum depth is 11,500 metres; its volume is 130 million km^3. These statistics give some idea of size of the last relatively unexplored regions of the Earth, sometimes called "inner space" by the popular press. The science of oceanography (or perhaps oceanology is a better term) started in earnest only 100 years ago during the first Challenger Expedition from 1872—76.

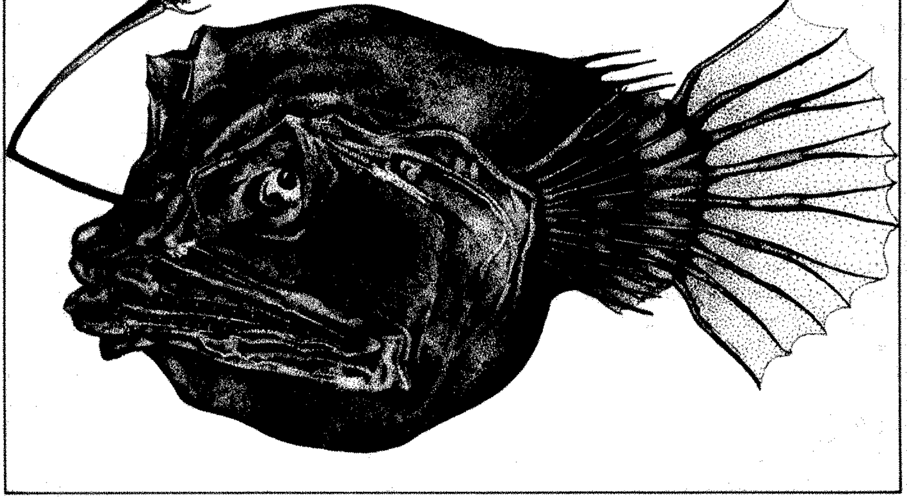
Professor Marshall's book reviews the current level of knowledge of biological oceanography. He attempted in the first instance to revise his 1954 book *Aspects of Deep Sea Biology.* So much had occurred, however, in the past 25 years he set aside his "paste and scissors" (and what a crime it would have been to dissect that volume), and started afresh. The first action of the reviewer was to take the 1954 book from his shelves and compare it with the new one. The latter has 50% more pages which probably indicates an increase of 50% in the volume of knowledge over 25 years. Some of the figures, drawn by Olga Marshall, are fortunately repeated but many are new.

The sections cover Deep Sea Environments; Sea Life, including oceanic plants, pelagic animals and life on the deep sea floor; Deep Sea Food Webs, including those in the pelagic zone, near the deep-sea floor and of the deep sea floor; Physiological Aspects, with chapters on buoyancy, bioluminescence, sensory systems and early life histories; and Biogeography. There is a good bibliography and extensive Species and Subject indexes. There are 170 excellent figures drawn by Olga Marshall and others, and two colour plates by Olga Marshall, the originals of which were hung in the Royal Academy Summer Exhibition.

The book conveys well the esoteric world of the deep sea. The uninitiated will be amazed at the variety and adaptations of oceanic organisms. The initiated will always remember the experience of seeing their first deep sea haul, not only the bizarre forms, but the variety of species and the paucity of the biomass — half a bucket is usually enough to contain the catch from four hours fishing. For every 10 metres depth the pressure increases by one atmosphere; hence many of the animals are living at pressures of hundreds of atmospheres or thousands of pounds to the square inch. Below 1000 metres it is dark except for flashes of bioluminescent light produced by the animals themselves; even above 1000 metres the light is dim and a monochromatic blue. Below the thermocline, which is usually sharp and acts as a barrier both to animal migration and the exchange of water and nutrients, the temperature is an unfluctuating 1—4°C with no seasonal changes. It is the lack of daily and seasonal changes which make the environment so homogeneous. The possibility of lateral distribution without severe physical, chemical or topographical barriers is the reason why deep sea hauls looks so similar, whatever part of the ocean is being fished. The ocean bed, however, is not uniform. Submarine mountain ranges run up the centre of the main oceans; these are the areas where tectonic plates originate which are involved in the separation of the continents. Between the continental shelf and the mid-ocean ridges lie ocean basins, many covered with deep sediments forming abyssal plains.

Professor Marshall describes biological life in the pelagic zone and in the depths. This section of the book is much longer than the previous book, reflecting the advances made since the War. This is essentially a review and in no sense a key to identification. The adaptations can be clearly linked to the shortage of food (large rapacious mouths, recurved teeth, highly distensible stomachs) and the need to attract prey or mate (bioluminescent lures and photophores). The downwardly pointing photophores of some deep sea fish are almost certainly a means for breaking up their form to predators looking up and searching for food in silhouette against the dim downwelling light.

The three chapters on food webs lead to the description of vertical migration, found to be a surprisingly regular and worldwide phenomenon wherever investigations have been made. This rise at dusk to the surface and sinking at dawn towards the sea bed are found in very divergent animal groups and seem to be linked to feeding and the avoidance of competition and predators. Non-migrant related species often occupy separate depth strata, whereas vertical migrants, being able to exploit different depths, often have coincident depth ranges. Although much was known about faunistic variation and the taxonomic make-up of deep sea organisms from earlier investigations, the past 25 years (while bringing some new species to light) has been marked by a better understanding of depth distribution. This is more significant than might be



Female angler-fish (*Oneirodes eschrichtii*)

N.B. Marshall, redrawn from Pietsch, 1974 apparent. It has required great ingenuity to develop equipment to fish at specified depth without "contamination" on the way down and on the way up, before and after the haul. It was disappointing to find that Professor Marshall had not included a section on fishing gear (though he quotes a recent reference) because great advances have been made in this field.

Studies on physiology have also been advanced significantly, although deep sea organisms, especially fish, are difficult to catch in good condition. The physiological discoveries have mainly resulted from a study of functional anatomy and biochemistry, both of which are possible on moribund or even newly-dead animals or on particularly hardy species. A whole range of buoyancy adaptations have been discovered such as low density (for example, ammonical) body fluids, high lipid flotation, reduced skeletons, and special pneumatic float and swimbladder modifications. The sensory systems may be specialised with upwardly directed "telescopic" eyes of high sensitivity with a banked retina of pure rod visual cells. The chemosenses and lateral line may also be elaborated. Life histories have to be maintained on impoverished resources. Often deep sea organisms have no breeding season and produce large eggs which yield larger more viable larvae, and these often rise to the surface during a distributional phase.

Professor Marshall unfortunately says little about oceanic resources, describing the deep ocean as a deserted living space in comparison with the highly productive areas of the continental shelf. Nevertheless, it is true that some of the new species likely to be exploited are further offshore. Apart from lantern fish, which are truly a deep water potential resource, squid, krill and blue whiting are all offshore species found over deep water.

The advances made in biological oceanography since the War must have been expensive: an ocean-going research vessel now costs several thousand pounds to run each day. In the current climate of recession, research vessels may be laid up and it is probable that the next 25 years may not be so productive as the last. Professor Marshall's book has probably been produced at a key time at the end of an almost logarithmic increase in research effort. He is one of the most informed of our deep sea biologists and his book is an important addition to the literature of biological oceanography. It has his characteristic style and it should find a place in the libraries of Universities, Institutes and individuals, as it has the merits of timeliness and readability as well as a modest price. □

Ancient climates

W.B. Harland

Climates Throughout Geological Time. By L.A. Frakes. Pp. 304. (Elsevier Scientific: Amsterdam and New York, 1979.) $58.50; Dfl. 120.

SEVERAL books have been published recently on the theme of ancient climates and especially of ice ages. Each has distinctive shortcomings and in every case there is the human limitation that prevents any one person from mastering more than a part of the vast relevant literature. Taking this into account Frakes has without doubt written the best. It is a serious study without journalese or padding and it reflects the author's own work over a wide range of the subject matter. It is a thorough attempt to integrate the latest palaeogeographical reconstructions and, results from the Deep Sea Drilling Program with ^{18}O investigations on palaeotemperatures, by an author with long experience investigating tillites of various ages in more than one continent. Throughout Frakes has carefully considered what is known about the likely properties and motions of the air and water masses enveloping the Earth in relation to the changing pattern of its land and sea. The whole work is internally consistent, having gone through one mind. (In this field too many authors have attempted to support their own prejudices with compilations of undigested data.) A point of view emerges that recurs and has some of the following characteristics.

Frakes gives only 10 out of 267 pages of text to Pleistocene events and he mistakenly includes Pleistocene as a division (the last 1.6 to 2.0 Myr) of the Neogene Period. Such a slip in writing down the Quaternary glaciations would be unthinkable to those brought up in the Northern Hemisphere where earlier ice ages are often treated as an appendix to The Great Ice Age. So this work usefully counter-balances our Arctic preoccupations and brings the southern oceans into play as they developed around Antarctica. There during the last 30 Myr is evidence of ice and a major ice sheet for at least half that time, ice sheets in the northern hemisphere developing only around 3 Myr ago. Although Frakes shows himself to be uncharacteristically ignorant of Pleistocene stratigraphy (and so not able to assess critically the Milankovitch cycles) the reviewer welcomes this refreshing approach that interprets the present as a transient phase evolving out of the past.

Throughout the work there is a continual, at times almost irritating, equivocation over interpretation as the author meticulously discusses each successive problem. So little can be concluded with certainty in considering ancient climates because of the complexity of interacting systems each with negative and positive feedbacks. For example, the interplay of solar constant, ocean gyres, thermal gradients, polar fronts, global albedo, atmospheric CO_2, carbonate compensation depth, biological activity and distribution, ^{18}O, evaporation and precipitation as ice or water, eustasy and tectonics provide the characters in an everchanging choice of scenarios for each episode of history. The first chapter sets out the relevant parameters from atmospheric and oceanic circulation but the applications are repeatedly discussed in context throughout. This explains how it is that many of the questions of palaeoclimatology that were asked more than 100 years ago remain enigmatic.

On the other hand equivocation over tillites and other evidences of ice has virtually been eliminated. The story of ice ages is the skeleton of climatic history and for this Frakes is as well equipped as any from his own researches. There is little new in the account of the broad pattern of glacial history but its integration into the stratigraphical record is thorough. No glacial deposits are recorded older than about 2700 Myr and the reason for supposing the Earth to have been warmer during the preceding 2000 Myr are familiar but well marshalled. A run of well described glacial events between about 2700 and 2100 Myr lack critical age or palaeogeographical control.

Another cluster of very widespread late Precambrian tillites occupies the time span between about 900 and 600 Myr. The receiver especially welcomes Frakes' clear conclusion that the evidence for part of this time, if for no other, requires there to have been low latitude glaciation. He now rules out the prevailing view to which he was earlier sympathetic that the wide distribution of these deposits could be accounted for by the imprint of a wandering pole. He then has to choose between either a global refrigeration that would be difficult to explain without a reduction in the solar constant, or a radically different obliquity at that time (for example, 54° instead of 23.5°). This could be ruled out if high latitude glacial deposits were to be established, for the essence of the obliquity explanation is that with Earth's poles pointing nearer to the Sun only low latitudes could be glaciated.

Phanerozoic history that follows is probably accountable in terms of terrestrial parameters. Palaeozoic ice sheets relate to the southern continent Gondwanaland containing the South Pole and this is a field in which Frakes is a long-standing authority. There may have been ice (possibly continuous) there throughout most of Phanerozoic time (600 to 240 Myr) but the well established ice ages occurred at the end of Ordovician time (435 Myr) and through much of Carboniferous and Permian time (say 330–240 Myr). The highest temperatures have been Devonian (400–350 Myr). The lack of ice in the

Mesozoic Era is fully discussed in terms of oceanic distribution and low albedo leading to peak temperatures in mid-Cretaceous time (say 100 Myr), since when a fluctuating decline ensued.

Frakes' work is scholarly; not every point of opinion is referenced; this may irritate some, but too frequent a punctuation with brackets would have been more irritating. There is, however, an adequate supply of references in the text to most data to be used, with a list at the end of about 500 to 600 works and an adequate index. This book establishes palaeoclimatology as an inseparable part of stratigraphy, itself the documentary basis for understanding most aspects of Earth history. □

W.B. Harland is Reader in Tectonic Geology at the University of Cambridge. He is currently leading the International Geological Correlation Programme Project No. 38 on Pre-Pleistocene Tillites.

Primordial germ cells

C.C. Wylie

Primordial Germ Cells in the Chordates. By P.D. Nieuwkoop and L.A. Sutasurya. Pp.187. (Cambridge University Press: Cambridge, 1979.) £14.50.

THE establishment of the gonad in early vertebrate embryos has fascinated developmental biologists and cell biologists for well over a century now. Basically, the problems fall into the following categories: (1) how is the germ line determined in the early embryo?; (2) what is the mechanism by which the primordial germ cells (PGCs) migrate from the site of their determination to the site of gonad formation?; and (3) what is the mechanism by which PGCs are guided to their target? Thus, many of the cellular processes which make development such a fascinating process are encapsulated in this particular piece of organogenesis, and this has been reflected in the considerable research interest in this subject.

It is therefore timely that Professor P.D. Nieuwkoop's book about the PGCs of the chordates has appeared, for this is a thorough and clear survey of work in this field over the past hundred years. However, despite the authors' considerable contribution to the field, and some five hundred cited pieces of work, we are still only able to answer the above three fundamental questions in the most general way.

Professor Nieuwkoop's main contribution, and indeed, the main preoccupation in his book, is the site and manner of determination of the first germ line cells (the "presumptive" PGCs). The fact that these seem to differ in two vertebrate groups which have been closely studied, the anuran and urodele amphibians, leads him to speculate that the evolutionary tree of the vertebrates, particularly with respect to the amphibians, may be more complex than has been hitherto suspected.

The study of taxonomy through careful study of ontogeny has a long and honourable history, and has tended to be neglected of late. This is largely due to a focussing of research interest on to the cellular and molecular events of embryogenesis, in an attempt to define causative factors in cell differentiation. It is therefore a timely reminder by the author that molecular and cellular phenomena of development are just as important clues in taxonomy as are anatomical features.

This concentration on the taxonomic aspects of the PGCs in chordates is both a strength and a weakness. The weakness is simply because the data on the establishment of the germ line cells, and the route they take to the developing gonad, are still only documented in a fragmentary and unsystematic way. The middle section of the book contains a truly excellent description of this. However, when examined critically, hard evidence on the means by which the germ line is established in chordates only exists for a small number of amphibian species, and not at all for the amniotes, making this a rather tenuous reason for tinkering with the chordate evolutionary tree. The strength of this approach, however, is that it is bound to stimulate research in this subject, particularly into those groups which so far have been neglected. This, in turn, will fulfil Professor Nieuwkoop's aim to gain insight into the way in which the causative factors in early development have themselves changed during vertebrate evolution. □

C.C. Wylie is Senior Lecturer in Structural Biology at St George's Hospital Medical School, London, UK.

Plasma proteins

M.J. Geisow

Plasma Proteins. Edited by B. Blomback and L. Hanson. Pp. 401. (Wiley: Chichester, UK, and New York, 1979.) £22.50.

SWEDISH readers will already know about this book because it first appeared in Swedish in 1976. The latest edition of this multi-author volume is a revised version in English and now includes some literature references up to 1978. The promotors are KABI AB, the Swedish firm which supplies plasma protein fractions.

Plasma Proteins is described as an educational text and a clinical handbook. This seems to be a fair description. The introductory chapter by Kai Pedersen is a small nugget of biochemical history. Apart from exposing the roots of plasma protein science, it also deservedly, but not selfishly, establishes the Swedish contribution to the field. The remaining chapters form a comprehensive account of the biochemistry, pathology and methodology of plasma proteins. The treatment of this material is similar to that in the more expansive work *The Plasma Proteins* (F.W. Putnam, ed., Academic: New York; 1975). In contrast with the latter work, however, you might consider reading the KABI book from cover to cover.

Inevitably for a textbook produced several years ago, there are omissions. For instance, the recent considerable advances in the three-dimensional structure of lipoprotein have not been incorporated in the otherwise excellent description. Nevertheless, as an educational text, the chapters are informative and easy to read. Despite multi-authorship, the closely-linked subjects of defence and repair (that is, the antibody/lymphocyte and blood clotting systems) are treated in a unified fashion.

At a molecular level, there is a pleasing emphasis in this book on the structures of plasma proteins. For example, there are good descriptions of the functions of the transport proteins albumin and haptoglobin in relation to what is known about their molecular structures. A similar molecular structure/biological function synthesis is achieved in the chapters on the protective proteins fibrinogen and plasminogen.

The bench worker is catered for by the thoughtful inclusion of much useful physical and chemical data relating to the individual proteins described. Both historical and current purification techniques are given and there is a discussion of industrial methods for the fractionation of plasma.

At a more clinical level, hospital biochemists have been given a generous amount of space in which normal and pathological states of plasma protein chemistry is covered. There are short but clear descriptions of the main diagnostic plasma protein analytical techniques, with electrophoretic separations in full colour.

I expect to see this book above the benches in the teaching hospitals — both in the pathology labs and in the medical schools. □

M.J. Geisow is a member of the research staff at the National Institute for Medical Research, London, UK.

Invertebrate vision

G. A. Horridge

Handbook of Sensory Physiology. Vol. VII/6: *Comparative Physiology and Evolution of Vision in Invertebrates.* A: *Invertebrate Photoreceptors.* Edited by H. Autrum. Pp. 728. (Springer: Berlin, Heidelberg and New York, 1979.) DM320; $176.

THIS splendid and authoritative series has so far been mainly on vertebrates except where invertebrates illustrate primary processes such as transduction, which was extensively reviewed in Vol. VII, Parts 1 and 2. Comparative studies of photoreceptors by authors who work on insects fill Part 6A but still hardly touch the diversity on invertebrate vision. Final coverage cannot be reviewed because two more sections of Vol. VII, Part 6 are expected.

Despite the emphasis on insects there is a wide spread. The refreshing article by Diehn on photic responses of Protozoa accentuates a need for a large protozoan that can be analysed as a single animal using numerous techniques. The negligible fraction of visual pigment and the small size of *Euglena* really limits advance. The thoughful reviews by Miller of optical filters classified by mechanism and by Snyder on light gathering mechanisms are models of the comparative approach at its best. We almost see the thought processes of the Creator as an optical engineer. Hamdorf's masterly account of visual pigments also gives the impression that so much is now known that we can imagine that most of the diversity is catalogued and the basic physics is understood. For that reason new students easily get the impression from the volume as a whole that the topic is cleaned out, but of course that is not so. For example, the action of any thick lens system such as an eye is understood in terms of principal planes and nodal points, but judging by this volume these are not known for any compound eye: in many eyes even the location of the lens is not known.

The discrepancy between the detailed, almost final, accounts of arthropod visual cells and our relative ignorance about other photoreceptors is emphasised by two splendid reviews: one by Bennett on the entrainment of diurnal rhythms with the conclusion that the receptor is usually not the eyes; and the other, by Yoshida, on receptors for light outside the eyes. It is difficult to understand why one animal group seems to extract the maximum information from its visual system while another seems to rely on a totally ineffective system like a dermal light sense. Why are they not all obviously at the optimum?

The book is, of course, full of in-jokes for the initiated; Stavenga's article doubly so, perhaps from the Dutch. I particularly like his caution that Swihart's "way of reflecting on butterfly eyes must be treated with care" (page 401). Snyder especially recommends an article (1969) by Kirschfeld but omits the reference. The unique index enables one to see at a glance that only two substantial contributors, Steve Shaw and Sigmund Exner, never published with co-workers, and that of the works of Exner, only his book is read today.

The 'classical' works of the past are praised in this volume but sometimes we find a misplaced trust in them and sometimes a neglect of their value. An example of the latter is the "thorough investigation of the butterfly visual sense cells" quoted by Stavenga. By measuring the reflection Bernard "made the startling discovery of a red absorbing visual pigment of which the spectrum peaks at about 610 mm". If he had read Max Schultze's classical paper on the compound eye written in 1868 Bernard would have related his red reflections at least partly to the strings of red pigment in the retinula cells. We cannot, however, always believe the classical authors. For example, Exner interpreted these red strings as additional out-of-focus rhabdoms. This was all noted by Ribi in a paper which Stavenga actually quotes in his references but does not incorporate. In fact, in every corner of the subject, as in all science, there are not only great gaps in our knowledge awaiting future genius, there are plenty of murky corners to be cleared out, also requiring lucidity and experiment. One notes the pietism on page 417: "One may assume from the present high interest in photoreceptor physiology and the accordingly rapid accumulation of new data, that some crucial questions will soon be answered"; but interest and data are not the whole story. □

G.A. Horridge is Professor of Neurobiology in the Research School of Biological Sciences, Australian National University, Canberra.

Silica chemistry

D. Dollimore

The Chemistry of Silica: Solubility, Polymerisation, Colloid and Surface Properties, and Biochemistry. By Ralph K. Iler. Pp.866. (Wiley: New York and Chichester, UK, 1979.) £39.50.

RALPH ILER is well known for his research publications and for his earlier book. *The Colloid Chemistry of Silica and Silicates* (Cornell University Press: Ithaca, New York, 1955). This new book will be judged by a comparison with the old. It must be stated that the author first intended this new venture to be an updated second edition of the earlier book. It must, however, in this expanded form be regarded as a new work.

The purpose of the present book is to provide an account of the chemistry of silica, including soluble silica and silicate precursors of soluble silica, the polymerisation to polysilicic acids, colloidal sols and gels, and the surface chemistry of silica. This provides the reason for the provision of the subtitles shown above. The consideration of some 2,500 new references since the first book make the comment of the author that science students graduate with little knowledge of silica's properties or chemistry very pertinent. It may be that this book will be an incentive for the provision of more silica chemistry in the undergraduate syllabus. The author states that the book is written for those engaged in work on silica, as a guide to the literature and for those in other fields who need specific information on the subject. The author does this in a book of 866 pages.

In a short introduction Dr Iler describes previous books and reviews of silica chemistry. He also defines terms such as Silanol, polymerisation and silica. Other names are, however, explained at the point of introduction in the text.

The subject is introduced by the consideration of the solubility of different forms of silica, the factors that influence dissolution and deposition, and the other aspects of the solution chemistry of silica. The various analytical methods are described and compared, and recommended methods given in detail.

Water-soluble silicates are then described as a prelude to the chapter on the polymerisation of silicic acid. A silica sol formation mechanism is clearly detailed together with the necessary factors that control the properties of the system. The various types of gels and powders are characterised, with a great deal of attention paid to their adsorption properties and their uses. There is a chapter on the role of silica in biology, in which the aspects of the occurrence of silica (including toxicity) in mammals and other life forms are discussed. □

D. Dollimore is Reader in Physical Chemistry at the University of Salford, UK.

Debugging systematic bacteriology

THE International Committee on Systematic Bacteriology (ICSB) has reason to be pleased with itself. For there is shortly to appear in the *International Journal of Systematic Bacteriology* the ICSB's new Approved List of Bacterial Names, a list that will include only about 2500 of the 30,000 bacterial species that have been named over the years. Only a handful of those species that have been excluded are likely to worm their way back onto the approved list since, by the standards laid down by the ICSB, their alleged identity is unacceptable.

The identification of bacteria dates back, in principle, to 1753 and the *Species Plantarum* of Linnaeus although in practise it was only from the middle of the nineteenth century that identification of species started in earnest. The problem that has grown ever since then is that by modern standards the vast majority of named species were given descriptions that were totally inadequate for them ever to be recognised again. Furthermore, for very few of the 30,000 alleged species was there a type culture — that is, an authentic specimen of the original beast — with which any new specimen could be compared.

In these circumstances it had become almost impossible for anyone to identify, unambiguously, a new species of bacterium. To do so meant laboriously consulting old and inadequate literature. It meant sifting through hundreds of names, scores of which might apply to the same species. Experts would disagree about which names applied to the same species and which single name to opt for. The competing names often lingered on in the literature with each in turn being overturned or revived as new evidence turned up. And when the issue might have been settled by re-examining the species themselves, cultures either did not exist, were of dubious authenticity or had clearly become outgrown by contaminating bacteria.

It was because of this situation that the International Committee on Systematic Bacteriology of the International Association of Microbiological Societies was persuaded to undertake the formidable task of hacking away the dying, decaying and merely dubious foliage in the hopeless jungle of bacterial nomenclature. After years of committee work, the experts have decided that there are only about 2500 species of bacteria that are currently recognised by most bacteriologists and which possess type strains or equivalent type material. From now on bacteriologists need only consider these approved species and, of course, any that are subsequently added to it. Additions will be carefully controlled by the requirement for better descriptions and designations of type strains than in the past. More controversially, new names will only be acceptable once they have been published in the *International Journal of Systematic Bacteriology*

Had the last requirement amounted to a monopoly of publication there would have been room to criticise it both on principle and as a workable proposition. The committee, however, have acknowledged that publication of the full details of newly named bacteria can be in any scientific journal or book whilst stating that they will not validate any name until it has been announced (with reference to the full paper) in the *International Journal of Systematic Bacteriology*. This makes good sense since it will mean that any initial search through past names can henceforth be made in a single journal.

It is also good that the Judicial Commission of the ICSB is willing to consider proposals to re-admit bacteria that have been excluded from the approved list. No gathering of experts, however conscientious, could have hoped to make all the correct decisions and doubtless a small number of old names will get back on the list. The Judicial Commission should be firm but sympathetic to anyone who is willing to champion the re-appraisal of their pet species provided that they are prepared to produce adequate evidence, a modern description and a satisfactory type strain.

This attempt of bacteriologists to put their house in order has implications for other biologists. The great conservatism of nomenclaturalists is well known. The idea of abandoning the principles of priority is anathema to them. But when the application of the principle causes more instability than the stability it is intended to preserve, then it is indeed time to make a fresh start. The plan adopted for bacteria may be directly applicable to only a few other groups of living organisms. But the principles followed in the plan may be of wider use when the nomenclature of other groups of living creatures, or of other scientific entities (eg genes, enzymes, ecosystems) comes to need revision. □

New UK Select Committee needs more attack

ONE of the first trials of the new UK select committee system took place last week, when the House of Commons Select Committee on Energy confronted the Secretary of State for Energy, Mr David Howell, and his junior ministers, on the government's recently announced nuclear policy. The Secretary of State undoubtedly won the battle.

Not that that was entirely due to the integrity of Mr Howell's case. While Mr Howell is a thoughtful minister, and well-briefed by his large department, there are inevitably weak points in his thinking and lacunae in his policy; and it is the job of the Select Committee to bring them out.

For example, what of the accusation that if the £10-12 billion of government money allocated to the nuclear plan had instead been allocated to existing and proven conservation technologies, three times the primary energy value of the reactors could have been saved? On a recent television programme, Mr Norman Lamot, the minister responsible for nuclear affairs, answered this with a remark about it being impossible to control the needs and desires of energy consumers, missing the point completely that both the nuclear plan and a conservation plan are matters of direct government spending, as when the gas-cookers of Britain were converted, at government expense, to North Sea gas.

Further, it is clear that one of the principle objectives of ordering ten new nuclear reactors is to assure the strength of the Biritish nuclear industry. But after the long history of set-back with the advanced gas-cooled reactor, and the loss of many highly-trained staff, is the industry capable of carrying the orders out?

The new arrangement of select committees, which parallels the arrangement of government departments and has hence eliminated the useful form of the Select Committee on Science and Technology, was intended to give MPs a more direct basis of attack on government policy. But on last week's performance it seems unlikely to have that effect. More of those serving on the committees should be prepared to do some hard homework, and the committees should be more prepared to organise themselves to attack and expose the weak points in government thinking. Neither the homework (except in one notable case) nor the organisation were particularly evident at the Select Committee on Energy last week. □

OSHA looks at occupational regulations for recombinant DNA use

REFLECTING the increasingly rapid movement of recombinant DNA techniques from the research laboratory to the industrial production line, occupational health agencies in Washington are beginning to discuss how they should handle any health hazards that may be involved.

Dr Eula Bingham, Assistant Secretary of Labour and head of the Occupational Safety and Health Administration (OSHA), has suggested that an expert panel be set up to address the hazards of DNA use "particularly as they apply to potential occupational exposures".

In a letter to Dr Donald Fredrickson, Director of the National Institutes of Health, Dr Bingham says she supports the system of voluntary compliance by private industry with the NIH guidelines which, after a period of public comment, was implemented last week.

But she adds that the agency feels that "more formalised enforcement of procedures and rules within the regulated private sector is warranted" — a feeling shared with Senator Adlai Stevenson Jr who last week introduced a bill into the US Senate requiring mandatory registration of all appropriate experiments not currently covered by the guidelines.

Dr Bingham has suggested that the new panel should be established under the chairmanship of Dr David Rall, Director of the National Institute of Environmental Health Sciences — and that it should include not only members of the NIH's Recombinant DNA Advisory Committee, but also technical representatives from unions, management and public interest groups.

She also suggests that OSHA might review the NIH guidelines and publish them as interim guidelines for industry. "While these do not hold the force of regulations, they would indicate our support for control in this area and would also produce information to employees indicating what we feel are appropriate precautions and procedures of recombinant DNA use".

Dr Anthony Robbins, Director of the National Institute of Occupational Safety and Health (NIOSH) told *Nature* this week that he agreed with OSHA that the time was appropriate for detailed consideration of the implications of occupational exposures. Commenting on the fact that, in the past, OSHA has been reluctant to involve itself in the debate over the safety of occupational activities involving recombinant DNA techniques, Dr Robbins said that previously the agency had hoped this would be done elsewhere. "Since no one else seems to be doing this, it seems to be the time to move", he said.

NIOSH is, in particular, suggesting that a registry be set up of all workers involved in such actitivies to enable the long term health effects to be adequately monitored. And as a precedent, he points to the recent decision by the Swedish government to set up a commission on the occupational hazards chaired by the head of the National Labour Protection Board.

No response to Dr Bingham's proposals has yet been formally received from Dr Fredrickson, who last week issued virtually unchanged revisions to the NIH guidelines which he had proposed last November and which significantly reduce containment requirements for a wide range of experiments.

In particular, Dr Frederickson has implemented his proposals that most experiments involving the bacterium *Escherischia coli* K-12 be reduced to P1 plus EK1 containment levels, and that such experiments no longer need be registered with the NIH.

In announcing his decision, Dr Fredrickson said that he had received five letters of comment suggesting that the relaxation of the guideline was premature. However he had also received more than 170 letters giving general approval to the proposed changes, which he had decided to implement as originally suggested.

Dr Fredrickson's announcement, widely welcomed in the scientific community, coincided with the introduction of the bill tightening up the requirements for private industry introduced by Senator Stevenson, chairman of the Senate Subcommittee on Science and Space. Explaining the general purpose of his bill, Senator Stevenson said that in a time of general concern about the health of industrial innovation, the conditions surrounding recombinant DNA research seemed "unusually favourable" for the achievement of significant innovation — and that in the circumstances government regulations should not be undertaken lightly.

"However the modest registration requirement I propose is justified as a minimal precaution against inadvertent harm to public health or the environment. Far from impeding the orderly progress of the research and its commercial exploitation, mandatory registration may actually facilitate it." ☐

Earth sciences and remote sensing agreements signed with China

THE United States and the People's Republic of China last month signed two protocols for scientific and technological cooperation in earthquake studies and earth sciences, as well as a memorandum of understanding on the use of the Landsat earth resources monitoring satellite.

The signing of these accords came almost exactly a year after President Carter and Vice-Premier Deng Xiaoping signed a general agreement on scientific and technological cooperation between the two countries in Beijing (Peking).

The earthquake studies protocol includes cooperation in earthquake prediction, earthquake hazards evaluation and earthquake engineering, as well as other related basic and applied studies. Joint research in these areas is to begin immediately.

The other protocol covers research in areas such as marine resources, energy resources, marine geology and geotectonics. The two protocols cover various forms of cooperation between scientists in the two countries, including exchange visits, joint organisation of scientific conferences, symposia and lectures, and the exchange of specimens and standard samples.

Under a separate agreement with the National Aeronautics and Space Administration the People's Republic will purchase a ground station to receive, process, archive and disseminate earth resource data from the Landsat D satellite.

The station will be located near Beijing and the Chinese Academy of Sciences has agreed to help share in the cost of operating the satellite by paying an annual access fee of $200,000, beginning six months after the station starts to receive data.

Other areas agreed by the Commission for possible future cooperation included aviation, statistics, nuclear energy (including nuclear physics and nuclear fusion), electronics and telecommunications. Administration officials in Washington last week rejected suggestions that moves to improve scientific and technological links with the People's Republic of China were directly related to the recent cooling of political and scientific relations with the Soviet Union.

Appearing before a Congressional committee hearing, Dr Frank Press, Director of the Office of Science and Technology Policy, said that scientific exchanges with China had been a positive element in the process of normalising US-China relations. **David Dickson**

Andrei Sakharov

US cuts back on official exchanges with USSR

THE US scientific community has been almost unanimous in condemning recent moves by the government of the USSR, in the occupation of Afghanistan and the internal exile of physicist Andrei Sakharov.

But while many support the legitimacy of individual protest, there remains uncertainty over how far official reaction should undermine the network of bilateral exchange agreements which have, in recent years, begun to produce mutual benefits.

On the one hand, Congressman George Brown, last week introduced a bill calling for a one-year moratorium on US-Soviet exchange except those essential to national needs or a matter of extraordinary circumstance of individual conscience.

The Carter administration, however, while keen to make clear to the Soviet government that it is not 'business as usual' for scientific exchanges, is also concerned to maintain what it can of the existing framework for scientific cooperation.

Thus all high-level meetings between scientists and scientific administrators from the two sides are being deferred. Three such meetings have already been postponed since the occupation of Afghanistan, and all current exchange arrangements are undergoing close review.

But the administration is at present keeping the door open for low-level contacts between scientists which it considers to have a purely scientific or humanitarian purpose. For example, a scientific delegation from the USSR studying the biological control of pests has been allowed in — but a delegation coming from the USSR to discuss science policy has not, since it was lead by a deputy minister.

The administration's determination to keep open channels of communication, even if limiting activities in these channels, was supported by Academy President Dr Philip Handler, who will be leading the US delegation to the scientific forum in Hamburg later this month to discuss the progress of the Helsinki accords of 1975. But he emphasised the Academy's position that the main responsibility lay on the shoulders of individual scientists.

Uncertainty over how tough the administration should be is reflected in the debate over what type of strategy the US delegation should pursue at the Hamburg science forum.

Few currently support a complete boycott of the meeting. And there seems general agreement that human righs considerations are central to international scientific communication and exchange.

But given agreement that the forum should discuss, in Dr Press's words, "the context within which scientific cooperation takes place, not simply those scientific subjects which are amply discussed in many other settings", opinions are divided on what such discussions should aim.

Dr Paul J Flory, for example, Emeritus Professor of Chemistry at Stanford University and a member of the US delegation, suggested that the scientific community should "reshape its criteria for participation" and lay down a set of minimum conditions for future international collaboration.

These might include the condition that "negotiations should be in the hands of scientists, not governments", and that participants be selected "without regard for their political conformity, race or ethnic background".

Others have suggested more modest goals. In particular Dr John T Edsall of Harvard University, chairman of the American Association for the Advancement of Sciences' Committee on Scientific Freedom and Responsibility, has suggested that the forum should establish a working group to collect and review reports about obstacles to international scientific cooperation. **David Dickson**

Soviet Union responds to western reaction

WITHIN a few minutes of the news of Sakharov's exile reaching the West, the Royal Society sent a cautious telegram to the Soviet Academy of Sciences, deploring the action and asking for the Academy's comment. Six days later, the Academy made its opinion known in a formal statement by the Presidium.

The statement condemned the activities of Academician Sakharov as being directed "against the interests of our country and the Soviet people, actions that help to build up international tension and bring into disrepute the exalted title of Soviet scientist". Ironically, the Presidium's statement accuses Sakharov of "undermining" precisely those ideals of peace, arms limitation and detente that underlie his whole involvement with human rights. Last year, indeed, he spoke out resolutely against overenthusiastic efforts to link US willingness to sign SALT-2 with human rights in the USSR.

Nevertheless, the statement contained no indications that moves would be made to expel Sakharov from the Academy. While feelings of solidarity may so far have prevented Sakharov's fellow-Academicians from expelling him from their ranks, there is little doubt that scientists of dissident outlook and lesser prestige now feel themselves under increasing threat. Andrei Tverdokhlebov, the young physicist, who had formerly worked closely with Sakharov in the human rights movement was expelled to the West just in time to testify before last week's congressional hearing in preparation for the Hamburg scientific forum. And a number of Jewish refusniks, notably Naum Meiman the mathematician and Aleksandr Lerner the cybernetician, have expressed fears for their own liberty.

Meanwhile, the Soviet authorities are attempting to counter western concern by denying that Sakharov has been, in any sense, exiled. "Administrative banishment", said one Tass statement "is neither 'arrest' nor 'exile'." Gor'kii, said comentator Yaroslav Khabarov on the foreign service of Moscow radio, "is one of the most beautiful towns in Russia, as well as a major industrial, cultural, and scientific centre with its own university". By simply stripping Sakharov of his awards and titles, and "moving him outside the city of Moscow", Khabarov explained, Sakharov has been given "the opportunity to continue to work in keeping with his profession". **Vera Rich**

Soviet Union

New appointment binds science closer to industry

ACADEMICIAN Gurii Marchuk has been appointed Chairman of the State Committee for Science and Technology, in place of Academician Vladimir Kirillin, whose resignation, was announced on the same day as the banishment of Andrei Sakharov from Moscow.

The appointment of Kirillin's sucessor came remarkably quickly. The post is of ministerial rank (and carries with it, virtually automatically, the position of a Deputy Chairman of the Council of Ministers). Posts of this calibre are seldom filled immediately — a lapse of several months has, of recent years, been the rule. Moreover, at 54, Marchuk is unusually young by Soviet standards, for high office. The average age of the country's leadership is in the late 60s.

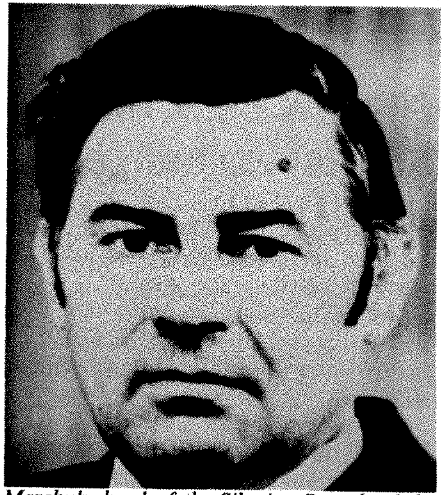
Not that Marchuk is unknown to Soviet science. He has already held the corresponding position of head of the Commission for Science and Technology of the Soviet of Nationalities (lower house). More important, he is head of the Siberian Branch of the Academy of Sciences.

The Siberian Branch of the Academy was set up in 1957, housed in the new Akademgorodok (Academic Village) at Novosibirsk, and briefed specifically to work on scientific problems of greatest relevance to the development of Siberia and the far east. By 1966, the branch had become surrounded by a network of research institutes, design bureaux and experimental production factories subordinated to individual ministries but under the scientific supervision of the branch.

This system of dual control has caused concern to a number of Soviet scientists, who have felt that the ministries might burden the R&D facilities of the branch with small-scale, day-to-day tasks, or even bypass the scientists altogether in decision-making.

Since he took over the chairmanship of the branch in 1975, Marchuk has written extensively on the dual control problem. Although at times he has complained that certain ministries have been lax in providing suitable conditions for successful work, his overall view is that the dual control system works well.

Of recent years, there has been constant emphasis in the Soviet press that science and industry must be more closely linked.



Marchuk: head of the Siberian Branch of the Academy of Sciences

Last November, when castigating the State Committee for slackness, Mr Brezhnev suggested that the Academy of Sciences should take a greater lead in organising the applied research the country needs. The precise division of labour and responsibility between the State Committee and the Academy is a complex subject (the head of the State Committee is regularly a Vice President of the Academy). Marchuk's Novosibirsk background, however, suggests that the long-discussed Soviet policy of integrated planning and the close coordination of research and production will be a keynote of the next five year plan for science.

Vera Rich

United Kingdom

Industrialist made part-time director of biophysics unit

THE UK Medical Research Council (MRC) has taken the unprecedented step of appointing as a part-time director of one of their research units a scientist who is permanently employed within industry. As soon as Professor Maurice HF Wilkins retires as Honorary Director of the MRC Cell Biophysics Unit at Kings College, London, he will be replaced by the combination of Dr David Rees, 43 year old Executive for Scientific Policy for Unilever Research and 56 year old Professor Brian Boycott who is on the Unit's staff. Whereas Professor Boycott's post will be full time, Dr Rees will be in the service (and pay) of the MRC for only one day per week, on average, and will retain his present position with Unilever.

The hunt for a new director has been on for well over a year since Professor Wilkins let it be known that he would like to retire as soon as a replacement could be found. But it has proved extremely difficult, and ultimately impossible, to attract someone of the right calibre and scientific background to be director. The solution adopted is based on the belief that Dr Rees' scientific credentials as a carbohydrate chemist with a strong interest in cell biology will complement those of Professor Boycott whose expertise is as a neuroanatomist of the retina.

Professor Boycott told *Nature* that he was glad to have someone familiar with current molecular biology as an Associate Director. The MRC expects Dr Rees "to inject good science into the unit" first by spending a continuous two to three months there and then by one day a week appearances and through having two of his research staff working in the unit. In return they hope that members of the unit will wish to sample the facilities and atmosphere of the Unilever Research laboratories.

A spokesperson for the MRC said that the link with industry was an experiment as much of serendipity as of design but that the MRC was now anxious to foster relationships between itself and industry. Although no other links were currently planned, as opportunities arose they would be considered seriously. □

Temperate vegetable seed bank set up

OXFAM, the Oxford-based famine relief organisation, has raised £700,000 by special appeal to establish a seed-bank for vegetables. A target of some 10,000 species will be collected in a -20°C store associated with potting facilities, laboratories, and greenhouses.

According to Oxfam's director, Mr Brian Walker, two-thirds of the seeds collected will be temperate, and only one-third tropical; but, says Walker, "in many parts of the Third World people eat temperate vegetables: cauliflower, onions, carrots, potatoes, cucumber, tomatoes.

"In a tropical country you only have to go a little way into the hills to meet temperate conditions. A large part of India's potatoes are grown in the hills." Moreover, winter in the northern plains of India was little different from the growing season in the US.

The origins of the Oxfam initiative go back to the Rome food conference of 1974, when it gathered a group of senior scientific advisors to survey world seed-banks and report on deficiencies. The group reported that while there was good coverage of cereals, there was no embracing collection of vegetables, which are important particularly for people growing cash crops around the borders of towns.

The seed-bank will be established at the UK Agricultural Research Council's Vegetable Research Station at Wellesbourne, Warwickshire. Oxfam's £700,000 will pay the capital costs, and the running costs for the first seven years. Then the bank will be taken over by the ARC. □

0028-0836/80/06514-01$01.00

NEWS IN BRIEF

Stanford president to head Rockefeller Foundation

Dr Richard W Lyman, currently President of Stanford University, California, has been chosen from a field of 1000 nominees to head the Rockefeller Foundation. Dr Lyman has been President of Stanford since 1970, and will leave his post in the summer. He will succeed Dr John H Knowles, who died last March, as President of the Foundation, of which he has been a trustee since 1976. University officials at Stanford will meet next month to discuss the selection of a new president.

US airlines told to restrict ozone intake

TEN years ago, it was a question of whether high flying aircraft would cause permanent damage to the Earth's ozone layer. Now US scientists are concerned that an excess of ozone inside such aircraft could be a hazard to passengers. And the US Federal Aviation Administration has issued rules requiring aircraft to reduce the amount of ozone entering aircraft, based on standards established by the Occupational Safety and Health Administration.

Initially proposed in 1978, the new rules will require airlines to screen out most ozone as it enters airline cabins by means of charcoal filters — or to follow routes that avoid areas of high ozone concentrations. On flights of less than four hours the maximum concentration of ozone will be 0.25 parts per million. On longer flights, the average level must be no more than 0.1 parts per million.

Pugwash takes up East-West dialogue

THE informal diplomacy practiced for 25 years by the Pugwash conferences was brought into play on 19-20 January in Geneva to "take up the slack caused by the present suspension of official East-West dialogues". Convened by the Pugwash Executive Committee, thirty three participants from 19 countries including high ranking Soviet and NATO officials met to discuss "the critical nature of current developments and the increasing danger of nuclear confrontation". Described as "useful", the talks included exchanges on the subjects of Afghanistan and the destabilising effects of the NATO nuclear modernisation programme. The participants will continue discussions at another specially covened meeting to be held in mid-April.

In the meantime the British Council of Churches is continuing its campaign against the installation of the latest Polaris missiles on UK submarines (29 November page 435). BCC representatives met with the Ministry of Defence last week where they raised the question of the military relevance of a UK submarine nuclear threat that would be under NATO, not UK,control. Citing the opinions of Lords Mountbatten and Carver in support,BCC representatives cautioned the Ministry against renewing the Polaris as "a matter of political machismo".

PETRA to boost luminosity by ten

PETRA, the existing 19 GeV on 19 GeV electron storage ring at DESY, Hamburg, will install the last of 60 accelerating cavities in February and so for the first time reach its peak energy. And as the luminosity of storage rings increases rapidly with energy, it is hoped to raise the present 50 per day event rate by a factor of ten. This should make it possible at last to perform the 'forward-backward asymmetry' experiments which should detect the low energy 'tail' of the Z^0, and bring early indications of the presence of the particle. According to the Weinberg/Salam unified theory of the weak and electromagnetic interactions, the Z^0 (intermediate vector boson) plays the same role in the weak interaction as the photon in the electromagnetic interaction. At 90 GeV, it would be the heaviest particle yet found.

Basques blow up nuclear power plant equipment

MEMBERS of the Basque separatist organisation ETA blew up electrical equipment scheduled for delivery to the troubled Lemoniz power plant near Bilbao last Sunday. A group of armed men captured the factory manager of the Segasa factory in Vittoria at his home, took him to the factory where they disarmed eight guards of their .38 calibre pistols and placed plastic explosive around special batteries intended for the Lemoniz plant. Warning the guards and manager to stay clear of the blast, the men left and the batteries exploded a few minutes later. The action occurred during a weekend of revolutionary violence in which ten people were killed in armed actions throughout the country.

Denmark shelves nuclear power indefinitely

THE Danish government last week announced an indefinite postonement of the introduction of nuclear energy. In a major policy shift, said to be strongly influenced by the accident at Three Mile Island, the ruling Social-Liberals supported by the Single Tax party, two smaller left wing parties and the major trade unions — who had previously supported nuclear power — decided to defer any parliamentary action on the question.

Citing uncertainties about safety and waste storage, Energy Minister Poul Nielsen pointed out that Denmark was too small to support safely more than five nuclear plants which would only supply 15% of Denmark's energy needs. In its place, development of North Sea gas in conjunction with Norway is expected to cover the major part of Danish, Swedish and Norwegian energy needs well into the next century with enough left over to export to West Germany. The government will now draft a new energy plan that will emphasise, a shift from oil to gas, energy conservation and increased commitment to the development of alternative energy sources.

French researchers protest CNRS reorganisation

FRENCH scientists of the Centre National de Recherche Scientifique continued their opposition to management reorganisation plans by holding a one day strike and demonstration last week. More than 1500 research scientists marched through Paris to the offices of the Secretary of State for Research to protest against recent changes in the law which would introduce a new four year probationary period, lower the maximum age for entry to research to 27 years and permit forced mobility at the discretion of research directors. The trade unions representing the researchers sent an open letter to Prime Minister Raymond Barre signed by 1000 scientists including 300 research directors, senior researchers and professors that demanded a suspension of the decrees as measures that "would compromise gravely the future of basic research in France".

SRC clamps down on post-docs

THE UK Science Research Council has instructed its research directors to apply "rigidly" all rules concerning employment of post doctoral research fellows. The orders, contained in a memorandum circulated to SRC research establishments last November will effectively prevent research scientists on post doctoral contracts from gaining extensions or further contract work when their present contracts expire. The SRC defends its policy in ethical terms. Stating that the reasons for the policy were not financial — "very few people will be affected" — an SRC official said "we have a moral responsibility to encourage new ideas. People who have been here six years have had their chance and now they must make way for fresh blood".

FEATURES

Research centres, libraries, journals flourish in new China

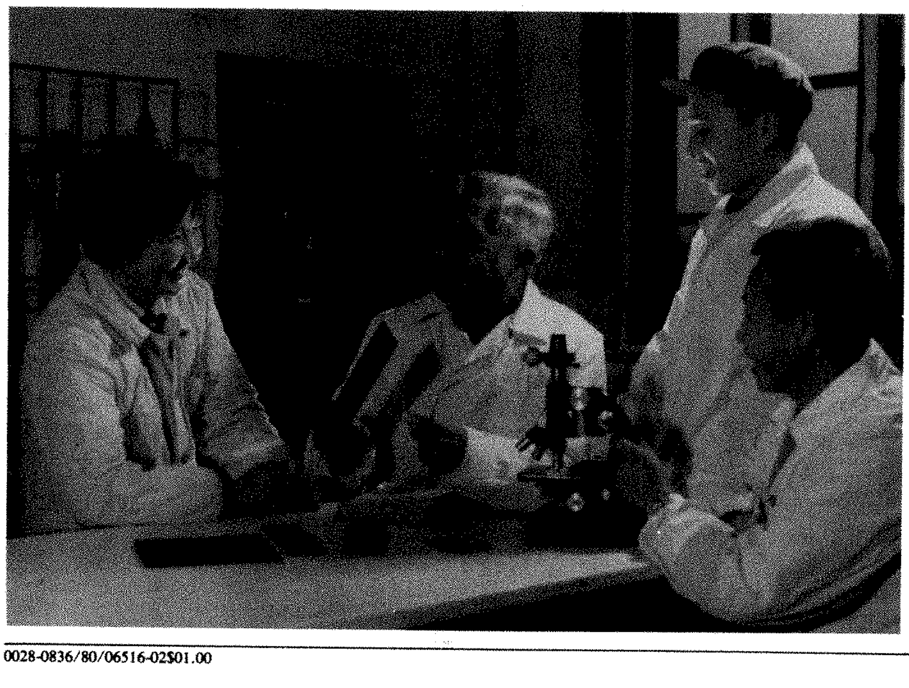
In the second of three articles on the development of science and technology in China, **Tong B Tang**, research fellow at Darwin College, Cambridge, UK, who visited China at the end of last year, examines scientific services

MOST Chinese scientists — indeed, the people as a whole — are friendly, forthcoming and purposeful, yet modest and earnest (sometimes to the point that reserved westerners find uncomfortable to reciprocate). Their optimism is derived from the positive and negative lessons of the Cultural Revolution (reputedly assessed by Chairman Mao to be 70% and 30% respectively), open discussions on present problems, and from a common resolve to achieve the four modernisations in agriculture, industry, national defence, and science and technology. To this aim, the political decision-making system is being scrutinised and modified to prevent the recurrence of a dictatorship by a minority, like that of the Gang of Four (GoF).

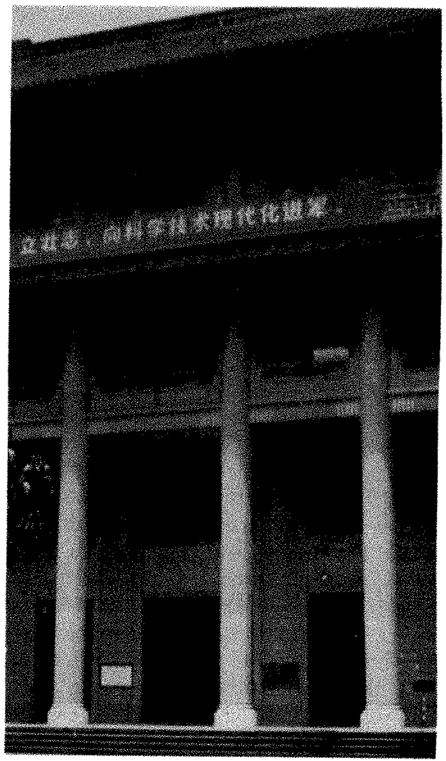
Both science and scientists suffered under the GoF. This was probably due not so much to deliberate policies as to the GoF's broadside attacks on "revisionism" and on people it labelled as "capitalist-roaders". Although the GoF had some supporters its treachery became increasingly clear with time: its attacks constituted the means rather than the end of its attempt to seize power. Sectarianism resulted and this reached a peak in 1975 when Mao condemned the factions semi-publicly. The aim of the present leadership is an extended period of stability and economic construction. The conditions are right for the growth of science.

Not surprisingly the Scientific and Technical Association, which barely existed three years ago, is expanding. Often affectionately referred to as the 'home' of scientists, it sponsored some 150 meetings in 1978; the number last year exceeded 650. The newest members include a futurology society and a solar energy society. As well as its function as a learned society, the association is responsible for the popularisation of science, which I shall talk about next week. Neither it nor any of its member societies acts as a qualifying body.

After the reopening of their 'home', our Chinese colleagues are also benefiting from other improvements. Problems had included insufficient time for research owing to a shortage of assistants and too many administrative commitments and family inconvenience such as wife and husband having to work in different institutions in different places. Now that research and/or teaching are judged to be the scientists' main duty, conditions of work are guaranteed. The buildings and appliances such as power points are often old and spartan by western standards, but functional. In general there are still not enough instruments yet, reassuringly, for the most part they are designed and produced in China. Laboratories may look run-down, but everyone using them knows exactly how the equipment works. Usually every bit of the equipment has not only been designed and built by the experimenters but is also maintained by them. Of course, there are some negative aspects. In a few places I noticed, for example, that resources appeared underused. But the main feeling is one of optimism.



Researchers at the Institute of Applied Chemistry, Kirin, discussing the structure and performance of a new polymer



The Academia Sinica at Guangzhou (Canton)

Most Chinese scientists (some 25,000 out of 36,000 of those in the Academia's institutes) were trained after the Liberation and before the Cultural Revolution. They were educated by teachers produced by the old social system; through remoulding and re-education, however, they are judged to have become "part of the proletariat" now that the gap between manual and professional labour is considered overcome. Many scientists are commended

0028-0836/80/06516-02$01.00

as advanced workers and are thus entitled to wage increments (the latest nationwide wage increase, on 1 November, was for 40% of state employees.) More important, more scientists are now allowed Party membership; they can be elected as deputies to the National People's Congress, or appointed to authoritative positions. In the past decade, a career structure, by qualification and seniority, has been designed and scientists can look foward to promotion.

A few institutions now adopt the convention that the authorship of papers will serve as a simple criterion of a member's contribution. All journals in China are, of course, published by the state and they have mandatory rankings, a paper in *Scientia Sinica* carrying the most weight. This may encourage the formation of self-centred sub-groups each pursuing prestigious research; the decline of collective authorship in the journals could be a reflection of this. More inventively, some institutions pursue the practice of arranging exhibitions of research results. All members are invited to assign 'work points' to the research on display according to personal judgements of its quality. Promotions are decided by the institution's 'academic committee' which refers to these collective evaluations. Some institutes also organise symposia at which their research is described and then discussed by co-workers invited from other institutes or universities.

Since 1978, scientists have been paid by the state for papers published whereas in the previous decade not even authors of books received royalties. Much stress is being laid on information science. Last August the China Society of Libraries was formed. Some of the larger university libraries plan to be computerised within a few years. Also in 1978 the Scientific and Technological Literature Press began issuing, for a whole range of subjects, monthly and bimonthly indices of foreign papers and specifications of open patents being applied for in Japan.

A national shortage of wood and wood pulp has constrained the publication of books and periodicals but is slowly being overcome. China now publishes a total of 1,200 periodicals in all areas and more will probably be launched. In electronics and communications technology, for example, there are some 20 primary journals with a general circulation. I also saw the following titles which are exclusively devoted to classical disciplines within physics: *Acta Physica Sinica, Wuli* (physics), *Acta Mechanica Sinica, Mechanics & Practice, Acta Acustica, Luminescence in Solids & its Application, Laser Journal, Gaofengzi Wuli* (high polymer physics), *Diwen Wuli* (low temperature physics), and *Physica Energiae Fortis & Physica Nuclearis*.

Students at the University of Science and Engineering, Tsinghua, engaged in an electronics experiment

Foreign journals are also used. Because of their high costs, however, most of them are centrally subscribed by airmail and then reprinted, the home-produced versions then being nationally distributed. The copies usually manage to reach the library shelves with no more than a few months' delay. There are no cover-to-cover translations into Chinese, and some readers may find this a problem.

The language problem can also affect visiting scholars. Speakers may find that their talks and the subsequent questions and answers are translated verbatim, sentence by sentence, with the help of the entire audience. Despite such difficulties, it is certainly a positive development that visits, in either direction, are increasing in both frequency and in the variety of disciplines covered.

'Centres of Scientific and Technical Exchange with Foreign Countries' have been set up in Beijing, Shenyang, Shanghai and Guangzhou (Canton) to assist the Foreign Affairs Bureau of the Academia Sinica and the Ministry of Education with scientific exchanges. The Scientific and Technical Association also oversees exchanges. Together with the US Committee on Scholarly Communication with the People's Republic of China (PRC), it is arranging for senior scientists as well as graduate students to stay for extended periods in China and participate in joint programmes. Sino-British cooperation in education, public health and culture was sealed by a five-year agreement signed at 10 Downing Street on 1 November 1979 during Hua's visit.

China now hosts international conferences more often, examples being the International Rice Research Workshop at the end of October last year in Guangzhou, and one on particle physics one month ago, at the same venue, under the chairmanship of Qian Sanqiang.

More than 1,600 academics, 180 research students and 420 undergraduates have been sent by China in the past two years to the US (500), UK (300), West Germany (200), France (200) and Japan (100). The overwhelming majority (1,800) are studying natural sciences. Advanced crash courses in languages, more often needed than not, are given just before departure or immediately after arrival at the host country.

Language will not, of course, be a problem for visitors of ethnic Chinese origin if they can speak the standardised dialect. Some of them have established close contact, and are on the 'academic committees' of some institutions. Scientists such as Chen-Ning Yang, Nobel prizewinner for the discovery of the violation of parity conservation, have made particularly valuable contributions, by participating in or advising on research, and inspiring young people, as well as cultivating friendship between China and their adopted countries.

'Sister universities' constitute another novel form of overseas ties. Zinghua at Beijing is affiliated to the University of California at Berkeley, Zhongshan in Guangzhou to the University of California at Los Angeles, and Nanjing to the University of Wisconsin. China is taking part in more bilateral and international scientific programmes. Recent examples are the measurement of $\nu_\mu e$ interaction cross-sections at the Fermi Laboratory and the Global Atmospheric Research Programme sponsored by the World Meteorological Organisation. As a result of these overseas links, increasing attendance at international meetings, and of submission's to western journals by Chinese scientists, it is now easy to find out who's doing what in the country. One source of information is the *Directory of Scientific Research Institutes in PRC*, produced by the National Council for US–China Trade in Washington, D.C. □

One man, two cultures, one discipline

Robert Walgate speaks to a former film-maker who subjected himself to the 'discipline' of science, and succeeded

"IT WAS a pretty nasty business" said Michael Shallis, gesticulating from his office chair against a blackboard backdrop of equations and graphs, "making cinema commercials. I spent a year as a staff film director for the Rank Organisation." He laughed. "It was really quite ludicrous — we'd make about six a day."

Dr Shallis is now a research fellow with Professor Donald Blackwell in the Department of Astrophysics at Oxford, making ultraprecise, painstaking measurements of the oscillator strengths of spectral lines of iron and other elements, to create a new basis for classical stellar spectroscopy.

He took no interest in science at school; avoided university; and joined a film school in London. He became an editor with Movietone News, the last of the cinema newsreel makers.

But during the sixties he bacame "exposed to science in one or two curious ways. I was absolutely spellbound by a series on television by J. Z. Young, the biologist — I've still got the little BBC two and sixpenny booklet that went with it. I found that the way he thought was very like the way I thought".

"In the film industry, the way I thought was very different from the people I was working with. I can't really explain it because I didn't at the time understand it myself."

Could he understand it retrospectively? Very diffidently Shallis said that he had an objective curiosity which he could see reflected in Young; whereas the people in the film business work mainly from their emotional rather than intellectual centres.

Shallis felt he wanted to make a film about the way science shaped us, how society might develop — but he found it difficult to interest a backer. "I spent quite a lot of time seeing if I could combine some sort of interest in the sciences with other things . . ."

Shallis's shift to the physically objective, the rational — wasn't that totally against the trend of the times, which was to abandon science and technology for the mystical?

"Yes, as that happened I did exactly the opposite. Then I reached a decision in 1970, when I was 27, that the only way I'd understand about science was by going and doing it."

The next thing was to work out how to do it, with A-levels in art and English. He started reading books on science, and began to see that he was more interested in cosmological and astronomical ideas than biological. Shallis was amazed to discover Professor Elton's conversion course from arts to sciences at the University of Surrey. He spent a year on that and emerged four years later with a first in physical sciences. Both courses have now closed.

There was a lot of spectroscopy in the course; he was interested in astronomy (he built a photometer for his telescope as a final year project); and when it came to choosing where to do research he chose Blackwell's group.

"I don't regret the decision. I think the work we do here is the most interesting in ground-based astronomy in this country. I'm a pragmatic person; so I'd always have been an experimenter or an observer. I was pragmatic in film-making too, interested in behaviour rather than inner psychological motives."

Wasn't the kind of science he was doing with Blackwell very painstaking and unspectacular? Wasn't the amount of emotional return that he could get from measuring the width of a spectral line pretty small?

"Well it was something I really needed to do. From the almost "anything goes" attitude within films, to the highly disciplined work that we do . . . I had to work very slowly and carefully, to learn that sort of rigorous discipline, which I'd never learnt in the arts at all. So I needed in the sciences very much to discover that rigour — in order, in fact, to release my creativity.

"The gap between the two cultures is probably widening. Up until the age of 27 I'd never met a scientist. At school they were completely a different breed. But now I've crossed the gap and discovered they are not a different breed at all, but actually doing the same thing. That has always interested me."

So why is the gap there? Partly for social and educational reasons — it's the way we are brought up; partly because scientists like it to be there. There's a sort of class distinction on both sides.

But also it's a matter of access; anyone can buy a book or a record. "You can go up to a man in the street and say have you seen the latest Woody Allen or have you heard about the Picasso exhibition at the Tate gallery and he'll say yes I have, I haven't seen it, but I know about it and I think Picasso's bloody awful; but if you ask him about the latest experiment in particle physics he'll look at you and gape and say, Ugh! At least the creative arts are accessible.

"People's hostility to science is growing and will continue to grow. As pollution and nuclear accidents and these things continue, hostility will grow and will grow rampantly.

"One of the problems scientists face is that they are so bound up in what they are doing, they generally fail to see why other people aren't. They find it very hard to see that other people don't necessarily find what they are doing fascinating. One sees this in the arts too. But it's more important in the sciences, because of the impact of technology on lives."

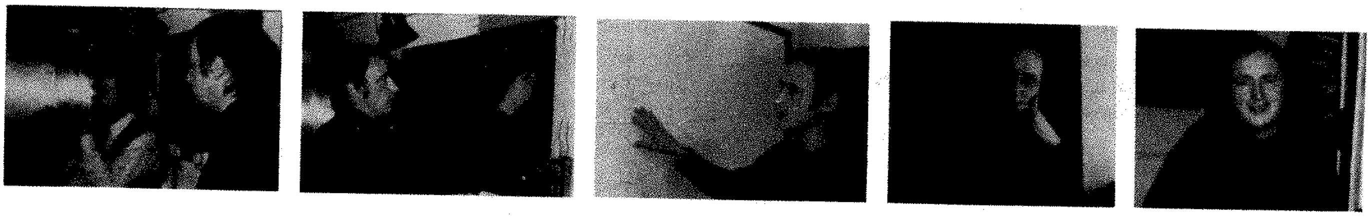
Now that Shallis has been through his creative period and his discipline he wants to loosen the discipline again.

"In a sense I want to integrate my experience. There are a lot of things I want to say about it. Which is why I want to move more into communication, writing books, teaching with the Department of External Studies. However fascinating research is, I still feel it is missing out on a lot of things, and there are other things I want to do.

"There are a lot of gaps to be filled in popularisation. The man in the street has very lopsided and wrong views about the nature of science, in ways that affect his life — like interpreting statistics.

"The thing that concerns me most within science itself is — I'm stepping carefully here — the lack of an ethical basis and the lack of a spiritual basis. It worries me very greatly.

"I came across a quotation from Jung last night: 'The rationalist unbeliever who has no gods left in his heart is tormented by the devils in his brain'. I think that's very good. Science as a collective thing has become a sort of rationalist unbelieving



Michael Shallis: film-maker turned astronomer

0028-0836/80/06518-02$01.00

entity with no gods left in its heart. And so it is tormented by the devils in its brain.

"One sees it in individual scientists to a greater or lesser extent. There's a scientist I know who believes — and it's a very widely held view — that ultimately everything in the universe can be reduced to physics. It is a very very sterile view, and one that I think is untenable. And in a sense their lives reflect this, their lives become extremely barren. Science is getting more and more materialist.

"Dora Russell said in her autobiography that science became inaccessible with relativity theory; and she saw that as the source of a lot of difficulties in the 20th century. Relativity theory was the first step towards obscurity."

How could ethics be grafted onto or grow out of science? "I'm sure there can be an ethical basis for science. The ethics have to come into the applications and the choice of science. It's tied up with the ethical basis of society."

Doesn't the scientist now have the ethics of the mercenary? Will he not do his science for whoever pays? "Yes. He thinks the freedom to investigate nature how he wants is his ultimate right. But I don't think anyone has ultimate rights.

"Take the use of animals. What ethical basis can you have for doing experiments with animals? The scientific community says animals should be available for whatever purposes we deem we need them for. We will be as humane as we can within those terms, but ultimately our interests over-ride the concern for the animals. I think that is a devastating ethic for science."

The discussions are always expedient, rather than ethical. "Of course that is a difficulty that our society in general faces — society doesn't have an ethic any longer that gives us any basis for our political judgements, our economic judgements, our personal judgements."

What about the spiritual element? "It is certainly lacking. Very few scientists have a feeling of awe about the universe; a few talk about it; but the whole thing becomes rather mundane for them."

But what should a group do? Every Saturday morning gather round and have a contemplation exercise? Shallis, laughing: "Maybe they should, quite possibly . . . . I haven't any answers, you see, I'm just beginning to become concerned with these things, and the more I think about it the more I become worried."

Does Shallis get any spiritual return from his spectral lines? "Out of science I get very little." But what kicks, I asked, *does* he get?

He is very enthused by the programme of Professor Balckwell's department. "Yes, that is very interesting, this is the kick, but so what? Can we justify that kick on other grounds? Is it enough? Matisse gets a kick out of doing a painting; a scientist out of his piece of science. On an individual basis that's fine. But what happens then? Science has, where art hasn't, an impact on the world. In science we have a whole group of people doing it for that kick, but we have also a vast power structure influencing the lives of all of us; and it is out of overall control. It is enough to Matisse; whether someone buys the painting or not is an irrelevancy to him; but the products of science are used and manipulated. I have no objection to the individual scientist; it is the influence of the collective. But then where does one draw the line?" ☐

Animal or vegetable?

THOMAS H. JUKES

VEGETARIANISM is a fascinating and delicate subject. It must be treated with tact because to many people it is of religious significance, but its scientific side compels interest and discussion. Bernard Shaw used to tell hostesses who invited him to dinner that he would not come to eat dead animals. He also refused to eat asparagus, which he said was a very nasty vegetable. His ebullient contemporary, GK Chesterton, in contrast, wrote some rollicking verses that made fun of non-meat-eaters, and non-milk-drinkers ("I will stick to wine and sherry, because they are so very, so very, very, very vegetarian").

An important step towards asserting the rights of plants was taken when it was found that cytochrome *c* of wheat and vertebrate animals had amino acid sequences so similar as to betoken the sharing of a common ancestor [1]. Indeed, the sequences of the cytochromes *c* show a phylogenetic relationship throughout the eukaryotes and extending to the purple bacteria. We cannot even eat a mushroom without devouring a relative. Some people talk and play music to their house plants, and we may soon hear of a Society For The Prevention Of Cruelty to Vegetables.

Deficiencies in foods of vegetable origin have been responsible in many countries for slow growth in children and, in consequence, for undersized adults. Even in the "developed" countries, it is sometimes ruefully pointed out that farm animals often receive better dietary treatment than human beings. This may be partly because cows do not read.

About 40 years ago it was evident that something in meat and fish, an "animal protein factor", was needed by chickens and pigs to correct a deficiency in diets consisting of foods of plant origin. Soybean meal, although a valuable food, lacked the missing substance. It was amusing and paradoxical that a vegetarian friend of mine, Lester Smith, successfully hunted down the missing substance in beef liver. In 1948, he isolated the anti-pernicious-anemia factor, which was also the animal protein factor. Simultaneously, the substance had been isolated from fermentation of a soil microorganism *Streptomyces griseus* [2]. The compound was was re-named "vitamin B_{12}", and the catchy designation did wonders for it. US professional football players, so I read recently, sometimes receive vitamin B_{12} injections to prepare them for the fray. Faith can move mountains.

Green plants do not make or need vitamin B_{12}. It all comes from microorganisms. Animals receive their supply from milk, or by predation, or from bacteria in the digestive tract, or by voluntary or involuntary coprophagy. The ruminating cow has an internal fermentation vat from which vitamin B_{12} gets in her milk to the benefit of lacto-vegetarians and other consumers of dairy products. Rabbits, less fastidious, consume their own faeces at night to obtain vitamin B_{12}. McGee [3] described the preservation, drying and consumption of faeces by the Seri Indians of Tiburon Island in the Gulf of California, who felt that endurance for the hard warpath on prolonged chase was augmented by this practice. Perhaps this was another case of faith moving mountains.

The consumption of meat is currently under criticism because its production is wasteful of food resources, such as cereal grains, that could be consumed directly by people. Against this, it is argued that grains are deficient in iron, and are poor sources of proteins. It is also true that ruminant animals supply us with meat and milk while consuming large quantities of forage and roughage, such as stalks and straw, that are not edible by human beings. The fermentation vat of the rumen converts the roughage to soluble nutrients. Some of the rumen organisms, *Methanobacteria* are strict anaerobes that may be "living fossils" of a very ancient era.

CORRESPONDENCE

Future world energy needs

SIR, — It would have been most instructive if we had been told the composition of the "Conservation Commission" of the World Energy Conference, whose 1978 Report on Energy Requirements between 1985 and 2020 was reviewed in *Nature* (November 15, page 344). Neither the Commission nor your reviewer appear to have addressed themselves to the possibility of meeting their projected goals. To reach them the Commission says that nuclear generating capacity must be doubled every six years from 1985. If we suppose that there would be no more than 200 1000 MWe reactors operating by that date, this growth rate would mean that 12,800 reactors of the same size would have to be built by 2020. To reach this number the world would have to build a reactor a day from 1985 onwards. Furthermore, since reactors are unlikely to last more than about 35 years, by 2020, this rate of building would have to increase to two per day unless of course demand miraculously levelled off at this point in which case it would merely be necessary to go on building a reactor a day for evermore.

The 12,800 reactors to be completed by 2020 AD would, during their lifetimes, need to consume up to 140 million tonnes of uranium metal, which is 10-15 times the 1979 estimates for the world's stock of uranium costing less than $30 a pound to extract.

The UK government has recently given an estimate of $£8 \times 10^8$ for building a 1000 MWe nuclear plant. 12,800 reactors of this type would therefore cost a total in the region of $£10^{13}$ in 1979 values. This and the fact that at present in the US it takes about 10 years between design and commissioning of a reactor (and reactors become steadily more complex in an effort to meet ever-stricter safety requirements) appear to indicate that the world's attitude to energy consumption will have to change radically within a few years from now.

In assessing energy "demands" one must remember that a 1974 UN forecast was that average energy "demand" in the developed countries up to 2020 AD would rise thirteen times as fast as population, whereas it was expected to fall in the developing ones. Projections of energy demand are therefore merely estimates of how much energy people will be willing and able to buy: they have nothing to do with opinions about what distribution of energy consumption would be socially or morally desirable. Perhaps we should start asking ourselves such questions now?

Yours faithfully,

R. B. TEMPLE

Physical Chemistry Department, University of Sydney, Australia

Biotechnology report

SIR, — I should be grateful if I might make it clear to your readers that the Biotechnology Report partly published by you (24 January, page 324) was not "made available to *Nature*" by the Working Party, who were unaware that you had obtained an early draft until two days before its publication. It was an uncorrected, tentative draft, sent to our three sponsors (ACARD, ABRC, and the Royal Society), and to many of those who gave evidence to us, in November. Their advice led to significant alterations, only completed on 21 January What I hope will be the final draft has now been sent to the sponsors for approval of publication.

Yours faithfully,

ALFRED SPINKS

Wilmslow, Cheshire, UK

Short-term research contracts

SIR, — It is indeed heartening to read your valuable and informed coverage of the problems of experienced and accomplished scientists stranded and unemployed in their thirties and forties. It is equally disheartening that *Nature* is almost completely alone, both in the specialist and the national press, in drawing attention to the problem and its magnitude.

Why is everyone apparently so complacent? Are research directors and professors alike so committed to the exploitation of cheap and expendable labour that they see no need to speak out against a system whose iniquities they have been fortunate enough to escape and whose benefits they shamelessly enjoy? Why do we hear nothing from the heads of research councils and grant-giving agencies? It may be argued that the present situation has developed of its own accord. Does this mean that nobody should now begin to set matters right? Where does responsibility for perpetuation lie?

I issue a challenge, to the head of any research council or funding organisation, to defend the present system of short-term contracts in scientific research. I challenge him to defend the practice of signing away rights in common law as a prerequisite for the acceptance of such contracts. I challenge him to justify the expenditure of public money on the training and usage of men and women drawn from the most talented sections of the community, to be tossed into the dole queue before their full potential is realised.

Yours faithfully,

ROBERT JONES

Am Steinberg 67, Heidelberg, Germany

Pheasants and spies

SIR, — Having just returned from Kathmandu, Nepal, where a highly successful International Pheasant Symposium was held from 21-24 November, I was horrified to read your story headline 'India's wildlife projects under spy cloud' (29 November, page 435). In this story, under a cartoon depicting Kashmir pheasant beaters, you report that "Foreign collaborators might use the [World Pheasant Association's] pheasant project [for the re-introduction of the Cheer pheasant] as a camouflage for spying in the sensitive borderland".

Had you checked with the World Pheasant Association you would have discovered that the "foreign collaborators" for this project confine themselves to despatching batches of Cheer pheasant eggs from Heathrow to Delhi, where they are met by Indians, hatched by Indians and reared by Indians with the full knowledge and support of the state governments concerned; clearly they do not share your correspondent's fear.

To set up the project I have myself visited the Wildlife Departments and other officials in Lucknow (Uttar Pradesh), Simla (Himachal Pradesh) and Srinager (Kashmir), all leading tourist centres and none of them on the 'sensitive borderland'. The publication of unmitigated nonsense like this can do the work of recognised charitable conservation organisations like the World Pheasant Association and its objectives nothing but harm.

Finally, the World Pheasant Association received from the Chief Minister of Jammu and Kashmir an invitation to hold the Second International Pheasant Symposium in Kashmir, (an invitation that is being accepted). Hardly the action of a government concerned with spies infiltrating its territory.

Yours faithfully,

K.C.R. HOWMAN

World Pheasant Association, Suffolk, UK

Standardisation of research citations

SIR, — Three groups of life science editors have tried to achieve the standardisation of reference citation for which P.C. Reid argues so cogently (17 January, page 242).

First, in 1973 the biochemists (IUB-CEBJ)[1] published a reference list style suitable for journals adopting either the 'Harvard' system (names and dates) or numbers for citations in the text:

Abel, B.C., Cain, A.D., Adam, E. & Eve, A. (1976) *Tree J.*, **12**, 90-99

Second in 1977 ELSE (European Life Science Editors' Association) and the Ciba Foundation organised a workshop on references and produced a set of suggestions[2] for a style that is also suitable for either names/dates or numbers in the text:

Abel BC, Cain AD, Adam E, Eve A 1976 Bark thickness in apple trees. Tree Journal 12:90-99 (*or* Tree J 12:90-99)

Third in 1978 the International Steering Committee of Medical Editors proposed what is now known as the Vancouver style[3], suitable only for citation by numbers:

Abel BC, Cain AD, Adam E, Eve A. Bark thickness in apple trees. Tree J 1976;12:90-99.

The main differences between the first and second systems lie in the punctuation, the typefaces, and whether article titles are included or omitted. The main differences between the second and third systems lie in the way references are cited in the text and in the punctuation and position of the date in the reference list. All three systems recommend that the 'International List' (ISO 833-1974; BS 4148 Part 1; 1970 and Part 2:1975) should be used for abbreviating journal titles, in preference to the World List.

The ELSE-Ciba Foundation system suggests that journal titles might be either unabbreviated or abbreviated, provided that each reference list is self-consistent on this point. A later suggestion is that editors and publishers should allow both names/dates and numbers in the same journal or book, provided that each article or chapter follows one style consistently. Since the American National Standard (ANSI Z39.29-1977) and the draft International Standard (DIS 690) on bibliographic references both permit flexibility in the position of the various elements, including the date, in reference lists it would be a great step forward if the third system became more flexible on this, so allowing names/dates to be used in the text. The second and third systems would then be even more alike than they already are, and the work of authors, typists and typesetters would be enormously simplified. (Copies of the ELSE-Ciba Foundation system are available in either a full or an abbreviated form from the editorial department of the Ciba Foundation, 41 Portland Place, London W1N 4BN, to anyone enclosing a self-addressed adhesive label with their request.)

Yours faithfully,

MAEVE O'CONNOR

The Ciba Foundation, London, UK

NEWS AND VIEWS

Communication between cells

from W.H. Evans

ANIMAL cells communicate in a variety of ways. The most direct and intimate communication must occur between assemblies of cells, allowing them to summate and coordinate their growth, development, division, metabolism, response to external stimuli and so forth. Exactly how this occurs is still a mystery, but as Unwin and Zampighi show on page 545 of this issue of *Nature* answers are beginning to be found at the cell's surface membrane — the repository of so many regulatory mechanisms.

A simple fact, appreciated widely only in the past 30 years — so persistent has been Schleiden's cell theory of 1838 emphasising that cells are self-contained independent units — is that most animal cells contain at areas of surface contact hydrophilic channels bridging the intercellular gap and directly connecting the cells' cytoplasmic milieu. These intercellular communicating channels can control the extent of equilibration of the cytoplasmic components, and they also provide the potential for the transfer or exchange of informational molecules across large sheets of cells — a property appreciated by developmental biologists. Provided that channel porosity is regulated, macromolecular individuality of the cooperating cells is maintained while the sharing of simple ions and molecules is permitted. The arrangement can appear as a sort of compromise between the independence seen in circulating blood cells and in nerve cells (which have developed alternative methods of communication using synapses) and the wholesale fusion of cells to form functional syncytia as seen in skeletal muscle.

By the 1960s a number of diverse biological observations converged to implicate plasma membrane junctions as the probable pathway for the rapid spread across tissues of injected fluorescent dyes, the passage of electrical current across heart tissue, and even the exchange of metabolic intermediates between cells in culture. Indeed, the last, termed metabolic cooperation (Pitts & Sims *Expl Cell Res* **104**, 153; 1977), has provided a most powerful experimental tool to investigate the specificity requirements leading to exchange of metabolites and has shown that channels are formed rapidly — within 30 min of intercellular contact (Epstein & Gilula *J. Cell Biol.* **75**, 169; 1977).

In 1966, Lowenstein (see *Biochim. biophys. Acta* **560**, 1; 1979) proposed a model for a direct cell–cell pathway that could permit ions and hydrophilic molecules of up to $\sim$1000 molecular weight to move more or less freely between cells. Soon after, the responsible anatomical structure in the plasma membrane of epithelial cells became clearer when Karnovsky and Revel used the lanthanum impregnation technique to distinguish clearly between tight and gap junctions between cells. The former seal off the intercellular space, whereas the latter have a 20–40 Å gap permeable to lanthanum. The use of the term 'gap junction' is perhaps unfortunate, for the intercellular gap revealed by electron-lucent tracers is bridged by leak-proof channels connecting the cell interiors. The functional distinction between these often-confused cell junctions could not be greater. Fast on the heels of the identification of gap junctions in tissue thin sections was the demonstration, by freeze fracturing the component plasma membranes, that gap junctions are easily identified as plaques of closely aggregated intramembranous particles. This quickly led to gap junctions being recognised throughout phylogeny — from simple coelenterates, such as *Hydra* to man — providing compelling evolutionary evidence for their functional importance.

The lattice-like nature of gap junctions is conspicuous when the junctions, purified from tissues, are viewed in the electron microscope after negative staining. Their striking hexagonal packing makes them attractive candidates for ultrastructural analysis by non-destructive electron microscopy and image reconstruction — approaches which have been developed by the Cambridge group using bacterial purple membranes. High resolution electron microscopy and X-ray diffraction have already provided plausible models of hepatic gap junctions in which proteins of the apposed plasma membranes are arranged hexagonally producing a channel traversing the membrane (see Bennett & Goodenough, *Neurosci. Res. Progr. Bull.* **16**, 375; 1978). In this issue Unwin and Zampighi put forward a new refined model to explain junctional communication between cells across hepatocyte gap junctions, the largest biomembrane channels known.

By tilting negatively-stained junctions in the electron microscope, and analysing the pictures using Fourier and image reconstruction techniques, the communicating unit (connexon) emerges as an hexameric polymer of six subunits spanning the membrane and protruding from either side. The subunits are tangentially inclined which explains the annular appearance of each connexon. The channel is approximately 20 Å wide at its exposed region, although the channel dimensions deeper inside the 'tunnel' are not resolved. Models of gap junctions should explain how channel porosity can be regulated between open (cells are coupled) and closed (cells are uncoupled) configurations, an important physiological function sensitive to changes in Ca^{2+} concentrations and/or *p*H. Unwin and Zampighi's model provides a neat and simple explanation for changes in channel porosity on the basis of maps of two junctional states by postulating a rotational displacement of the hexameric subunits, so opening and closing the narrow channel.

Models of junctions between animal cells have leapt ahead of our knowledge of junctional biochemistry and the nature of ions and molecules transferred in specific functional states. Crystalline lattice structures are often the outcome of molecular parsimony, and although it is often assumed that the hepatic gap junction, like the purple membrane, is composed of a single monomeric polypeptide, the biochemical evidence is still unsatisfactory. The lipid composition is unexceptional (Hertzberg & Gilula *J. biol. Chem.*, **254**, 2138; 1979), and the isolated junctions, prepared by detergent extraction of plasma membranes, are strictly lipid depleted, detergent-binding fragments.

Some clues have recently emerged implicating cyclic nucleotides as possible important metabolic control signals transferred across junctions. It was shown by Lawrence *et al.* (*Nature* **272**, 501; 1978) that hormonal stimulation can be transmitted between cocultured granulosa and myocardial cells. The cells were joined by gap junctions and since hormonal stimulation of both cell types is cyclic AMP dependent, it is possible that cyclic AMP is the agent responsible for cross-stimulation. Cyclic nucleotides may also feature in intercellular communication in heart tissue where synchronously contracting cardiocytes are joined by intercalated disks which incorporate gap junctions. The possibility arises that cyclic nucleotides first arose primordially as

---

W.H. Evans is at The National Institute for Medical Research, Mill Hill, London.

0028-0836/80/06521-02$01.00

signal molecules sufficiently tiny to move directly and rapidly across junctions between cells before they also became implicated in hormone receptor-mediated communication between organs. In the same vein are reports of a correlation between gap junction formation and hormonal activation in myometrium (Garfield *et al. Science* **198,** 958; 1977) and oocytes (Browne *et al. Science* **203**, 182; 1979). And finally, to the transmission of hormonal stimuli between cells connected by gap junctions one can also add that the action of interferon is also likely to be mediated and amplified by the same intercellular pathway (Blalock & Stanton *Nature* **283**, 406; 1980). Clearly, now that gap junctions have emerged as widely-distributed plasma membrane organelles tailored for intercellular communication, the finer detail of their biological role still remains a wide-open question. □

Information exchange in the Palaeolithic

from Clive Gamble

DEVELOPMENT in palaeolithic culture can no longer be adequately explained in terms of increasing intelligence, for recent studies have demonstrated the existence, some 300,000 years ago, of mental ability equivalent to that of modern man. The dramatic developments in material culture, such as the appearance of art, now seem to be more closely related to changes in the amount and kind of information needed by palaeolithic societies, rather than dependent on the evolution of the brain.

Archaeologists have generally concentrated on the obvious in their studies of the earliest art. Understandably they have felt most at home when discussing the representational images that were either painted, sculpted or engraved by palaeolithic man. The renderings of animals and humans have been analysed in terms of composition and the chronological development of artistic styles. Their visual content has been interpreted in terms of either magical or religious significance. These images are seen as a key with which the archaeologist can unlock the psychology of early man while also providing an opportunity to investigate the cognitive development of the genus *Homo*.

These painted bison and carved figurines are however only part of the artistic output of palaeolithic man. A large body of less obvious art has also been recovered and consists of scratches on ornaments, pieces of bone, stones, the walls of caves and impressions drawn in clay. Their interpretation has barely proceeded beyond regarding them as the first 'doodles'; an analysis that stems from their apparently random execution. In a series of recent papers Alexander Marshack has subjected these scratches to a detailed systematic analysis (*Curr. Anth.* **20,** 271; 1979; *Form in Indigenous Art* (ed. Ucko) Australian Institute of Aboriginal Studies 1977). His method of investigation involves microscopic examination of how these abstract images were made. His studies have revealed that far from being random these scratches were formed in an intentional sequence whereby composite abstract images were built up. He has further grouped the scratches on the basis of repeated motifs into descriptive classes such as meanders, fishilike images, zig-zag and parallel lines.

The majority of these scratched signs and their painted counterparts on cave walls are found associated with upper palaeolithic stone tool assemblages. They appear some 32,000 years ago at a time when the fossil record indicates the replacement of *Homo sapiens neanderthalensis* by *Homo sapiens sapiens*. This is also the period when the first representational art is found in Europe. However Marshack has also been able to show that in two instances the same intentionality in scratching signs predates the appearance of modern man. This important finding suggests that the potential for image composition of this kind was possessed by both neanderthal and *Homo erectus* populations. This raises the possibility that the traditional explanation for such behaviour, which regards art as a unique developed mental ability of *Homo sapiens sapiens*, is no longer entirely adequate. Wynn (*Man* **14,** 371; 1979) has analysed the operational intelligence of handaxe manufacturers from Isimila, a site comparable in age to Pech de l'Azé where Marshack has documented the first intentional scratched meander. His analysis uses Piagetian genetic epistemology as a framework to investigate the cognitive procedures involved in the manufacture of these artefacts. On the basis of this study Wynn concludes that the hominids who made the handaxes were not significantly less intelligent than any modern adult. His important conclusion is therefore that increasing intelligence cannot be used as an explanation for developments in material culture over the past 300,000 years.

These provocative studies challenge what has to be explained by palaeolithic archaeologists. If we accept their conclusions then it becomes clear that it is no longer sufficient to look at human evolution over the past 300,000 years as simply a process of increasing intelligence and offer explanation in terms of changes in the brain. Instead we must approach the problem from a different perspective and look for changes in social circumstances which selected for and brought into play these latent patterns of behaviour.

One current line of enquiry stresses the role of information exchanges in palaeolithic society. In this context art and the scratched signs become part of a visual system of communication designed to handle information in this mode. The sudden appearance of art in the upper palaeolithic is thus a response to handling more and different types of information. Style provides the means by which order is brought to this form of communication so that messages can be sent and received. All items of material culture can be modified by stylistic rules to provide such additional visual information. This perhaps explains why there is such a sudden increase in stylistic behaviour among the stone tool assemblages at the same time as the art first appears since, as Wobst (*Papers for the Director* (ed. Cleland) Anthropology Papers, **61,** Museum of Anthropology. University of Michigan, 1977) has pointed out, if the communication system is to function without ambiguity then either everything or nothing must be used to transmit information in this fashion. Moreover, the organisation of the system according to symbols would also lead to a greater visual economy and an ability to make the system compact and easily manageable. A limited range of symbol/signs can be used to code a great variety of messages and would prevent the system from becoming too unwieldy if only representational images were used. Conkey (*Social Archaeology* (eds Redman *et al.*) Academic Press, 1978) has proposed that it is in the upper palaeolithic that the first pictorial symbol systems are found and which indicate that information was being organised according to this mode. The scratched motifs identified by Marshack from this period are most probably examples of such symbol systems.

But why should these hunter-gatherer societies have needed new means to exchange information about membership, status and position? Is it in fact possible to demonstrate changed social circumstances that would have selected for visual systems of communication? If we concentrate on the appearance of art and symbol systems and assume that these were a response to new social conditions then the argument becomes very circular. Where it might be possible to see changes is in the external circumstances of these societies. The first of these could relate to climatic changes at the time the art first appeared. It is first found when the climate of the last ice age turned towards much harsher, colder conditions that culminated in the

0028-0836/80/06522-02$01.00

maximum extensions of the icesheets some 18,000 years ago. This would have resulted in groups becoming more dispersed as they adjusted to the new environments and the resources they contained. There would have been considerable advantages in seeking further ways of signalling membership in order to link such groups together. However this must have been a problem that faced palaeolithic groups during the earlier phases of the European ice ages and yet they did not produce art as a response. The second factor in the equation most probably concerns population. Hassan (*Advances in Archaeological Method and Theory* (ed. Schiffer) **1**, Academic Press, 1978) has estimated both higher annual growth rates and greater population densities between the upper and middle palaeolithic. If this was the case then there must have been considerable pressure to hive-off population into new territories as well as to maintain growth rates at accustomed levels in just those areas that were now being affected by climatic change. The extra information would therefore be needed to relate groups to resources and to define the extra population. Verbal communication may previously have been sufficient to exchange information but now the possibility of language differentiation would arise and this could most economically be averted by instituting a new form of communication based on visual messages that were coded stylistically. It is noticeable that at this time global population increased its range with groups colonising Australia, central Asia and hence ultimately the Americas.

The proposition that art and the intentional scratches are part of a system of communication does raise many interesting possibilities in terms of what changed in the course of human development. It also suggests that archaeologists recast their explanations for variability in the palaeolithic record toward questions concerning information rather than intelligence. □

Possible hazards of photochemotherapy for psoriasis

from Bryn Bridges and Gary Strauss

THE photosensitising psoralen drugs are being increasingly used in combination with near-ultraviolet light (PUVA) as a very effective treatment for psoriasis and other skin conditions. PUVA controls excess cell division in the skin by virtue of its ability to damage DNA. In experimental systems PUVA lesions are able to elicit all the usual consequences of DNA damage, for example inhibition of DNA synthesis, mutation, chromosome aberrations and cell transformation, as well as initiating skin tumours in mice (see Bridges *et al. Clin. exp. Dermatolol.* **3**, 349; 1978; Vella Briffa & Warin *J. Roy. Soc. Med.* **72**, 440; 1979). The possibility that it might initiate skin cancer in humans was much in the minds of dermatologists; indeed the UK Medical Research Council has set up an *ad hoc* Working Group to consider the possible hazards of PUVA.

Although natural plant sources of psoralens have been used to treat vitiligo (lack of skin pigmentation) for thousands of years, the first report of their carcinogenicity in man followed PUVA treatment of some patients suffering from xeroderma pigmentosum, a condition in which the cells cannot repair damaged DNA effectively. Skin tumours began appearing within a month of initiation of treatment and one patient developed a lymphatic leukaemia (Reed *Acta Dermatovener. (Stockholm)* **56**, 315; 1976; Reed *et al. Arch. Dermatolol.* **113**, 1561; 1977). The surprisingly rapid appearance of the tumours was disturbing and unexpected for they appeared too soon after treatment to be readily explained by an increased rate of tumour initiation *de novo*. More recently an increased rate of skin cancer has been reported within the first two years of PUVA treatment of psoriasis patients (Stern *et al. N. Engl. J. Med.* **300**, 809; 1979). Although the magnitude of the increase is arguable (no matched control group was used, it being a longitudinal 'before and after' comparison) it is clear that the excess tumours are associated with the previous history of the patient, either of radiation exposure or previous skin cancer.

Taking these two sets of observations together, it seems that PUVA is acting not only as a direct initiator of skin tumours (though this has yet to be established in man) but as a type of so-called 'promoter', allowing the full expression of potentially malignant foci. The idea of promoters arose from observations that some chemicals, notably the phorbol esters, although not mutagenic or carcinogenic in themselves increase the incidence of tumours if given after a very low dose of a known carcinogen (see for a short review Marx *Science*, **201**, 515; 1978).

Support for the idea that PUVA, although potentially mutagenic and carcinogenic in itself, is acting in this case as a promoter comes from experiments in which ultraviolet-induced skin tumours were transplanted to syngeneic mice. The tumours grew in mice treated with PUVA but not in untreated mice (Spellman *N. Engl. J. Med.* **301**, 554; 1979).

How could such a promoter effect be operating in this case? One possible mechanism is the suppression of immunological surveillance in the skin. The idea that the body has a natural surveillance mechanism by which cells of the immune system recognise and destroy cancer cells is now generally discredited. But the skin may well be an exception to this rule. The demise of the immunosurveillance theory followed observations that there was no general increased incidence of tumours in immunosuppressed patients; however, although suppression of cell-mediated immunity by drugs such as azothioprine does not lead to a general increase in cancer, there is a rise in the number of lymphoreticular tumours and of squamous cell carcinomas of the skin (Walder *et al. Lancet*, Dec. 11, 1282; 1971; Kinlen *et al.*, *Brit. med. J.* **2**, 1461; 1979). In Stern *et al.*'s study cited above, the excess tumours were also squamous cell carcinomas whereas basal cell carcinomas predominate in the general population. This raises the possibility that PUVA may be immunosuppressive in man. In guinea pigs PUVA treatment of skin blocks delayed hypersensitivity responses in exposed areas and to a lesser but quite significant extent at unexposed sites (Morison *et al. J. invest. Dermatol.* **72**, 273; 1979). The cause of the immunosuppression is as yet unknown. Roberts and Daynes (quoted by Spellman, above) have recently reported that treatment of mice with PUVA induces the development of suppressor cells. In man, a significant decrease in T cell number and function has been reported in patients undergoing PUVA therapy (Cormane *et al. J. invest. Dermatol.* **68**, 253; 1977; Morison *et al. J. invest. Dermatol.* **70**, 216; 1978). There is no doubt that in man circulating lymphocytes are exposed to substantial doses of PUVA when passing through the skin of treated psoriatics (see Strauss *et al. J. invest. Dermatol.* **73**, 211; 1979). Furthermore, there are telling arguments in favour of the existence of resident lymphocytes in the skin (see for example, Streilein *J. invest. Dermatol.* **71**, 167; 1978).

That the promoting effect of PUVA is indeed a consequence of DNA damage is indicated by rather similar immunosuppressive effects being reported for far ultraviolet light (Daynes *et al. Transplantation* **23**, 343; 1978; Kripke & Fisher *Natn. Cancer Inst. Monogr.* **50**, 179; 1978) and by the very much more rapid appearance of tumours observed in PUVA-treated xeroderma pigmentosum patients compared with individuals with normal DNA repair ability. The target cells for the PUVA-induced immunosuppression seen in rodents are presumably different in type from those in human psoriatic plaques that respond to the therapeutic effects of PUVA, but whether the immunosuppressive response is specific for DNA-damaging treatments or whether

Bryn Bridges is Director of the MRC Cell Mutation Unit and a Professor at the University of Sussex; Gary Strauss is supported by the Cancer Research Campaign at the University of Sussex.

0028-0836/80/06523-02$01.00

it could be elicited by other agents using other mechanisms of cytotoxicity, is an open question.

Taken together these observations suggest several possibilities of considerable fundamental as well as clinical importance. (1) Immunological surveillance may well be a reality in the skin; (2) immunological surveillance in the skin may be suppressed by DNA-damaging agents; (3) if PUVA is both a promoter and an initiator, its long-term sequelae in man may be even more severe than has hitherto been suspected.

Finally, the results with PUVA must inevitably lead to an examination of the effects of naturally occurring psoralens present in some sun-tan preparations since the activity of these in sunshine must surely result in DNA damage to the skin (Ashwood-Smith *Brit. med. J.* 3 Nov. 1140; 1979). ☐

The case for layered convection

from Peter J. Smith

INTEREST in the possibility of mantle-wide convection has revived recently, sparked off largely by the conclusion, derived most impressively by Cathles (*The Viscosity of the Earth's Mantle,* Princeton University Press, 1975), that contrary to previous widespread belief the viscosity of the mantle does not necessarily increase significantly with depth. With one of the most important restraints to the continuation of convection into the lower mantle removed, support for convection limited to, say, the asthenosphere is weakened, and a return to the earliest concepts of mantle-wide flow becomes possible.

Or does it? In a most thoughtful paper Richter (*J. geophys. Res.*, **84,** 6783; 1979) points out that viscosity is not the only criterion to be applied to the case for and against crust-to-core convection cells. Whatever the hypotheses about variation of viscosity in the mantle, it is an inescapable fact that earthquakes never occur below a depth of about 700 km, implying strongly that in trench zones (where the deepest earthquakes occur) the subducting lithosphere cannot pass into the region below 700 km. When an increase in viscosity with depth was accepted, this resistance to penetration seemed hardly surprising; but with that limitation removed, some other explanation of the barrier is required.

And the phenomenon is even more remarkable than a simple 700 km limit would suggest. From a new analysis of earthquakes in the Tonga–Kermadec subduction zone, Richter not only shows that all foci are shallower than 700 km but demonstrates (using focal mechanisms) that where shocks occur below 600 km the corresponding sections of the downgoing slab become subject to downdip compression. This confirms for a particular case a generalisation made earlier by Isacks and Molnar (*Rev. Geophys. Space Phys.*, **9,** 103; 1971) and strengthens support for the view that subducting lithosphere meets insurmountable resistances when approaching 700 km depths. So, indirectly, does Richter's discovery that the seismic energy released in the Tonga–Kermadec region decreases generally with depth but then increases phenomenally between 500 and 700 km — that is, in the zone immediately above the seismic cutoff. The significance of this increase is that it more or less rules out non-barrier explanations of the 700 km limit. It is possible to argue, for example, that subducting lithosphere does pass into the region below 700 km but that by then it has become sufficiently warm to deform by creep rather than brittle fracture, thereby eliminating earthquakes. But it is difficult to imagine a deep energy peak arising from a lithosphere gradually becoming hotter with depth. Similarly, it has been suggested that lithosphere passing through the 650+ km zone changes phase, giving rise to a ductile high-density form incapable of supporting earthquake mechanisms. This proposal is more difficult to evaluate; but again the energy release peak at depth poses a severe problem.

So the 700 km limit must represent a real barrier to the passage of lithosphere, for the large energy release in the 500–700 km interval can only be explained in terms of large compressive stresses resulting from the approach towards an irresistible obstacle. What is that obstacle if it is not a viscosity increase? It could easily be chemical inhomogeneity, claims Richter, who envisages a chemically layered mantle with density increasing with depth from layer to layer. If this sounds implausible, the converse — a homogeneous mantle — sounds even more implausible, at least as Richter explains it. If the mantle is homogeneous, he argues, it must have been homogeneous right from the start or it must have become so by thermal convective mixing. But mantle conditions are such that thermal mixing will only remove inhomogeneities of less than about 1%. In other words, the conditions for the occurrence of a homogeneous mantle are more restrictive than those likely to give rise to a mantle with more than minimal inhomogeneities.

Convective systems with chemical density variations have been studied in considerable detail in seawater. Extending the principles thereby derived to the mantle, Richter concludes that a significantly inhomogeneous mantle will develop layering in which convection is restricted to the discrete layers. Precisely how many convective layers there are in the mantle will depend on how the Earth accreted and how the mantle developed originally as the residue left by the removal of crustal and core materials — and these factors are uncertain. But since the mantle is more likely to be inhomogeneous than homogeneous, it is more likely to have more than one convective layer than it is to have just one. So, although whole-mantle convection is a plausible option again thanks to revised views about the mantle's viscosity, the details of the convection could be rather different from those envisaged by the early supporters of the idea. ☐

Antigenic shift and drift

from a Correspondent

INFLUENZA has been relatively dormant as a human disease for the past several years. However with the advent of recombinant DNA technology and of monoclonal antibodies, work on the influenza virus has burgeoned. Particularly exciting are the recent advances in knowledge of the structure of the viral haemagglutin (HA) and of the mechanisms which allow its antigenic variation and the consequent emergence of new viral strains. So it was not surprising to find that this molecule was of central interest at a workshop* held early in December near Canberra, Australia.

HA, the major glycoprotein of the viral envelope (molecular weight 75,000) is coded by an mRNA specified by one of the eight segments of RNA present in the virus particle. Pandemics of influenza occur in the human population when a major shift in the antigenic structure of HA allows the virus to infect people who are immune to previously circulating strains. Obviously one would like to compare the complete primary amino acid sequence of HAs of several different pandemic strains. However, despite considerable effort by the protein chemists (M. Waterfield, ICRF; C. Ward and T. Dopheide, CSIRO, Melbourne) such information has proved difficult and laborious to obtain. Consequently the nature of the variation involved in the creation of new pandemic strains has remained unknown. As reported at the workshop, several groups now have cloned in prokaryotic vectors, full length cDNA copies of the HA genes from viruses belonging to two of the three major pandemic groups. Complete DNA sequences have been established for the Asian H_2 strain, which first emerged in 1957 (M-J. Gething, ICRF); for several members of the Hong Kong series which first appeared in 1967 (N. Sleigh & G. Both, CSIRO, Sydney; W. Min Jou, Ghent; G. Threlfall, Searle) and for the Rostock strain of avian influenza virus (A. Porter & J.S. Emtage, Searle, High Wycombe). In all cases the general organisation of the HA gene is remarkably similar. There are untranslated regions (albeit of varying lengths) at both 5′ and 3′ ends of the gene. The 13 nucleotides which lie at the 3′ ends are identical in all viruses so far examined and are presumably used in replication (J. Skehel, NIMR, London); the remainder of the untranslated regions show little evidence of common origin or function (G. Air, Australian National University, Canberra). In all cases the coding portion of the gene exists as a continuous block of nucleotides so that removal of intervening sequences apparently is not involved in the expression of HA. However the mRNAs of influenza are known to sequester 5′-capped termini from nascent or newly-synthesised cellular RNAs, and splicing, or something like it, may play a part in this transfer (R. Krug, Sloan-Kettering Institute, New York).

---

*An International Workshop on 'Structure and Variation in Influenza Virus', organised by Graeme Laver and Gillian Air, Australian National University, Canberra, Australia.

The sequence of amino acids, deduced from that of the DNA, confirms that HA invariably contains three distinct hydrophobic regions. One of these forms the N-terminus of the primary translation product. It is cleaved from the mature protein and is believed to be responsible for insertion of the nascent polypeptide into the membrane of the endoplasmic reticulum. A second hydrophobic region located at the C-terminus is involved in anchoring the mature HA in the viral envelope. Both of these hydrophobic regions show a surprising degree of variation and it seems that hydrophobicity *per se* is more important than primary amino acid sequence for interaction of HA with membranes. By contrast, the amino acid sequence of the third hydrophobic region which lies roughly in the centre of the molecule is absolutely conserved between viral strains. Ultimately it forms the new N terminus of the smaller subunit of HA (HA2) which is created by proteolytic cleavage of the full length polypeptide. This cleavage, which is necessary for infectivity of the virus, is thought to allow the third hydrophobic region to interact with the membrane of the target cell. Approximately 60% of the amino acid sequences of HA2 are conserved between strains. The remainder of the molecule (HA1) shows much more extensive variation. Nevertheless, because the locations of bridging cysteine residues in both HA1 and HA2 are totally conserved, it is likely that the three-dimensional structure of HA (currently under investigation, D. Wiley, Harvard University) will turn out to be very similar in different viral strains. These results are consistent with the idea (D. Jackson, University of Melbourne) that the major antigenic sites are located in HA1 and that it is variation in these sites which allows the virus to escape from neutralising antibody. However the results reported at the workshop show the HA1s of different pandemic strains to have diverged to such an extent that it is impossible to map their sites of antigenic difference merely by comparing their amino acid sequences. Furthermore the fact that the HAs of two human strains are no more similar to each other than to the HA of the avian strain means that it is impossible to establish a genealogical tree which would define the evolutionary relationship between different pandemic strains.

At present therefore, it is impossible to decide between the two alternative hypotheses which attempt to explain how new pandemic strains of influenza virus arise. One suggestion, for which circumstantial evidence exists (see Laver & Webster *Brit. Med. Bull.* **35**, 29; 1979) is that new pandemic strains are recombinants formed between influenza viruses of humans and those of domestic or wild animals. The second possibility is that the emergence of 'new' pandemic strains in the human population represents no more than the reappearance in essentially unchanged form, of viruses that had circulated years previously, and then had entered a latent state in humans or lower animals. Although such a latent state is entirely conjectural, this idea has received serious consideration because of the reappearance in 1977 in China of a strain of influenza virus that was in wide circulation until 1950 and then had disappeared. The re-emergence of this strain adds an entirely unexpected complication to both the epidemiology of influenza and the evolution of the virus. It implies that influenza virus, at least in some circumstances, in some hosts, can preserve its antigenic structure for long periods of time. Such is not the general case in humans.

Between the major shifts in antigenic structure which define the beginning and end of each pandemic era, the virus undergoes a series of smaller changes. As the human population becomes immune to infection by extant strains of influenza virus, so the pressure rises to select variants which by displaying small but significant changes in antigenicity can evade the immune response. This process is known as antigenic drift.

The changes which are responsible for antigenic drift accumulate with time, and field strains isolated several years apart from within a single pandemic era show a surprising number of nucleotide and amino acid substitutions (Both), in one case 20 amino acids in 9 years (Air & Laver). Presumably some of these substitutions affect viral antigenicity. However it is also possible that some of these changes may be antigenically neutral or may cause antigenically significant conformational alterations in distant parts of the HA molecule. Therefore, it has not been possible so far to correlate the locations of antigenic sites with the positions of amino acid substitutions.

To simplify the system, several groups have attempted to mimic antigenic drift *in vitro*. The virus is grown in the presence of large quantities of either high titre neutralising antibody (B. Moss, CSIRO, Sydney) or more recently, monoclonal antibodies directed against single antigenic sites in HA (R. Webster, St. Judes Children's Hospital, Memphis; Laver; W. Gerhard, Wistar Institute, Philadelphia). Variants which are resistant to inactivation by the antibodies arise at a frequency of 10^{-5} to 10^{-6}. Peptide mapping and nucleotide sequencing show that such variants arise as a consequence of changes limited in both number and location within HA1. Thus in 10 variants selected with monoclonal antibodies, a proline at position 143 of HA1 has changed to serine, threonine, leucine or histidine. The simplest interpretation of this result is that the region around position 143 is at or near an antigenic site. This is consistent with the finding that field strains which presumably have been undergoing a similar selection process *in vivo* often display changes in the same region of the protein, although for reasons which are not clear the proline at position 143 is invariant.

As stated above, the field strains show alterations in many additional regions of the HA molecule. Thus the total number of antigenic sites may be greater, their topological relationship more complex and the selection pressures which mould them more subtle than we at present appreciate. Nevertheless the capacity to select a sequential series of isogenic mutants and analyse them rapidly at the molecular level is an important advance that represents the best hope of dissecting the process of antigenic drift. ☐

Man in space

from Anthony Goode

MANNED space flight now spans almost two decades but it began amidst considerable scepticism; an Astronomer Royal summed up a widely held belief by stating, somewhat incautiously, that space travel was utter bilge, and certainly in 1961 extensive and catastrophic effects of exposure to weightlessness were predicted. Despite this, man is now firmly committed to space. Exploration of its full potential depends on his well-being in this unique environment. The reusable Space Shuttle, whose first flights are planned for 1980, will open up space to a wider range of users, including the working scientist and provide a chance to assess more clearly the potential medical problems.

Cardiovascular changes

Although the catastrophic effects of exposure to weightlessness have not materialised gross changes do occur in the

0028-0836/80/06525-02$01.00

bodies of astronauts. Going up into orbit immediately induces a massive redistribution of about 2 litres of blood and interstitial fluid into the head and thorax causing venous distension. The face becomes puffy whereas the legs shrink. This redistribution directly influences cardiac activity and indirectly, the control of the circulation, and produces changes in the clearance of salt and water through the kidneys. This thoracic engorgement persists in flights of up to 84 days giving rise to fears about the longer term possible consequences of cardiac hypertrophy and arterial hypertension. The changes however, do not affect work capacity in orbit. Return to Earth results in a decline in circulatory tolerance to an erect posture, reduced cardiac output and stroke volume and a decreased capacity for physical work. After Skylab flights these changes were reversed to normal pre-flight values within 10 days. The precise degree of thoracic engorgement and how close the pressure levels in the pulmonary artery come to inducing pulmonary oedema will be investigated early in the Space Shuttle series.

Changes in red cell morphology have been found after spaceflight together with loss of up to 8–10% of red cell mass after Apollo and Skylab missions. The reason for this is obscure; chromium-51 labelling of red cells has shown no increased destruction. Cell proliferation in tissue culture is normal in flight and the cellular and hormonal components of the immune response *in vivo* remain unchanged. Renal function is satisfactorily maintained but a possible diuresis early in flight is accompanied by a fall in antidiuretic hormone and an increase in aldosterone with paradoxical solute excretion.

Bone and muscle

In the first days in orbit there is a 3-4 kg loss in body weight as a result of loss of body fluid and, to a lesser extent, a reduced fluid intake. After a longer period in flight, 2–3 kg are lost, mostly as body muscle, although this loss may be reduced by about 50% by an intensive excercise regimen. The loss does not therefore simply reflect muscle atrophy, but no additional cause has yet been found. Bone calcium is lost continuously at a rate of 0.5% of total body calcium per month, about three times the loss induced by prolonged bed rest. Apart from increasing the risk of renal calculi in astronauts, this excretion could limit flights to about a year's duration before bones become to brittle to support the body on Earth. Rigorous excercise regimes, hormone analysis and dietary measures have failed to elucidate the underlying cause, and muscle and bone metabolism will be an area of intensive future investigation.

Man has a well-developed skeleton and musculature suited to Earth's gravity but such attributes may be an embarrassment in space. One observer has speculated that young amputees may be ideal crew members for longer flights, as they would be subject to less fluid shift and mineral depletion.

Sensory systems

On Earth man maintains his sense of balance by the gravity-sensitive vestibular system in the ear, which together with the somatosensory and visual systems allow spatial orientation and the control of posture and locomotion. However, in zero *G* the gravity-sensitive otoliths of the vestibular system fail to indicate the orientation of the head as indicated by the other sensory mechanisms and this mismatch causes a perceptual conflict during movement, either of the whole body or of the head alone. In zero *G* astronauts have experienced perceptual deficiencies or illusions such as a compelling sensation of flying upside-down or of turning or tilting when they move their head rapidly. Skylab astronauts reported that they were less able than normal to locate objects relative to their body when their eyes were closed.

Early flights in Mercury and Gemini capsules in which astronauts were restrained on couches and unable to move their body and head freely prevented the space motion sickness which had been reported during the Russian Vostok flights. However, during Apollo and Skylab missions half the crewmen developed sweating, pallor, nausea and vomiting, which began within minutes to hours of their starting to move around in the capsule and which remitted within 3 to 6 days. The phenomenon is probably due to intersensory mismatch and once the body has become accustomed to the new environment, head movements no longer cause nausea. Anti-motion sickness therapy may relieve the symptoms but the undesirable sedative side effects can result in less efficient performance during critical early phases of the mission. NASA has selected an experiment for Spacelab 1 in which astronauts will be exposed to a selection of motion sickness tests first on Earth and then in zero *G*. These tests should provide useful predictions of individual susceptibility to space motion sickness. The European Space Agency (ESA) has designed a linear accelerating stimulus device — the 'space sled' — which will allow studies of human sensory physiology, measurement of perceptual thresholds and analysis of eye movements and muscle activities affected by defined rectilinear accelerations.

Radiation hazards

Certain components of cosmic radiation may be a hazard to man in space. The Apollo 11 crew saw faint spots and flashes of light every half minute or so on the return flight from the Moon. This was the result of HZE particles (of high charge and energy up to 10^{14} MeV) penetrating the spacecraft and the astronauts' eyes and producing visual sensations after interaction with the retina. The 'Biostack' experiments were designed with monolayers of biological objects sandwiched between nuclear track detectors, and demonstrated serious biological effects. The most arresting results with *Artemia salina* eggs showed that the hatching rate was reduced, that HZE particle collision with nauplius larvae caused abnormal growth and behaviour with a high mortality after hatching, stunted growth, delayed sexual maturity and reduced fertility. Advanced 'Biostack' experiments are designed for Spacelab to investigate this phenomenon which may pose a danger to non-regenerating human tissues particularly those of the central nervous system.

Space Shuttle

The reusable Space Shuttle will allow life scientists to work on orbit in a shirt sleeve environment for up to 30 days. The payload specialist will have a gentler ride than in the Saturn/Apollo system as now the maximum gravity load will be 3*G* and he will be content in the knowledge that a rescue capability is available. With less physical stress during flight and no direct flight responsibilities it is hoped that medical criteria for payload specialists will be much less strict than those applied to astronauts although this has not been the case with the initial selection.

A legacy from Project Apollo has been a feeling, reflected in government thinking, that spaceflight is remote from reality and too expensive. A policy of selecting life sciences payload specialists principally for their professional abilities may help to overcome this, improve the quality of research and in turn contribute to the safe, effective and extensive use of space. Both NASA and ESA are properly dependent on budget allocations from the member state governments and recent monetary restrictions may reduce the frequency of flights dedicated to the life sciences. This parsimonious attitude is perhaps surprising as astronomy, from the days of Stonehenge an interesting but costly diversion with little direct impact, is well funded. It is perhaps salutory to remind government agencies that space flight provides an important stimulus for diverse investigations with unpredictable results.

Shuttle flights will probably begin in 1980. The initial submission of life science experiments has been good and indicates considerable interest in the life science community. Finance for experiments may be more difficult but this system offers an opportunity to study the behaviour of biological systems in a new environment, and the applications are potentially unlimited. We should all now consider more carefully how we can use the unique properties of space to complement and enhance current research projects. □

REVIEW ARTICLE

Three-receptor, clonal expansion model for selection of self-recognition in the thymus

A. R. Williamson

Department of Biochemistry, University of Glasgow, UK

The postulate is made that dual recognition by T lymphocytes is due to two types of receptor, one encoded by antibody genes and one by a distinct multigene family with simple rules for expression. This postulate leads to a model explaining ontogenic and evolutionary selection for self recognition, T lymphocyte effector function, the apparent high frequency of alloreactive T cells and immune response gene activity. The model is contrasted with previous explanations of self-recognition phenomena.

ALL of the cell surface products coded for by genes of the major histocompatibility complex (MHC) have a crucial role in the regulation of the immune response. The cell surface products of the mouse H–2 complex have been divided into two classes: (1) those originally recognised as transplantation antigens (K and D); and (2) those recognised as immune associated (Ia) antigens (encoded at the H–2 I region). Initially I-region genes were shown to be important in regulating immune responses but more recently K- and D-region gene products have been shown to be involved in recognition and killing by T lymphocytes of cells that display foreign antigens on their surface. Thus cytotoxic T cells which have been generated in response to virus-infected cells[1], hapten-modified cells[2] or minor histocompatibility antigens[3] are only capable of lysing those target cells which bear the same foreign antigen and the same major histocompatibility antigens as the immunising cells. This phenomenon has been termed major histocompatibility restriction (thus for the mouse H–2 restriction) of cytotoxic T-cell responses.

Immune responses other than those involving cytotoxic T cells also show H–2 restriction. The proliferative response of T cells to antigen presented on the macrophage surface requires histocompatibility at the H–2 I region of the two cell types[4]. Similarly cooperation between helper T cells and B cells exhibits H–2 I restriction[5]; the fact that in chimaeric animals H–2 incompatible T and B cells are able to cooperate[6,7] being explained by the hypothesis that lymphocytes can adaptively differentiate, that is, develop the ability to recognise cell interaction molecules on allogeneic cells[8]. To explain the various types of H–2 restriction two types of hypothesis have been proposed[9].

The dual recognition hypothesis states that T cells exhibit two separate receptors on their surfaces, one of which shows specificity for H–2 antigens, the other for non H–2 antigens. In one form of this hypothesis the T-cell receptor for H–2 is itself an H–2 coded product whereas the receptor for foreign antigens is presumed to use the antibody gene repertoire[10]. In an alternative form of the hypothesis the two receptors are identical at an early stage in development and must therefore be encoded either by the H–2 linked gene system or by the antibody gene repertoire[11].

The altered self hypothesis postulates that T cells bear a single receptor which is only capable of recognising antigens in association with H–2, for example, new antigenic determinants created by the interaction of the foreign antigen with the H–2 antigen. In most models immunoglobulin variable region genes (V genes) have been assumed to code for the receptors.

Some form of dual recognition hypothesis is most attractive. The evidence for I-region restricted systems is more easily compatible with a dual recognition hypothesis than with an altered self hypothesis. Also, for the cytotoxic T cell, the dual recognition hypothesis has recently emerged as the favoured candidate. Indeed it has been argued forcibly that there is no viable form of altered self hypothesis[18].

In the initial demonstration of H–2 restriction the evidence was consistent with the idea that the immunising or target cells presenting the foreign antigen, needed to share histocompatibility antigens with the cytotoxic T cell. Thus restriction was seen as synonymous with a recognition of self antigens. Subsequently it was demonstrated that identity of histocompatibility antigens between immunising or target cell and the cytotoxic T cell is not necessary for recognition of self. The T cell 'learns' to recognise as self the histocompatibility antigens displayed on the epithelial cells of the thymus during the processing of T-cell precursors through that organ. This finding stems from experiments involving the use of bone marrow chimaeras and grafts of irradiated thymus tissue. Bevan[12] used chimaeric mice constructed by injecting (A × B) F_1 bone marrow into an irradiated parent A recipient to show that cytotoxic T cells generated against minor histocompatibility antigens recognise these antigens preferentially in association with the *H–2* haplotype of the parent A, as opposed to that of parent B. Zinkernagel *et al.*[13] constructed similar chimaeras and showed exclusive restriction for the H–2 type of parent A in cytolysis of either virally infected or hapten-modified target cells. Chimaeric mice constructed by injecting (A × B) F_1 bone marrow into irradiated (A × C) F_1 recipients were constructed and the lymphocytes sensitised against (B × C) F_1 cells chemically coupled to the hapten trinitrophenyl (TNP). In this case cytotoxicity was restricted to TNP-modified cells of the *C* haplotype. Thus T cells heterozygous for the haplotypes of A and B parents have learnt to recognise the H–2 type of the C mouse as self but failed to recognise the H–2 type of the B mouse (genotypically a self haplotype) as self. The use of irradiated thymus grafts in adult thymectomised irradiated recipients of bone marrow cells showed that the H–2 type of the thymus epithelium determines what the newly generated T cell learns to recognise as the self H–2 type[14].

Self recognition is clearly not determined by the identity of the H–2 haplotype between T cells and target cells. Zinkernagel *et al.*[13] pointed out that the learning of self recognition in the thymus is best explained on the basis of a dual recognition hypothesis because the altered self hypothesis would require the special rule that the specificities generated by modified self in thymus A do not overlap with the specificities generated in thymus B. However, the authors made no clear prediction as to whether dual recognition is achieved by two separate receptor molecules or two parts of a single receptor molecule.

These experiments and hypotheses had been influenced greatly by Jerne's prediction[15] of a role for the thymus in the selection of T-cell specificities. The model proposed by Jerne took as its starting point an inherited set of T-cell receptor antibodies each specific for an allelic form of one of the major transplantation antigens of the species, with the total repertoire reflecting the extent of polymorphism of the histocompatibility antigens of the species. The model then invoked rapid somatic

0028-0836/80/060527—06$01.00

mutation of the genes coding for receptor antibodies. Cells carrying receptors for non-self alloantigens were not eliminated in the thymus and emerged into the periphery in the high proportions expected for the products of germ line structural genes. These clones of cells explained the high frequency of allo-reactive T cells. T cells maturing in the thymus and expressing anti-self receptors were assumed to be eliminated unless those receptors mutated. In this way rapid somatic mutation was postulated to generate the total repertoire of receptors for all foreign antigens from the inherited genes for anti-self. This hypothesis was subjected by Bodmer[16] to the major criticism that individual members of a species could not be aware of the extent of polymorphism of the histocompatibility genes within the species. How then could there be a sufficient selective pressure for each animal to carry germ line genes coding for antibodies against the total repertoire of histocompatibility alleles? A second major criticism of the Jerne model for the generation of antibody diversity lay in the apparent difference in receptor repertoires between T and B lymphocytes. In particular it was not possible to detect the predicted high proportion of allo-reactivity at the B-cell level.

In spite of these major objections to the Jerne model it did predict the crucial selective role for the thymus that has been demonstrated recently. This has led Jerne and his colleagues[11] to propose a modification of the somatic mutation hypothesis for clonal selection within the thymus. Their modification involved two identical anti-self receptors, allowing mutation and selection to act on only one of them. This modification requires that special genetic mechanisms be invoked in addition to rapid somatic mutation. Other hypotheses explaining T-cell specificity in terms of V gene products also require rapid somatic mutation or rules of V gene expression unique to T cells[17–19]. I have therefore devised an alternative model for the selective function of the thymus and the reactivity of T lymphocytes.

Three-receptor, clonal expansion model

It is the main purpose of this article to propose a clonal selection hypothesis for the generation of T cells in the thymus that emphasises clonal expansion (rather than clonal deletion as in the Jerne model) and does not require somatic mutation.

The starting point for this model is the need to explain the basis for 'learning' of self from the phenotype of the thymus rather than from the genotype of the pre-T cell. It is proposed that the genotype of the pre-T cell must contain the information for a receptor molecule that can recognise allo-H–2 antigens as self and that this receptor is not an antibody molecule.

The model takes dual recognition as the basis for H–2 restriction and T-cell specificity and states that dual recognition is effected by two distinct receptor repertoires encoded by separate sets of genes. One type of T-cell receptor is encoded by immunoglobulin variable region genes and embraces the same repertoire and similar rules of expression as B-cell antibodies. The postulated second set of T-cell receptors is distinct from immunoglobulins, but has a repertoire of specificities similar to that originally described for immunoglobulin variable region *V* genes in the Jerne model[15] (but with contrasting consequences).

If pre-T cells of each genotype can recognise any thymus phenotype as self through an appropriate non-immunoglobulin receptor, then it follows that each animal carries genes coding for a repertoire of receptor molecules capable of recognising the repertoire of allo-antigenic specificities of major histocompatibility antigens. Thus receptors $R_1R_2R_3 \ldots R_n$ will recognise respectively the MHC antigens $H_1H_2H_3 \ldots H_n$.

The genes coding for these histocompatibility antigen receptors (R anti-H) are assumed to constitute a multigene family present in all members of the species. It is postulated that expression of genes in this family is limited to a single gene per haplotype in each cell, with no requirement for allelic exclusion. Expression of R anti-H occurs initially on pre-T cells. Each pre-T cell will express two R anti-H molecules selected at random from the inherited repertoire. A simple matrix of cell specificities is shown in Fig. 1. The combinations of R anti-H molecules on pre-T cells will be, in order of frequency: (1) both specific for allo-MHC antigens (R anti-allo-H); (2) one specific for a self-MHC antigen (R anti-self-H); (3) both specific for self MHC antigens. Examples of these three cell types in the matrix (Fig. 1) are: (1) R_2R_2; (2) R_1R_2; (3) R_1R_1.

Within the thymus the epithelium provides MHC antigens to interact with the R anti-H molecules on pre-T cells. The presence of at least one (or occasionally two) R anti-self-H molecules on a pre-T cell allows interaction with self-MHC antigens and this is postulated to give a proliferative stimulus to that pre-T cell (Fig. 2). Clonal expansion generates mature T cells all of which carry a receptor for a self-histocompatibility antigen. Because of the random diploid expression of R anti-H molecules the expanded population of T cells will be subdivided, in approximately *n* equal proportion, into *n* clones carrying either a second R anti-self-H or a single R anti-allo-H molecule. If we make the simple assumption that there are 100 R anti-H genes corresponding to 100 distinct allo-H specificities, then 1% of all T cells will carry one R anti-allo-H molecule corresponding to any particular allo-H specificity. The clonally expanded population of T cells will be exported from the thymus to the periphery. Pre-T cells which do not express at least one R anti-self-H molecule will not receive a proliferative signal leading to clonal expansion; such cells, if not eliminated, will be diluted out.

During the clonal expansion of pre-T cells driven by the interaction of R anti-self-H with self-H antigens each cell becomes committed to the expression of a particular receptor antibody molecule using the same repertoire of V genes encoding B-cell antibody molecules (Fig. 2). In B-cell development commitment of the pre-B cell to a single antibody specificity demands allelic exclusion and κ/λ exclusion. This exclusive commitment is probably effected by rearrangement of gene segments involving only two of the six V gene families present in the diploid cell[18–20]. For simplicity in the present model it is assumed that the differentiating T cell makes the same commitment as the differentiating B cell. Thus each T cell will express at random a single antibody V gene coded receptor molecule (whether both V_H and V_L contribute to this receptor is not important for the model). The entire repertoire of V gene encoded receptors will be expressed on individual T cells within each of the *n* expanding clones of pre-T cells defined by expression of pairs of R anti-H receptor molecules. It is necessary to invoke as a developmental limitation that when T cells become committed and express a V gene encoded receptor they cease being sensitive to the proliferative signal driving clonal expansion via the R anti-self-H receptor.

The postulated developmental limitation is simply explained by postulating an interaction between R anti-H and V anti-X. This interaction, or coupling, ensures that two signals are now required to stimulate the mature T cell. Because it is necessary to introduce a self tolerance selection acting on V anti-X this could be accommodated by the proposal that if V anti-X encounters X before the coupling of R anti-H and V anti-X the cell will be eliminated and tolerance will result. This tolerance model could involve dual recognition of X and self-H as proposed previously (ref. 23 and J. M. Phillips-Quagliata, personal communication).

Each mature T cell entering the periphery will carry three receptor molecules: (1) R anti-self-H; (2) R anti-allo-H ($100/n$% of the cells will carry second R anti-self-H); (3) a *V* gene encoded receptor antibody (Fig. 2). Restriction of responsiveness of T cells in the periphery will be accounted for if it is required that dual recognition involving R anti-self-H and a receptor antibody specific for the foreign antigen (X) is necessary for triggering an immune response. Restriction will be limited effectively to self-H specificities as determined by the R anti-self-H present on all T cells and selected in the thymus, but independent of the self-H type present on peripheral cells. A small subset of T cells will carry R anti-allo-H receptors capable of being involved in dual recognition of antigens presented together with allo-H specificities but, in the numerical example

quoted above, such antigen presentation with allo-H specificities could only evoke a response at the 1% level relative to self-H presentation. However, in a situation where self presentation is not possible clonal expansion of this minor population of T cells could explain responsiveness[24].

Evolution of the R anti-H multigene family

One of the basic tenets of the present hypothesis is that each member of the species has the genetic capacity to make R anti-H molecules specific for the species repertoire of allo-H antigens. This parallels the specificity repertoire envisaged for germ line *V* genes in Jerne's hypothesis[15]. In that case, Bodmer[16] argued that it was almost impossible to conceive of a selective mechanism which could be powerful enough to maintain a situation requiring parallel evolution of histocompatibility antigens and immunoglobulin genes. Why then in the present model should a multigene family coding for R anti-species-H specificities be considered to be a feasible starting point. To answer this question we must look at the evidence which leads one to invoke such a multigene family and the selective pressures which could have led to the evolution of the gene family.

The unexpected ability of pre-T cells to 'learn' to recognise as self the phenotype of the thymus epithelium, even when this phenotype is at variance with the genotype of the pre-T cells, leads to the logical postulate that the genotype of one strain codes for receptor molecules able to recognise histocompatibility antigens of another strain. The limitations to this allo-recognition process can only be uncovered by further experimentation. The evidence also indicates that it is essential for immune responsiveness that each animal exhibits complementary R anti-H and H molecules[14]. If the genes coding for R anti-H and H are segregating independently and the H antigens are highly polymorphic there will be a selective pressure for the accumulation in the R anti-H gene family of genes coding for all possible R anti-H specificities. Genes coding for a complete (or extensive) repertoire of R anti-H specificities will be maintained in the germ line of the species because of the strong selective pressure for each member of the species to be able to recognise its own histocompatibility antigens as self. It is important to this argument that gaps in the immune responsiveness of T cells due to an absence of certain R anti-self-H genes in a given member of the species will lead to an increased susceptibility to viral infection and therefore an increased probability of the elimination of that individual before reproduction. There will be a strong selective pressure, enhanced by any polymorphism of the R anti-H genes, for MHC heterozygosity to maximise the chance that self can be recognised.

The multigene family coding for R anti-species-H specificities is postulated to be distinct from the immunoglobulin gene families and is not postulated to be encoded at the MHC as previously invoked for the T-cell receptor. However, it is important to realise that the expression of particular R anti-self-H genes will be controlled by the MHC so that the R anti-H T cell receptor will appear to be encoded at the MHC.

It might be expected, on the basis of the known specificity of restriction, that each R anti-H recognises a private histocompatibility antigen. This prediction explains the finding[25] that a private (and not a public) H–2 specificity is recognised in the restriction of a cytotoxic response to virus infected cells although public H–2 specificities are recognised in anti-allo-H–2 responses, both cytotoxic and proliferative. In both responses the private H–2 antigen is postulated by the present model to interact with R anti-H. In the anti-viral response the V receptors will recognise viral antigens while in the anti-allo-H–2 response the V receptors will be specific for both private and public H–2 antigens. It should be possible to define the repertoire of R anti-H specificities from the restriction of responses by private H–2 specificities.

T-cell effector types

The hypothesis automatically accounts for the finding that separate populations of T cells recognise antigen in association with each histocompatibility antigen (for example, in the mouse T cells are specific for either K, D or I antigens). The model is consistent with the division of T cells into subsets having different effector functions but each displaying a full repertoire of specificities[26,27]. The expression of R anti-K or R anti-D will lead to T cells destined to become cytotoxic cells, while the expression of R anti-I will lead to T cells destined to become helper cells. The model predicts that individual clones of cytotoxic T cells will show either K or D restriction[28–30]. This specificity will be provided without the need to invoke separately controlled repertoires of genes coding for R anti-K, R anti-D and R anti-I. A single multigene family containing an assortment of genes coding for each of these receptor types will, on the basis of the random expression of one receptor per haploid set per cell, infrequently give rise to a cell expressing two receptors with specificities for antigens of the same haplotypes. Most cells will display one R anti-self-H together with one R anti-non-self-H. Allelic exclusion of R anti-H expression is not necessary for clonal restriction to K, D or I recognition.

The small percentage of T cells displaying two different R anti-self-H specificities would not be expected to make a significant contribution to immune responsiveness, which will therefore be effectively clonally restricted for a single H specificity (K, D or I). However, the small fraction of T-cell clones with any given third receptor for R anti-allo-H will be able to recognise the foreign antigen in association with that allo-H specificity. Such a subset of T-cell clones has been found in limiting dilution experiments[31].

Frequency of allo-H-2 reactive cells

One of the major problems which any model for T-cell receptors and self recognition must explain is that of the high frequency of cells showing specificity for allo-histocompatibility antigens[32-34]. The present clonal expansion model contains an inherent explanation for this phenomenon. Before this explanation is discussed, the nature of the problem should be clarified. There may well be both a qualitative and a quantitative difference in the perception by T cells of H-2 antigens relative to all other antigens. The absolute frequency of allo-H-2 reactive cells is clearly high but is a difficult figure to establish with any accuracy. Frequently allo-H-2 reactive cell frequencies in excess of 1%[35-38] are compared with frequencies of $10^{-6}-10^{-5}$ for cells responsive to conventional antigens (the latter figure appears to be drawn from data on the specificities of B cells). When precursor cell frequencies for allo-H-2 reactive cytotoxic T cells determined in a limiting dilution assay were compared with the frequency of cytotoxic cells specific for a hapten (TNP) the frequency of hapten responsive cells was of the order of tenfold (between eight- and thirty-fold) less than the frequency of alloreactive cells[37]. Moreover when the allo-H-2 difference was restricted to either the K or D end of H-2, the frequencies of reactive cells were comparable with those specific for TNP. It is therefore possible that the major difference in frequency of antigen specific cells is between the B-cell and T-cell populations rather than between the frequency of allo-H-2 reactive T cells and T cells of all other specificities. In this regard it is noticeable that B-cell responses to H-2 allo-antigens are much less pronounced than corresponding T-cell responses.

With the above discussion in mind, let us look at the receptor specificities predicted by the present model to be present on cells reactive with allo-H-2 antigens or other foreign antigens (designated X). T cells reactive to X must display R anti-self-H (K, D or I) together with a V receptor specific for X. The V receptor repertoire on B cells and T cells is identical but it is reasonable to expect that with dual recognition there will be activation of T cells possessing V receptors with lower affinity for X than is necessary for activation of a B cell. This difference in affinity threshold could account in part for the apparently higher frequency of T cells reactive with X relative to B cells reactive with X. T cells reactive with allo-H-2 differences will need to possess R anti-allo-H (K, D or I) together with V receptors specific for H-2 allo-antigen differences. In the case of responses limited to differences at K or D loci the frequency of reactive cells would not be expected to be higher than the frequency of cells reactive to X. However, many measurements of alloreactivity have been made using strains of animals different at multiple loci (major and minor histocompatibility differences). In such cases a much bigger proportion of T cells bearing R-anti-allo-H molecules could be activated because the repertoire of V receptors specific for all other antigenic differences would be susceptible to stimulation in a dual recognition manner.

Passive selection systems involving the absorption of T cells by exposure to monolayers of histoincompatible cells[39] or by passage through histoincompatible animals[40] have been used to assess the fraction of T cells binding a particular antigen. In posing the problem of the proportion of allo-H-2 reactive cells the frequencies determined in these passive selection assays should be clearly distinguished from the frequencies determined in assays for precursors of effector cells. It should be remembered that in the B-cell system the frequency of antigen-binding cells is often found to be 10- to 100-fold greater than the frequency of B cells acting as precursors for specific antibody-producing cells[41]. It is reasonable to assume that V receptors behave similarly on both B and T cells and that a difference in frequency between antigen-binding cells and antigen reactive cells might be seen for T cells as it has been for B cells. In the present model this would imply that a considerable proportion of T cells carrying R anti-allo-H-2 might be removed in passive selection. In addition cross reactivities at the level of R anti-H receptors, not detectable at the level of responding cells, might be revealed by passive selection methods.

The percentage of cells responding in allo-aggression has led to the suggestion, and to evidence supporting that suggestion[32,42], that T cells are not monospecific as required for clonal selection. In the present model the T cells responding in allo-aggression are monospecific (monoclonal) with respect to R anti-allo-H specificity but that population comprises a multiplicity of T cells each monospecific with regard to its V region coded receptor and each expanding in an antigen-driven monoclonal fashion.

In addition to containing an inherent explanation of alloreactivity the present model appears to offer explanations for a number of other phenomena.

T-cell receptor idiotypes and antibodies to T-cell receptors

Considerable evidence is accumulating to show that T cells specific for either foreign antigens or alloantigens have receptor molecules carrying idiotypes identical to B-cell antibodies specific for the same antigens[43,44]. It is axiomatic to the present hypothesis that these idiotypes are encoded by the same genes.

The presence of identical idiotypes on B and T cells allows for the physiological action of anti-idiotypic antibody on both sorts of cells postulated in an idiotypic network hypothesis[45]. It is reasonable to suppose that the R anti-H family of molecules, unlike the V encoded idiotypes, will not be included in the network. Therefore, the T cell would be susceptible to anti-idiotypic network signals only through its allelicly excluded *V*-gene encoded receptor. One exception to the latter postulate might occur in allogeneic responses. Immunisation of an animal with allogeneic cells (MHC differences) will result in production of antibody to the MHC antigens. An antibody response to the R anti-H molecules on the antigenic cells could also occur. Antibody specific for R anti-H molecules might be expected to act like antibody against the idiotype of anti-MHC antibodies[46] and therefore might regulate the production of antibody against MHC antigens.

The reverse situation, that anti-idiotypic antibodies specific for the V encoded idiotypes cross react with R anti-H molecules, is also possible and might account for those data indicating a high percentage of T cells bearing allo-MHC specific idiotypes[47]. Note that in other studies such a high percentage of idiotype-bearing T cells has not been found[48].

The possibility, engendered by the present model, that antibodies might be raised against R anti-H in an immunisation regimen designed to raise antibodies against MHC antigens, has implications for the use of such antisera in functional assays. Blocking of T-cell function attributed to anti-MHC antibodies could be due to the presence of anti- (R anti-H) antibodies. Monoclonal anti-MHC antibodies will not be subject to this problem.

functional aspects of dual recognition have been discussed extensively by Langman[49] and by Cohn and Epstein[18]. The fact that the receptors in the present model arise in part from genes not previously invoked, and without the need for the somatic mutation and selection necessary in previous models does not alter the functional arguments. The requirement for a concerted response to X and an MHC antigen can be met either by interaction between X and MHC[19] or by interaction between the receptors for X and MHC[18]. In the present model an interaction between the two types of receptor occurs and is necessarily selected for during development. This interaction prevents stimulation of the R anti-H receptor. Binding of antigen to V anti-X will make R anti-H available to bind H present on the same cell surface as X. When R anti-H binds H, this completes the stimulatory complex initiating the precursor cell to proliferate and differentiate and triggering the cytotoxic cell to kill. The stimulating signals can be delivered to the cell via either R anti-H alone or R anti-H plus V anti-X; this is true in the present model for all interactions, whether self presentation or allogeneic responses, because an R anti-H molecule is always involved. There is no need to postulate (as in other models[18]) either that no signal can be delivered by the R anti-H receptor or that allogeneic reactions do not involve the R anti-H receptor.

It is necessary to postulate that interaction of V anti-X with X while the R anti-H remains unsatisfied will not deliver a signal to the T cell. Indeed the requirement for both receptors to be filled for passive absorption of cytotoxic T cells[50] suggests that the V anti-X interaction with X may be transient.

Functions of T-cell receptors: responses involving the I region

A special role has been demonstrated for the I-region products in the generation and function of helper cells for antibody production[4,5] or in mixed lymphocyte reactions (MLR)[51]. However, MLR stimulation can be demonstrated between cells matched at the MHC[52] or differing at K or D antigens but matched for the I region; the extreme examples are the H-2 mutants which appear to be point mutations of either the K or D products[53]. In the present model all MLR stimulation will involve dual recognition. In a fully allogeneic MLR, including antigenic differences at I-region gene products, dual recognition will involve an R anti-allo-I molecule and a V gene encoded receptor specific for any antigenic difference. With a minimal difference the active cells in MLR between parent strain and H-2 mutant strain would be T cells carrying R anti-self-I together with V receptors specific for the mutant histocompatibility antigens.

A valid model of T-cell function should explain MHC-linked immune response (*Ir*) genes[54]. These *Ir* genes regulate the production of antibody. An *Ir* genotype is classified as allowing either high or low responsiveness; the low responder phenotype exhibits a lack of functional helper T cells specific for the antigen under *Ir* gene control (but low responders do have T cells capable of binding that antigen[55]). Inheritance of *Ir* genes has been interpreted as showing either dominance of the high responder gene[54] or co-dominance[56].

A recurrent explanation[18,19,54] offered for *Ir* gene function is that *Ir* genes encode the T-cell receptor. Such explanations postulate that the structural genes for the T-cell receptor map in the I region, thus contradicting evidence that the T-cell receptor is encoded by structural genes linked to immunoglobulin heavy chain genes[43] (although there is evidence for genes at the MHC controlling T-cell receptor expression[48]). Two contrasting explanations of the non-responder phenotype have been offered in terms of the somatic mutability of V genes. In one model[15] all V anti-X genes are generated by mutation of V anti-self genes but in the Ir low responder a V gene specific for the antigen cannot be generated from any anti-self V gene. In another model[18,49] it is postulated that only an anti-self V gene can generate a V gene coding for a product specific for the antigen under *Ir* gene control and low response is due to the need to retain V anti-self unmutated to perform its function in dual recognition. In neither of these two models is it obvious why *Ir* genes controlling antibody production map in the I region rather than in K and D regions of the murine MHC. A different explanation for Ir defects describes *Ir* gene products as a second recognition system with non-responsiveness resulting when the *Ir* gene product cannot associate effectively with an antigen[19]. The explanation for MHC-linked *Ir* genes in the present model attributes non-responsiveness to the binding of the antigen to the R anti-I specific for the non-responder I-region product. The functional *Ir* gene is thus one of the T-cell recepors; it is not encoded at a locus linked either to an immunoglobulin gene family or to MHC but expression of *Ir* gene phenotype will be controlled by I-region products so that the MHC appears to encode *Ir* genes.

Complete humoral responsiveness to every antigen is postulated to involve the R anti-I T-cell receptor but in most cases Ir control is not seen because low responsiveness is displayed only when an antigen fortuitously binds to the R anti-I, thus blocking the interaction of R anti-I with I in the dual recognition process. This defect will be seen at the level of antigen presentation on macrophages and at the level of co-operation between T and B lymphocytes because both processes involve simultaneous recognition of I region and antigen. The postulate that Ir phenotype coincides with R anti-I specificity leads automatically to an explanation for the findings that pre-T cells with a non-responder phenotype, when processed by a thymus of responder genotype, emerge as responder T cells[57] because there will have been selection for R anti-responder-I specificity. In keeping with the evidence[57], the model says that T cells generated thus will only function as responder helper cells when complementing responder B cells and macrophages. Because this model requires that all R anti-self-I molecules are selected for in the thymus it follows that *Ir* genes should show co-dominant expression[56].

Predictions

The model proposed here predicts that each T cell carries three receptor molecules. Two of these are non-antibody receptors, at least one of which is specific for a self-MHC molecule (either K, D or I in the mouse). Detection and characterisation of R anti-H molecules would provide evidence for the model. A small fraction of T-cell clones responding to a foreign antigen recognised together with a self-H antigen will also be able to recognise the antigen presented with an allo-H antigen due to the postulated third receptor (R anti-allo-H). Evidence for the latter subset of T-cell clones has been published[31].

Receptors specific for self-MHC are postulated to be the products of a multigene family encoding receptors for many allo-MHC products. The extent of that gene family will be revealed by further tests of the ability of pre-T cells to be selected in the thymus for recognition of a range of MHC types as self. Because expression of receptors for self-MHC molecules is postulated to be selected by the MHC antigens of the thymus the MHC appears to code for the T-cell receptor. An involvement of anti-self-MHC receptors in I-region linked non-responsiveness is postulated.

While recognising that I have invoked a new gene family that may or may not exist, I trust that the concept has some merit in ordering existing data and that it may influence future experimental design.

I thank Andrew McMichael, Dale Kipp and John Shire for stimulating and helpful discussion.

ARTICLES

Observations of flexure and the geological evolution of the Pacific Ocean basin

A. B. Watts & J. H. Bodine
Lamont-Doherty Geological Observatory, and Department of Geological Sciences, Columbia University, Palisades, New York 10964
N. M. Ribe
Department of Geophysical Sciences, University of Chicago, Chicago, Illinois 60637

The response of the Pacific plate to oceanic island and seamount loads has been used to estimate the distribution of ridge crest and off-ridge volcanism on the plate since the late Jurassic. The most extensive event, forming the Hess rise, Line Islands ridge, Necker ridge, and Robbie ridge, occurred on the Pacific/Farallon and Pacific/Phoenix ridge crests during the interval 90–120 Myr BP *(Barremian to Turonian). This event, which extended over a much larger area than comparable volcanism on the continents, is one of the largest to be documented in the geological record.*

THE Pacific Ocean floor is characterised by numerous oceanic islands and seamounts of mainly volcanic origin[1-4]. Although the age of the oceanic crust of the Pacific basin is now reasonably well known from marine magnetic lineations and Deep Sea Drilling Project (DSDP) sites, the origin and age of these volcanic features are largely unknown. These oceanic islands and seamounts are of geological interest as they are located within the interior of the Pacific plate and may therefore provide information on intra-plate volcanism. This article presents a method, based on oceanic plate flexure, for determining the origin and age of some of these volcanic features in the Pacific Ocean basin.

Lithospheric flexure

The concept of plate tectonics is based on a strong rigid lithosphere which overlies a weaker asthenosphere. The principal evidence for a strong lithosphere on long time scales ($>10^6$ yr) has come from studies of its response to surface loads[5-15]. These studies have shown that in several cases, geological and geo-

0028-0836/80/060532—06$01.00

physical data in the region of surface loads can be explained by a simple model in which the lithosphere responds to long-term loads in a manner similar to that of a thin elastic plate overlying a weak fluid.

The results of recent studies of oceanic plate flexure are summarised in Fig. 1 in which the elastic thickness of the oceanic lithosphere T_e is plotted as a function of the age of the lithosphere at the time of loading. Different types of geological features have been plotted in Fig. 1. The age of the lithosphere at the time of loading was estimated at each feature by subtracting the age of the load from the age of the underlying sea floor. The studies by Watts[9] and McNutt and Menard[10] are shown as dashed lines because a single estimate of T_e was obtained for a wide range of age at the time of loading (>60 Myr). Also shown as a dashed line is the study by Caldwell[14] at the Aleutian trench as it is difficult to separate the Aleutian outer rise from a broad regional rise in bathymetry which occurs seawards of the trench[16]. Figure 1 summarises all recent estimates of T_e, except those from the Philippine and Tonga–Kermadec trenches[14] where the age of the subducting oceanic crust is too poorly known.

The main results shown in Fig. 1 are that surface loads formed on young lithosphere, such as the topography of oceanic Layer 2, are associated with relatively small values of T_e while loads formed on old lithosphere, such as the Hawaiian–Emperor seamount chain, are associated with relatively high values. The simplest interpretation of these results is that as the oceanic lithosphere increases in age it cools, thickens, and becomes more rigid in its response to surface loads. Figure 1 shows that there is good general agreement between T_e and the 300 to 600 °C oceanic isotherms, based on a cooling plate model[17].

As the age of the surface loads plotted in Fig. 1 are in the range of a few Myr to several tens of Myr, Fig. 1 suggests T_e is acquired at the time of loading and does not change appreciably with time. This result is consistent with thermal models which predict that the thickness of the lithosphere increases with age[9] and with inferences of the rheology of the oceanic lithosphere based on extrapolations of data from experimental rock mechanics[18,19].

The results in Fig. 1 have important implications for studies of the geological evolution of the ocean basins. For example, Fig. 1 suggests that an oceanic island or seamount formed on young sea floor would be associated with a relatively small T_e, while an oceanic island or seamount formed on old sea floor would be associated with a relatively large T_e. Thus by determining T_e at an oceanic island or seamount of unknown origin it should be possible to estimate whether it formed on young (ridge crest) or old sea floor (off-ridge).

A geophysical observation which can be relatively easily measured on a surface-ship and depends on T_e is the free-air gravity anomaly[7–9,12]. For the theoretical seamount load shown in Fig. 2 there is a significant difference in both amplitude and wavelength between computed gravity anomaly profiles for $T_e = 5$ km, corresponding (Fig. 1) to formation of the load on relatively young sea floor (2–8 Myr), and $T_e = 25$ km, corresponding to formation on relatively old sea floor (>35 Myr). Thus since the overall accuracy of gravity data in the Pacific Ocean is 5–10 mGal (ref. 16), Fig. 2 suggests it should be possible to use observed free-air gravity anomaly profiles to distinguish whether a geological feature originated on a ridge crest or off-ridge.

Data analysis

We have compared observed free-air gravity anomaly profiles obtained on more than 100 cruises of mainly US and USSR research vessels in the Pacific Ocean to calculated profiles based on the elastic plate model. We assumed values of $T_e = 5$ and 25 km since these values clearly represent a ridge crest or off-ridge origin respectively (Fig. 1). The calculated profiles were obtained using linear transfer function techniques[7,9] in which theoretical filters are constructed and convolved with observed bathymetry profiles. Both two- and three-dimensional filters[7] and the effects of non-linearity in the computation of the gravity anomaly have been considered.

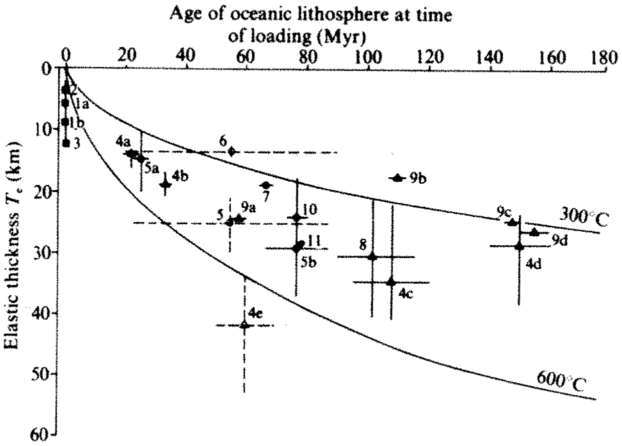

Fig. 1 Plot of elastic thickness of the oceanic lithosphere T_e against age of the lithosphere at the time of loading. 1a, East Pacific rise crest[5]; 1b, Mid-Atlantic Ridge crest[5]; 2, Juan da Fuca ridge crest[6]; 3, Mid-Atlantic Ridge crest[7]; 4, Deep-sea trench outer rise systems[14]; 4a, Nankai trough; 4b, Middle America trench; 4c, Kuril trench; 4d, Mariana trench, 4e, Aleutian trench; 5, Hawaiian–Emperor seamount chain[9]; 5a, Emperor seamounts north of 40° N; 5b, Hawaiian ridge and Emperor seamounts south of 40° N; 6, Pacific Ocean atolls[10] (Cook Islands, Australs, Tuamotu Islands and Henderson); 7, Great Meteor seamount, NE Atlantic[8]; 8, Kuril trench[15]; 9, Deep sea trench-outer rise systems[13]; 9a, Aleutian trench; 9b, Kuril trench; 9c, Bonin trench; 9d, Mariana trench; 10, Hawaiian ridge[11]; 11, Hawaii Island[12]. Each estimate of T_e is related to the flexural rigidity of the plate and is based on an assumed Young's modulus of 1×10^{12} dyn cm^{-2}. The age of the lithosphere at the time of loading was estimated by subtracting the age of each load from the age of the underlying sea floor. For the ridge crest estimates and trench estimates the loading is assumed to be of the present age (0 Myr). For the seamount and oceanic island estimates, the age of loading is obtained from dated samples on the crests or flanks of these features. The solid lines are the 300 °C and 600 °C oceanic isotherms based on a cooling plate model[17].

Figure 3 shows the comparison between observed and computed gravity anomaly profiles for four selected geological features in the Pacific Ocean. The observed gravity anomaly profiles of the Line Islands ridge and Mid-Pacific mountains can be most satisfactorily explained by the computed profile with $T_e = 5$ km (Fig. 3*a*). The computed profile with $T_e = 25$ km predicts too large an amplitude gravity anomaly over the crest of these features compared with the observed amplitude and wavelengths that are too long over flanking regions. The observed gravity anomaly profiles of Makarov Guyot[3] and Louisville ridge, however, can be most satisfactorily explained by the computed profile with $T_e = 25$ km (Fig. 3*b*). The computed profile with $T_e = 5$ km predicts too small an amplitude over the crest of these features compared with the observed amplitude and wavelengths that are too short over flanking regions.

The comparisons in Fig. 3 can therefore be interpreted as indicating the Line islands ridge and Mid-Pacific mountains formed on a ridge crest (on sea floor of 2–8 Myr age) while Makarov Guyot and Louisville ridge formed off-ridge (on sea floor of >35 Myr age). These conclusions on the origin of these features are, of course, uncertain as they are based on a single gravity anomaly and bathymetry profile and refer only to the origin of the major part of each feature. We have shown[21], however, that uncertainties in the computed profiles, due either to variations in the crustal structure and density of topography assumed or to non-linearity in the computed gravity effects would not significantly alter these conclusions.

Results

The results of the data analysis for each of the cruises in the Pacific Ocean are summarised in Fig. 4: the symbols represent an estimate of the geological setting of an individual bathymetric feature along each ship track. Figure 4*a* summarises those

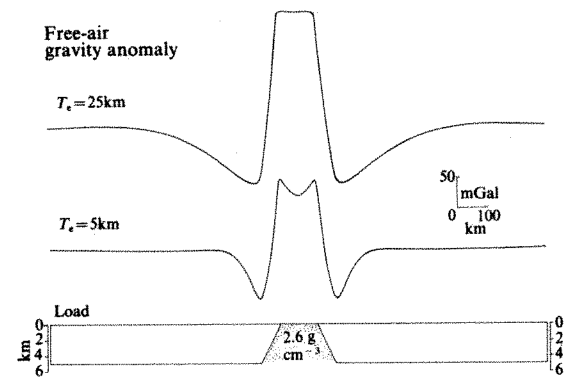

Fig. 2 Computed free-air gravity anomaly profiles based on the continuous elastic plate model and the theoretical seamount load shown. The flexure of the plate has been computed using linear theory[20] and the free-air gravity anomaly has been computed using a two-dimensional line-integral method.

estimates which are interpreted to be of ridge crest origin and Fig. 4*b* those estimates which are of off-ridge origin.

A comparison of Fig. 4*a* with available bathymetry maps of the Pacific Ocean[24,25] show that most of the ridge crest estimates correlate with bathymetric features in the western and central Pacific. These include the Manihiki plateau, Shatsky rise, Hess rise, Necker ridge, Line Islands ridge and Tuamotu Islands and some features in the Magellan seamounts, Mid-Pacific mountains and Emperor seamounts. A number of these features were associated with more than two ridge crest estimates (for example, Shatsky rise (5), Necker ridge (3), Hess rise (4), Line Islands ridge (5) and Tuamotu Islands (10)). Most of the ridge crest estimates (Fig. 4*a*) apparently occur between the 90 and 120 Myr isochrons, based on magnetic anomaly lineations and DSDP sites[22].

The off-ridge estimates (Fig. 4*b*) mainly correlate with bathymetric features in the western Pacific Ocean. These include Society Islands, Samoa, Melanesian border plateau[23], Cross-Line Island trend and Louisville ridge and some features of the Hawaiian ridge and Emperor seamounts, Geisha and Marcus–Wake Guyots[3] and Magellan seamounts. A number of these features were associated with more than two off-ridge estimates (for example, Samoa (3), unnamed seamount in the Magellan seamounts (3), Louisville ridge (3), and Society Islands (3)). The off-ridge estimates show no obvious relationship to the isochrons although the estimates for the Cross-Line Island trend, Hawaiian ridge and Marcus–Wake Guyots correlate with bathymetric features which generally trend WNW–ESE[4], across the local trend of the isochrons.

We recognise that although data from a large number of cruises have been used in this study, the number of estimates in Fig. 4 is small compared with the total number of oceanic islands and seamounts which actually exist in the Pacific Ocean. We believe, however, that although any one estimate in Fig. 4 may be subject to uncertainties, the occurrence of several similar estimates from the same geological feature is evidence that the overall distribution of ridge crest and off-ridge estimates (Fig. 4) is correct. A better test of their reliability, however, is to compare the predicted age of the bathymetric features associated with these estimates to geological ages based on bottom sampling.

The ages of the bathymetric features associated with each estimate (Fig. 4) can be predicted if the age of the underlying sea floor is known (Fig. 1). Table 1 summarises those estimates which are associated with a nearby reliably dated bottom sample. There is a good general agreement between predicted and geological ages for the ridge crest estimates, particularly for Hodgkins, Line Islands, Easter Island and the Tuamotu Islands. The agreement is not as good for the off-ridge estimates because the predicted ages are only maximum estimates.

Table 1 therefore suggests that it should be possible, at least for the ridge crest estimates (Fig. 4*a*), to predict the age of the associated bathymetric features with some confidence. The main uncertainties, however, are in estimating the age of the sea floor, particularly in regions of the magnetic quiet zones. We tabulated the predicted ages for each ridge crest estimate in 30-Myr intervals through geological time. The smallest number of estimates (3) occur for the interval 150–180 Myr BP (Kimmeridgian to Pliensbachian) and the largest number of estimates (26) occur for the interval 90–120 Myr BP (Barremian to Turonian).

The distribution of the off-ridge and ridge crest estimates in the Pacific Ocean basin for the 90–120 Myr BP interval are plotted in Fig. 5. The solid triangles represent ridge crest estimates associated with the Hess rise, Necker ridge, Line Islands ridge, Manihiki plateau and Robbie ridge and the solid circles represent off-ridge estimates associated with the Geisha Guyots, for which there is geological control (Table 1). The bathymetric features associated with the ridge crest estimates extend over a broad region of the Pacific Ocean basin (Fig. 5). We therefore infer that the interval 90–120 Myr BP was a time of significant volcanism on the Pacific plate.

As the solid triangles in Fig. 5 represent ridge crest estimates they may indicate the former position of the accreting Pacific

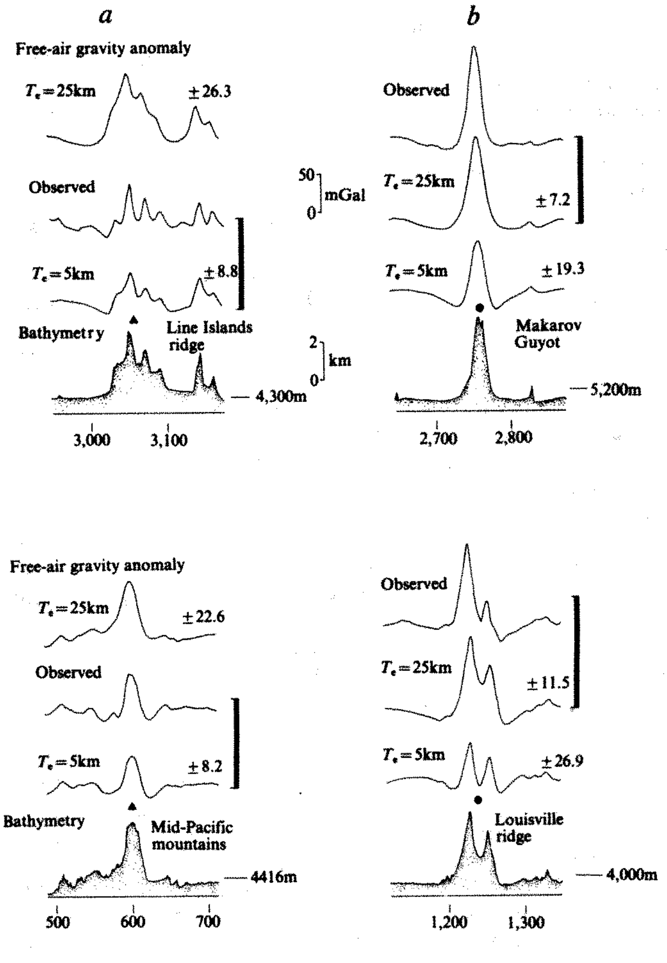

Fig. 3 Comparision of observed free-air gravity anomaly profiles with computed profiles based on the elastic plate model and assumed values of the elastic thickness $T_e = 5$ km and 25 km. *a*, USNS Eltanin 31 profile of the Line Islands ridge at lat 1.7° N and long 157.0 °W and RV Vema 24 profile of the Mid-Pacific mountains at lat 18.5° N and long 179 5° W. *b*, RV Vema 21 profile of Makarov Guyot at lat 29.6° N and long 153.5° E and USNS Eltanin 40 profile of Louisville ridge at lat 39.3° S and long 167.5° W. The observed profiles of the Line Islands ridge and Mid-Pacific mountains can be best explained by the computed profile of $T_e = 5$ km and the observed profiles of Makarov Guyot and Louisville ridge can be best explained by the profile for $T_e = 25$ km. A ridge crest origin (▲) has been assigned to the Line Islands ridge and Mid-Pacific mountains; an off-ridge origin (●) has been assigned to Makarov Guyot and Louisville ridge. The numbers to the right of each computed profile are the r.m.s. differences between observed and calculated gravity anomalies and the number below each bathymetry profile is the distance in nautical miles along a ship track, used to locate each feature.

Table 1 Comparison of predicted ages based on flexure studies with geological ages

Seamount or oceanic island	Ship crossing feature	Position of ship crossing		Method of geological age determination	Position of geological age		Estimated age of underlying sea floor (Myr BP)	Predicted (flexure) age* (Myr BP)	Geological age (Myr BP)	Geological age ref.

* Computed assuming a ridge crest estimate corresponds to an age of the lithosphere at the time of loading of 2–8 Myr and an off-ridge estimate corresponds to an age of >35 Myr.

† This seamount has a reliable palaeomagnetic pole[49]. The new constraints on the age suggests this pole (lat. 53.0° N, long. 302°) is probably of early Cretaceous age.

plate boundary. In particular, the Line Islands ridge, Necker ridge and Hess rise probably formed close to the crest of the former Pacific/Farallon plate boundary[36] and the Robbie ridge probably formed close to the crest of the former Pacific/Phoenix plate boundary[36]. Therefore, either volcanism occurred along a major portion of the Pacific plate boundary during 90–120 Myr BP or, beginning about 90–100 Myr BP major ridge jumps occurred along the Pacific plate boundary[4] accompanied by extensive volcanism on the abandoned ridges. Because of the scatter of the ridge crest estimates (Fig. 5) and the fact that only one-limb of the 90–120 Myr BP spreading system is preserved at present, it is not possible to distinguish between these possibilities.

Recent evidence from DSDP site 462[37] and from seismic reflection profiling with a large volume sound source[38] support the earlier suggestion of Winterer[4] that the relatively old crust of the central Pacific basin and the Line Islands area may be obscured by a younger deep-water volcanic event. DSDP site 462[37] (Fig. 5), drilled on oceanic crust of probable late Jurassic age, recovered a volcanic igneous complex of Albian to Aptian age (100–110 Myr BP). Houtz and Ludwig[38] have mapped a seismic reverberant layer, using sonobuoy and single channel vertical incidence data, which reaches thicknesses exceeding 2 km in parts of the central Pacific Ocean basin. Although the reverberant layer may be of calcareous origin[38], the presence of a thick layer (>600 m) in the region of DSDP sites 462 and 169 suggests the layer may be, in part, of volcanic origin and therefore similar in age to the volcanic rocks drilled at the DSDP sites.

These considerations suggest the 90–120 Myr BP ridge crest volcanism which formed the Line Islands ridge, Hess rise and Necker ridge (Fig. 5) may have been accompanied by an extensive deep-water volcanic event in the adjacent ocean basins. The solid line in Fig. 5 outlines the area of the Pacific plate which seems to have been most affected by this event. We have included only evidence from the ridge crest estimates (Fig. 4*a*), the off-ridge estimates for which there is geological control (Table 1) and the contemporaneous deep-water volcanism inferred from DSDP sites and seismic reflection profiling. Thus although other undated oceanic islands and seamounts in the Pacific, not crossed by the cruises, may possibly be of similar age to this event we have not plotted them in Fig. 5.

Discussion

We have documented a major geological event involving an extensive outpouring of ridge crest volcanism on the Pacific plate during the interval 90–120 Myr BP (Barremian to Turonian). This event was probably accompanied by deep-water volcanism. The area of the plate affected by the volcanism is $\sim 10^7$ km^2 (Fig. 5), which is significantly larger than areas of comparable volcanism on the continents (for example, western US since the Miocene[39]).

The origin of the ridge crest volcanism on the Pacific plate during the interval 90–120 Myr BP is not clear at present. The fixed or moving hot-spot hypothesis[40–42] cannot simply explain the volcanism unless a large number of contemporaneous hot spots are proposed along or near the former Pacific/Farallon and Pacific/Phoenix plate boundaries. The lithospheric fracture hypothesis[43] explains the widespread similarity in ages but cannot explain the volcanism unless a stress system is invoked which causes tensional failure of the plate in a direction generally parallel to the trend of the former Pacific/Farallon and Pacific/Phoenix plate boundaries. Thermal contraction of the oceanic plate[44], for example, would cause tensional failure which propagates in the direction of sea floor spreading.

An additional source of stress in the plates, however, are those associated with the driving mechanism of plate tectonics[45]. There is evidence, for example, from magnetic lineation patterns[36] that the 90–120 Myr BP volcanic event on the Pacific plate (Fig. 5) occurred at a time of relatively rapid spreading rate on the Pacific/Farallon ridge crest. This spreading rate increase, if it occurred[46], may have been accompanied by either the initiation of subduction or an increase in the convergence rate on another Pacific plate boundary. If this increase in convergence rate was accompanied by an increase in the driving force on the subducting plate[47], additional stresses may have been transmitted to the horizontal part of the plate. These stresses may have been sufficient to cause the Pacific plate to fracture at its weakest point and allow magma to flow from the underlying asthenosphere to the area around the ridge crest.

We have also documented the distribution of off-ridge volcanism on the Pacific plate (Fig. 4*b*). As some of the estimates of off-ridge volcanism are from the oldest part of the Pacific plate (Fig. 4*b*) this volcanism is therefore of late Jurassic or younger age. The main problem, however, is that with the exception of

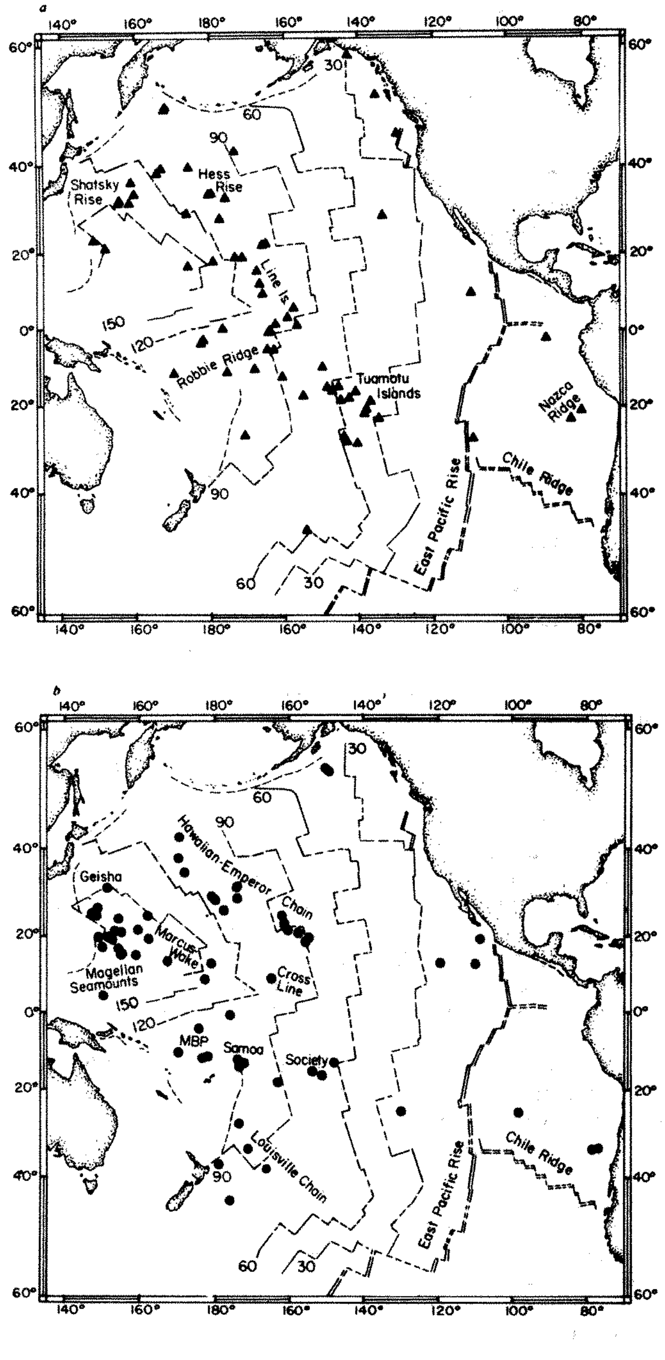

Fig. 4 Plot of estimates of ridge crest (*a*) and off-ridge volcanism (*b*) on the Pacific plate. The solid lines indicate isochrons based on observed magnetic lineations and DSDP sites and the dashed lines indicate interpolated isochrons based on tectonic reconstructions for the Pacific plate[22]. MBP, Melanesian border plateau[23].

the Hawaiian–Emperor seamounts and some features in the Geisha Guyots, where there is adequate geological control, the age of the off-ridge volcanism is generally unknown (for example, Table 1).

There is evidence, however, that at least part of the off-ridge volcanism in Fig. 4*b* may be of younger age than 90–120 Myr BP. The Line Islands ridge between latitudes 5°N and 15°N are intersected by the WNW–ESE Cross-Line Island trend which, based on bathymetry[4] and the estimated age of the off-ridge estimate at latitude 12°N longitude 165°W (Fig. 4*b*), are younger than the Line Islands ridge. The Melanesian border plateau, Samoa and Society Islands, which seem to form part of a broad WNW–ESE trend in off-ridge volcanism in the central Pacific (Fig. 4*b*), are probably younger than middle Cretaceous (see Table 1). The age of the off-ridge volcanism of the Magellan seamounts and Marcus–Wake Guyots is not known, however, although they are associated with similar WNW–ESE trends in bathymetry as the Cross-Line Island trend[4,24].

The presence of WNW–ESE trends in the bathymetry of features associated with off-ridge volcanism (Marcus–Wake Guyots, Magellan seamounts, Cross-Line Island trend) is of particular interest as they cross isochrons and are generally parallel to the direction of present day absolute Pacific plate motions. One possibility therefore is that the off-ridge volcanism is a surface expression of small-scale convection[48] in the underlying mantle. The ages of these features are not well enough known, however, and more studies need to be carried out before this possibility can be examined.

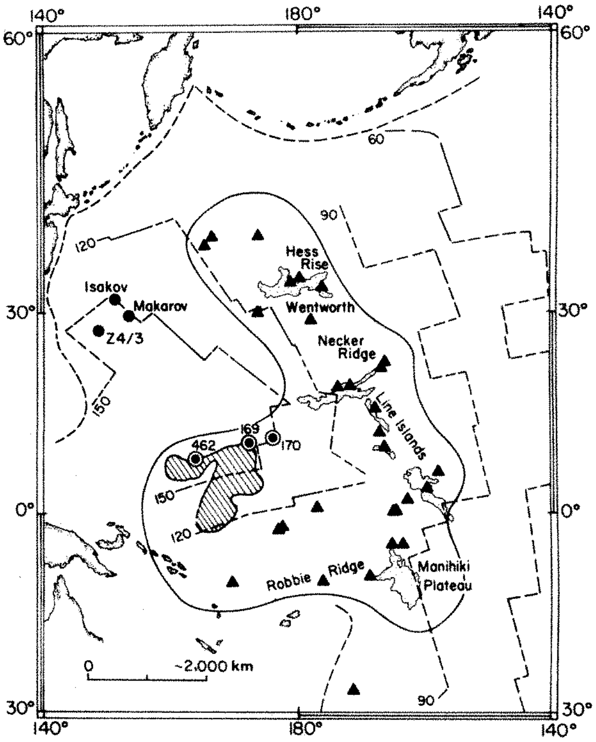

Fig. 5 Map summarising the inferred distribution of volcanism on the Pacific plate during the interval 90–120 Myr BP (Barremian to Turonian). ▲, Bathymetric features formed at a ridge crest; ●, features formed off-ridge. The ridge crest features probably originated on or near the Pacific/Farallon and Pacific/Phoenix ridge crests[36] and the off-ridge features originated in the interior of the Pacific plate away from the accreting plate boundaries. ◉, The deep water DSDP sites which were drilled on oceanic crust of probable late Jurassic age and sampled basaltic igneous rocks of Albian to Aptian age (100–110 Myr BP). The shaded area is the >600-m isopach of the seismic reverberant layer[38] in the region of DSDP sites 462 and 169 and the stippled area indicates the extent of shallow (<4,000 m)[24] sea floor in the region of the Manihiki plateau, Line Islands ridge, Necker ridge, Hess rise and Mid-Pacific mountains.

In vitro and *in vivo* products of *E. coli* lactose permease gene are identical

Ruth Ehring & Konrad Beyreuther

J. Keith Wright & Peter Overath

Max-Planck-Institut für Biologie, Corrensstr. 38, D7400 Tübingen, FRG

The lacY *gene product synthesised* in vitro *is identical to lactose permease isolated from cytoplasmic membranes as determined by apparent molecular weight and N-terminal amino acid sequence. The amino acid composition of the* in vivo *product agrees well with that predicted from the DNA sequence. The data assign the translational start on the DNA sequence and demonstrate that this protein is processed only by deformylation but not by proteolytic cleavage at the N-terminus.*

In both bacterial and eukaryotic cells, most secreted proteins are initially synthesised as precursors with hydrophobic amino-terminal extensions which are removed by proteolytic cleavage during or after translocation of the protein through the membrane[1,2]. Such precursors have been demonstrated for some integral membrane proteins, such as the coat protein of the bacteriophage M13 (refs 3, 4), whereas in other cases the primary translation product formed *in vitro* seems to be identical to the membrane-associated *in vivo* product[5,6]. We describe here the *in vitro* synthesis of lactose permease (lactose carrier, product of the *Y* gene of the *lac* operon) of *Escherichia coli*[7] and show that the *in vitro* product is identical to permease isolated from the cytoplasmic membrane of this organism. As a model for the biosynthesis of a hydrophobic protein, lactose permease seems particularly attractive because this protein must attain a highly organised tertiary structure in the membrane in order to function as a lactose/proton-symporter[8].

Cell-free protein synthesis directed by hybrid plasmid pGM21

pGM21 is a hybrid plasmid between the vector pACYC 184 (ref. 9) and a previously described *lac Y* gene-containing fragment[10,11] integrated into the single site for the restriction enzyme *Eco*RI located in the gene conferring resistance to chloramphenicol. The fragment comprises about 2,300 base pairs and carries an intact *lac* promoter and operator region, an intact *Y* gene, but only minor parts of the *A* (thiogalactoside transacetylase), *Z*(β-galactosidase) and *I*(repressor) genes [genotype $lac\Delta(I)P^{+}O^{+}\Delta(Z)Y^{+}\Delta(A)$]. The restriction maps of this fragment and the *lac Y* gene-containing fragment sequenced in the preceding paper[12] are identical in the region of the *Y* gene. *In vivo*, pGM21-directed synthesis of lactose permease is inducible. The protein comprises up to 15% of the cytoplasmic membrane protein and is functionally intact as judged by transport and substrate binding experiments[10,13,14].

When added to a coupled transcription–translation system according to Zubay *et al.*[15], plasmid pGM21 efficiently promotes cell-free protein synthesis. In an incubation mixture containing ^{14}C-phenylalanine as the only radioactive amino acid, 11% of the label is found in a high molecular weight (MW) form, whereas in the absence of pGM21 only 0.1% of the input radioactivity becomes acid precipitable. An aliquot of the total incubation mixture was analysed on a polyacrylamide gel (Fig. 1*a*). It is clear that pGM21 directs the synthesis of one major product (slice nos 36–42, 33% of radioactivity) of apparent MW 30,000 ± 1,000. This radioactive peak corresponds in both mobility and width to purified lactose permease (prominently stained band in gel at the top of Fig. 1) or permease labelled with ^{3}H-*N*-ethylmaleimide in intact cytoplasmic membranes (Fig. 1*b*). Thus, the main product of the *in vitro* synthesis is identical to lactose permease within the resolution of the method.

As pGM21 contains an intact promoter–operator region, *in vitro* expression of the *Y* gene should be stimulated by cyclic AMP and reduced by *lac* repressor. Furthermore, repression should be relieved by addition of the inducer isopropyl β-D-thiogalactopyranoside (IPTG). Analysis of *in vitro* protein synthesis reaction mixtures on acrylamide gels demonstrates that the major product (apparent MW 30,000) is indeed subject to regulation by cyclic AMP and repressor (compare lanes 6–9 of Fig. 2). In terms of total incorporation of radioactive amino acids into protein (see Fig. 2 legend), cyclic AMP stimulates about twofold, repressor suppresses this synthesis by 60%, and addition of IPTG relieves the inhibition almost completely. These effects of cyclic AMP and repressor are small compared with control studies on *in vitro* synthesis of β-galactosidase directed by DNA from *lac* transducing phage λ in the same conditions. As quantitated by catalytic activity, the synthesis of this enzyme

0028-0836/80/060537—04$01.00

was reduced to less than 5% of the control by the omission of cyclic AMP or by addition of repressor (data not shown). The different behaviour of the two DNA preparations may be related to the use of circular DNA in the case of pGM21.

Depending on the conditions of gel electrophoresis, variable amounts of radioactivity in polypeptide material are distributed almost homogeneously throughout the high-MW region of the gel. As lactose permease has a marked tendency to aggregate, this material could at least in part represent *Y* gene product. This assumption is supported by the observation that the diffusely distributed radioactivity is also subject to regulation by cyclic AMP and repressor (Fig. 2). Moreover, co-electrophoresis of ^{3}H-labelled protein synthesised in the presence of repressor and IPTG and ^{14}C-labelled protein made in the presence of repressor only shows that the normalised radioactivity profiles essentially coincide from the start to the front of the gel (data not shown). Thus, repressor affects not only the synthesis of the main product (apparent MW 30,000) but also that of material of lower mobility and small polypeptides moving to the front. The diffusely distributed radioactivity in the high-MW region together with the permease band form about 60% of the total radioactivity on the gel.

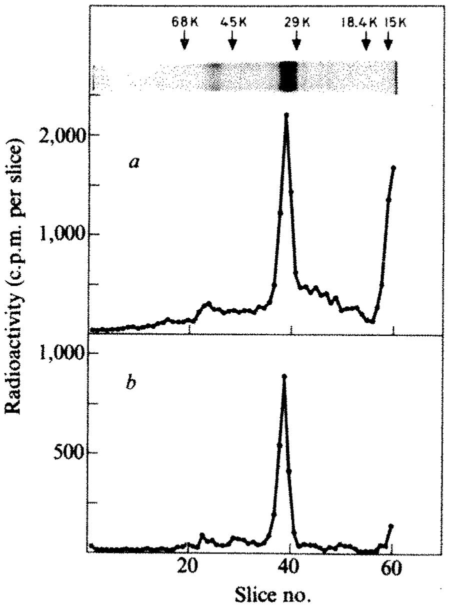

Fig. 1 Comparison of *in vivo* and *in vitro lac Y* gene products. *a*, Polyacrylamide-gel electrophoresis of *in vitro* products. A cell-free extract of *E. coli* K12 strain 514 (carrying a deletion of the *lac* operon) was used in a coupled transcription translation system as described previously[15,19]. First, the extract was incubated for 60 min at 0°C with 1 mM phenylmethanesulphonyl fluoride. To minimise accumulation of degradation products and of incomplete polypeptides, radiolabelling by ^{14}C-phenylalanine was limited to the interval from 15 to 25 min after the start of the reaction and was followed by a 5-min chase with a 25-fold molar excess of unlabelled phenylalanine. The 20 unlabelled amino acids were present at 0.22 mM each, pGM21 DNA at 30 μg ml^{-1} and polyethylene glycol 6000 at 25 mg ml^{-1} (all final concentrations). After the addition of ^{14}C-phenylalanine to 100 μCi ml^{-1}, the concentration of this amino acid was 0.36 mM. A further incubation for 10 min at 37°C with DNase I and RNase A (each added to a final concentration of 25 μg ml^{-1}) terminated the reaction. The complete reaction mixture incorporated 10.5% of the ^{14}C-phenylalanine into material insoluble in hot trichloroacetic acid. In the absence of pGM21 DNA, only 0.1% of the label was incorporated. An aliquot of 3 μl synthesis mixture was mixed with 27 μl sample buffer, incubated for 30 min at room temperature and applied to a slab gel (compare with ref. 20, 14% acrylamide–0.12% bisacrylamide). Free radioactive phenylalanine was removed during staining with Coomassie brilliant blue R 250. The figure shows the radioactivity distribution in sections of the gel counted as described previously[13]. *b*, Radioactivity distribution of a cytoplasmic membrane preparation in which permease was labelled with ^{3}H-*N*-ethylmaleimide[13,21] The top of the figure shows electrophoresis of lactose permease isolated in an inactive state from strain T206 (ref. 16). Arrows refer to marker proteins (bovine serum albumin, MW 68,000; ovalbumin, 45,000; carbonic anhydrase, 29,000; β-lactalbumin, 18,400; haemoglobin, 15,000.

Table 1 Amino acid composition of *lac* permease

Amino acid	No. of residues	
Asp	20.96	(6)
Asn		(16)
Thr	19.10	(19)
Ser	27.20	(29)
Glu	21.79	(11)
Gln		(11)
Pro	11.65	(12)
Gly	35.28	(36)
Ala	34.35	(35)
Cys	6.55	(8)
Val	28.70	(29)
Met	13.50	(14)
Ile	28.67	(33)
Leu	49.84	(54)
Tyr	11.67	(14)
Phe	35.40	(56)
His	4.28	(4)
Lys	12.05	(12)
Arg	12.56	(12)
Trp	4.72	(6)
Sum		(417)

Amino acids were analysed as described elsewhere[22] on a Beckman 121M amino acid analyser. The numbers given for valine, isoleucine, leucine and phenylalanine were derived from 192-h hydrolysates. Cysteine was analysed as cysteic acid. The integral values in parentheses are based on the DNA sequence[12].

A control experiment is shown in Fig. 2 (lanes 3, 4). The vector pACYC184 codes for one major product concentrated in a sharp band of MW 25,000±2,000. We attribute this band to the expression of the chloramphenicol resistance gene[9] which is inactivated by insertion of the *lacY*-containing fragment. Therefore, this product is lacking in pGM21-directed *in vitro* synthesis.

Amino-terminal sequence of the *lacY* gene product synthesised *in vitro*

The amino acid sequence of the product encoded by pGM21 DNA *in vitro* was partially elucidated. The material synthesised in the presence of ^{14}C-phenylalanine, ^{3}H-lysine, ^{14}C-leucine or ^{35}S-methionine was subjected to automated sequence analysis (Fig. 3). These four amino acids appear in the following positions—Phe: 9, 12, 15, 16, 17, 18, 20, 21, 27, 29 and 30; Lys: 5 and 42; Leu: 4, 14 and 34; Met: 1, 11 and 23. These assignments agree completely with the prediction of the DNA sequence[12] and thus identify the major protein synthesised from pGM21 DNA *in vitro* as the product of the *lacY* gene. This species represents the predominant product of cell-free synthesis, as sequence analysis does not reveal the presence of amino acids in positions other than those predicted by the DNA sequence.

Neither the permease nor another protein component exists predominantly with a formylated N-terminus. The ^{35}S-methionine liberated after the first degradation cycle is 74% of that observed when the product is chemically deformylated (Fig. 3*d*). The newly deblocked material contains no additional methionine residues up to position 21, suggesting that no different sequences are made available for analysis. Thus, methionine-1 is probably encoded by the initiation codon of the *Y* gene, and the protein is efficiently deformylated in the cell-free extract. The yield of radioactive methionine released from the deformylated material in the first sequencing step was 72% of that expected from the methionine content of permease (see Table 1 and Fig. 3). The yields of the more stable amino acids Phe, Leu and Lys were 82–91% (Fig. 3).

The *lac* permease synthesised *in vitro* was biosynthetically labelled with 15 amino acids and submitted to direct microsequence analysis (Fig. 4). After 42 sequencing steps, 34 residues could be identified. The unassigned positions correspond to

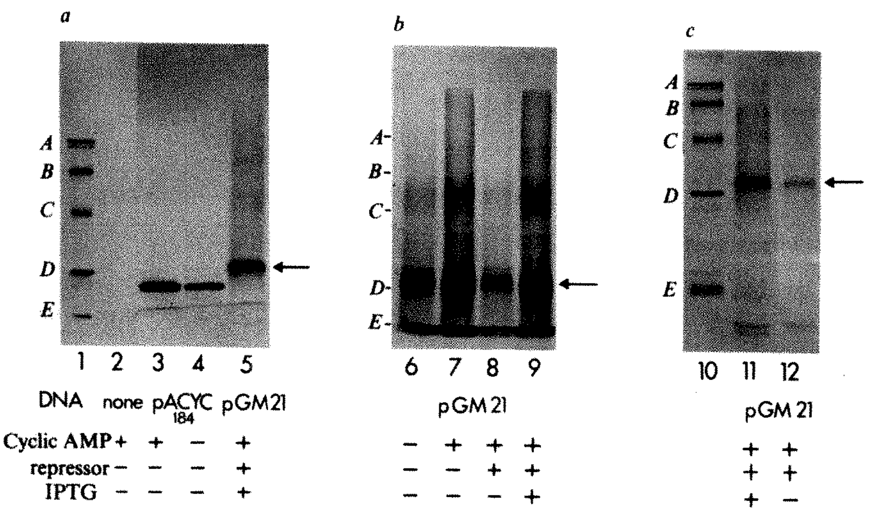

Fig. 2 Regulation of expression of pGM21 *in vitro*. DNA-directed cell-free protein synthesis was carried out as described for Fig. 1 with the following alterations. Radiolabelling for samples of *a* and *b* was continuous throughout a 30-min synthesis period with a mixture of ^{14}C-labelled amino acids (algal protein hydrolysate, Amersham-Buchler) added to the complement of 20 nonradioactive amino acids all at 0.2 mM final concentration. Additions indicated below the figure were as follows: pACYC184 (vector) or pGM21 (plasmid carrying *lacY*) DNA (30 μg ml^{-1}), cyclic AMP (1 mM), *lac* repressor purified to the final DEAE-cellulose step (ref. 22, 8.5 μg ml^{-1} for samples in *b* and 30 μg ml^{-1} for samples in *c*), and IPTG (0.2 mM). Incorporation of radioactivity into hot trichloroacetic acid-insoluble material was 1, 13, 5 and 18% for lanes 2–5; 11, 24, 9 and 22% for lanes 6–9 and 10 and 3% for lanes 11 and 12, respectively. Aliquots of 5 μl (*a* and *b*) or 2.5 μl (*c*) were applied to 12% (*a* and *b*) or 20% (*c*) polyacrylamide gels without (*b*) or with (*a* and *c*) prior heating for 5 min to 95°C. ^{14}C-methylated marker proteins (*A–E* lanes 1 and 10): phosphorylase (MW 92,500, bovine serum albumin (69,000), ovalbumin (46,000), carbonic anhydrase (30,000) and cytochrome *c* (13,000).

the amino acids asparagine, histidine, tryptophan and serine, according to the DNA sequence. With the exception of serine, these amino acids were not present in the mixture of radioactive amino acids used for the labelling *in vitro*. The partial sequence obtained is: H_2N-Met-Tyr-Tyr-Leu-Lys-X-Thr-X-Phe-X-Met-Phe-Gly-Leu-Phe-Phe-Phe-Phe-Tyr-Phe-Phe-Ile-Met-Gly-Ala-Tyr-Phe-Pro-Phe-Phe-Pro-Ile-X-Leu-X-Asp-Ile-X-X-Ile-X-Lys (42 residues; X, not determined). These residues correspond exactly to those predicted by the DNA sequence.

The ability to determine a unique sequence directly from the reaction mixture underscores the homogeneity of the *in vitro* product and the usefulness of pACYC184 as a vector provided only one gene is expressed from an insert into the *Eco*RI site.

Comparison of *in vivo* and *in vitro* products

lac permease isolated from the cytoplasmic membrane of the plasmid-containing *E. coli* strain T206 in an inactive state (see gel on top of Fig. 1 (ref. 16)) was degraded manually without prior chemical deformylation. Residues 1–9 and 11–15 of the *in*

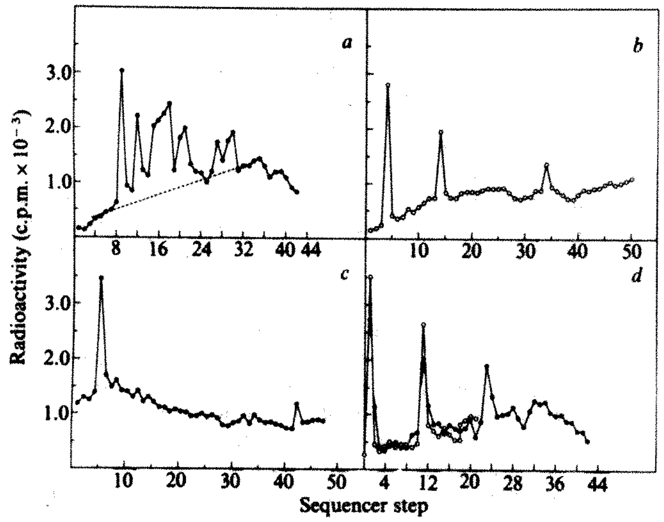

Fig. 3 Amino acid sequence analysis of the total cell-free products programmed by pGM21 plasmid DNA. The products were labelled with one radioactive amino acid at a time: *a*, ^{14}C-phenylalanine (256,000 c.p.m. in the sample analysed); *b*, ^{14}C-leucine (231,000 c.p.m.); *c*, ^{3}H-lysine (62,000 c.p.m.); *d*, ^{35}S-methionine (110,000 c.p.m. in both experiments). Total synthesis mixtures were dialysed against 50 mM ammonium bicarbonate, *p*H 8.5, lyophilised, chemically deformylated[23] (with the exception of *d*, ●), dialysed against 10% formic acid in the presence of 4 mg oxidised chicken lysozyme and subjected to automated Edman degradation in an updated Beckman model 890B sequencer equipped with a Sequemat P-6 automatic converter. Degradations were carried out in the presence of precycled polybrene (1.5 mg) using a 0.2 M quadrol program with double cleavage[24]. The radioactivity in the fraction obtained at each cycle of degradation was determined in 10 ml Aquasol-2 (NEN) containing 2% methanol with a Packard Tri-Carb liquid scintillation spectrometer. The analysis of the phenyl thiohydantoin derivatives of the carrier lysozyme was as described elsewhere[22,25]. Repetitive yields of the protein carrier and of the radioactively labelled materials ranged between 94 and 96%. Absolute yields corrected for background and carry over[26] of the radioactive amino acids studied were 90.6% (*a*), 84.7% (*b*), 81.6% (*c*) and 72.1% (*d*, ○) for chemically deformylated products and 53.0% without chemical deformylation (*d*, ●).

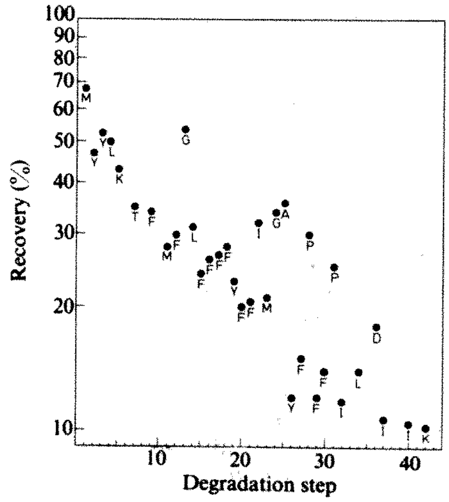

Fig. 4 Partial amino-terminal sequence (residues 1–42) of *lac* permease synthesised *in vitro*. Cell-free products programmed by pGM21 plasmid DNA were labelled with ^{35}S-methionine and the following ^{14}C-labelled amino acids: aspartic acid (D), threonine (T), serine (S), glutamic acid (E), proline (P), glycine (G), alanine (A), valine (V), isoleucine (I), leucine (L), tyrosine (Y), phenylalanine (F), lysine (K) and arginine (R) as described for Fig. 2. The sedimentable material of the protein synthesis mixture obtained by centrifugation at 100,000*g* for 60 min[27] was treated and sequenced as described for Fig. 3. The radioactive phenylthiohydantoin derivatives at each sequencer cycle were identified by radiolabelled amino acid analysis after back-hydrolysis with 6M HCl containing 0.2% $SnCl_2$ (ref. 28) using the Beckman 121M amino acid analyser with effluent collection in principle as described by McKean *et al.*[29]. The efficiency of radioactive counting was 33% for regenerated ^{14}C-labelled amino acids. The recoveries based on specific activity measurements are plotted on a logarithmic scale against step number[26]. The relative specific activities of the amino acids were estimated by radiolabelled amino acid analysis of particulate matter after acid hydrolysis and are based on the amino acid composition of *lac* permease deduced from the DNA sequence[12]. No correction for hydrolytic loss of the regenerated amino acids was made. Total radioactivity loaded on the sequencer was 2 × 10^{6} c.p.m.

Fig. 5 Summary of sequence data on *lac* permease. *a*, Partial amino-terminal sequence analysis of the *in vitro* synthesised permease (see Figs 3, 4); *b*, automated (underlined residues) and manual sequence analysis of permease isolated from cytoplasmic membranes; *c*, from DNA sequence (12). *X*, not determined.

vivo product could be determined by the 4-*N,N*-dimethylaminoazobenzene 4′-isothiocyanate/phenylisothiocyanate double-coupling method of Chang *et al.*[17]. Automated Edman degradation was carried out for five cycles to determine the amount of the amino-terminal residue which could be released by sequential degradation. Methionine was found in the first sequencing step with a yield of 65%. Figure 5 compares the amino-terminal sequences of permease synthesised *in vitro* and *in vivo* with that deduced from the DNA sequence of the *Y* gene. The agreement of the N-terminal sequences confirms the identity of these two products. The amino acid composition determined for the *in vivo* product is very similar to that deduced from the DNA sequence (Table 1). There is good agreement of the values for Glx, Pro, Gly, Val and Arg, each of which occur twice in the C-terminal 15 residues of the permease as deduced from the DNA sequence[12]. Any C-terminal processing would then seem unlikely also. The value for phenylalanine is, however, too low. Even after 192 h of hydrolysis, only 35 of the expected 52 phenylalanine residues are found. The unusually high number of potentially acid-resistant Phe-Phe linkages in the sequence[12] may account for the low recovery of phenylalanine from the acid hydrolysate[18] of the *lac* permease.

Conclusions

The N-terminal sequence of both the *in vitro* and *in vivo* products of the *lac Y* gene unambiguously assigns the translational start of the protein to the methionine codon corresponding to base pairs 106–108 in the sequence of Büchel *et al.*[12] rather than to the alternative codons at base pairs 136–138 or 172–174. The identity of the *in vivo* and *in vitro* synthesised proteins in terms of apparent MW and N-terminal sequence shows that this protein is not processed by proteolytic cleavage at the N-terminus. Moreover, both products are deformylated at the N-terminal methionine, suggesting that the amino-terminal residue is not directly inserted into the membrane and thus shielded against the action of the deformylating enzyme. Other membrane-associated *in vivo* products of bacterial and mitochondrial origin have been shown to retain the fMet residue[6]. There is good agreement between the amino acid composition of the *in vivo* product and that predicted from the DNA sequence. Furthermore, preliminary experiments show that cleavage of the *in vivo* product by cyanogen bromide yields the expected number of polypeptide fragments. These observations make it unlikely that processing at the C-terminus occurs. The MW predicted from the DNA sequence (46,500 (ref. 12)) is much larger than the apparent MW of permease on acrylamide gels. This behaviour could be attributed to increased binding of SDS, as expected from the high hydrophobicity of this protein.

As the cell-free extract used in our studies has not been freed of membranes, it is not clear whether the protein becomes associated with membranes during or after synthesis. Preliminary experiments indicate that the *in vitro* product is readily pelleted by centrifugation but remains more susceptible to proteolysis by trypsin than the functional protein in the membrane, suggesting that the major part of the *in vitro* formed protein is in a non-membranous environment. Whether the lactose permease is synthesised *in vivo* on membrane-bound ribosomes is particularly relevant in view of the location of the *Y* gene between two genes which are probably translated by free ribosomes. Alternatively, the intitial formation of a soluble (possibly modified) form of the protein which spontaneously inserts into the membrane cannot be excluded. Obviously , the highly hydrophobic N-terminus of the permease may serve as an initial recognition site for integration into the membrane.

We thank G. Aichele, M. Fürst, E. Kühn and K. Neifer for technical assistance. Support by the Deutsche Forschungsgemeinschaft through SFB 74 to R.E. and K.B. is acknowledged.

Sequence of the lactose permease gene

Dagmar E. Büchel, Bruno Gronenborn & Benno Müller-Hill
Institute for Genetics, University of Cologne, Weyertal 121, D-5000 Cologne 41, FRG

The nucleotide sequence of the lacY *gene coding for lactose permease (M protein) in* Escherichia coli *has been determined. The sequence includes the intergenic regions between the* lacZ *(β-galactosidase) and* lacY *genes as well as the region between the* lacY *and* lacA *(transacetylase) genes. Lactose permease is predicted to consist of 417 residues (71% nonpolar), resulting in a protein with a molecular weight of 46,504. The reading frame was confirmed by the sequence of a nonsense mutation changing codon 33 from UGG to UAG.*

LACTOSE PERMEASE is a protein which transports and accumulates galactosides through the inner membrane into *Escherichia coli*. It was discovered by Rickenberg *et al.*[1], who described it as the product of a structural gene *Y* of the *lac* system of *E. coli* capable of transport and intracellular accumulation of exogenous galactosides. The product of the *lacY* gene (M protein) was later identified and partially purified in inactive form by Fox and Kennedy[2]. Recently, a plasmid has been described which overproduces *lac* permease[3]. However, the isolation of inactive *lac* permease has been difficult and the isolation of active permease has not been achieved.

lac permease probably operates without the help of any other protein. We considered that an understanding of its structure would lead to the understanding of its function, transport, therefore we have determined the nucleotide sequence of the *lacY* gene. The sequence allowed the prediction of the primary structure of *lac* permease: the primary translation product consists of 417 residues. Ehring *et al.* (see accompanying article[4]) have shown by protein sequence analysis that *lac* permease synthesised *in vivo* and *in vitro* starts with the native sequence predicted by us.

Cloning of the *lacY* gene

We used the transducing phage *λh80dlacI857Ssus7* (ref.5), carrying the wild-type *lac* operon, as the source of *lacY* DNA. A DNA fragment containing the *lacY* gene was obtained by restriction endonuclease digestion with *Eco*RI and cloned in the filamentous single-stranded DNA phage *M13*mp2 (refs 6, 7) (for details see Fig. 1 legend). We expected the insert to be 18,000 base pairs long. The DNA length of the cloning vehicle *M13*mp2 is about 7,200 base pairs, and so an insert of 18,000 base pairs would increase its length about 3.5-fold. Phages of that size would replicate rather slowly, favouring the accumulation of phages carrying deletions in the population. Indeed, we found inserts to have a size of about 5,500 base pairs. One of them was again reduced *in vivo* to 2,100 base pairs (*M13*mp2561). This insert contained the last 17 codons of the *lacZ* gene, the *lacY* gene and part of the *lacA* gene. We also cloned it in the inverted orientation in *M13*mp2 and in the mini ColE1 plasmid pVH51 (ref. 8). The latter plasmid (pGB2601) served as a source of smaller restriction subfragments which were required for sequence analysis.

Expression of the *lacY* gene under control of the *lac* promotor of the phage *M13*mp2 was shown on minimal agar plates containing 0.2% melibiose (see Fig. 1*a* legend). Although we had expected bacteria carrying about 200 copies of the replicative form (RF) of *M13*mp2561 DNA to overproduce *lac* permease, in such bacteria, we found that the transport activity was only 50% of that measured in a strain carrying one copy of the *Y* gene on a F′-*lac pro* episome. Therefore, it was possible that we had selected one or several mutations which reduced either the amount or the activity of permease. It was thus essential to compare the DNA sequence of the *lacY* gene cloned in conditions preventing expression with the sequence of the *Y* gene cloned under selective pressure for expression. We inserted a 3,500-base pair *Eco*RI-*Bgl*II fragment of *λh80dlacI857Ssus7* in *M13*mp2 DNA (Fig. 1*b*). This fragment carried the *lacY* and the *lacA* genes. The tranducing phages thus obtained (*M13*mp2702) were grown in a cap^-cya^- strain which reduces *lac* expression to about 2% (ref. 9). The inverted orientation of the fragment was derived by inserting it into *M13*mp3 DNA[7] (*M13*mp3110).

To confirm the reading frame of the *lacY* gene and to define the start of permease, the Y^- amber mutation NE4, mapping in the fourth deletion group of the *Y* gene[10], was directly crossed into *M13*mp2561 from an F′-*lac pro* episome (see Fig. 1 legend).

DNA sequence analysis

We determined the nucleotide sequence of the *lacY* gene using the methods described by Maxam and Gilbert[11] and by Sanger *et al.*[12]. For the chemical modification technique[11] we prepared restriction subfragments of the 2,100-base pair insert of pGB2601. We constructed a restriction map of *Msp*I, *Hha*I, *Hae*III and *Mbo*II restriction endonuclease cuts (Fig. 2). Other restriction cuts were deduced during sequence analysis. Single-stranded DNA of *M13*mp2561, mp2601, mp2702 and mp3110 was prepared[13] from the respective phages and used as template for sequence analysis according to the method of Sanger *et al.*[12] modified as described by Schreier and Cortese[13]. Primers were prepared as restriction subfragments from the 2,100-base pair insert of pGB2601. Details of the sequencing procedures are given in Fig. 2 legend.

The *lacY* gene sequence of the 2,100-base pair insert, including the intergenic region between *lacY* and *lacA*, was determined on both complementary strands using primarily the enzymatic sequencing method[12]. The sequence of the end of the *lacZ* gene and the intergenic region between *lacZ* and *lacY* was obtained from one strand by both the chemical[11] and the enzymatic[12] procedures, and the beginning of the *lacA* gene from one strand was obtained by the technique of Sanger *et al.*[12]. The *Y* gene sequence of the 3,500-base pair fragment and that of the amber mutant NE4 were determined from one strand by the method of Sanger *et al.*[12]. A comprehensive description of the sequencing experiments is given in Fig. 2 legend.

Nucleotide sequence

The DNA sequence (Fig. 3) beginning with the *Eco*RI cut at the end of the *lacZ* gene shows the 17 C-terminal codons of *lacZ*. The sequence is compatible with the protein sequence determined by Fowler and Zabin[14]. The end of the *Z* gene is characterised by an unusually strong stop signal: three ochre codons in a row.

In the DNA following the *Z* gene only one frame is free of barriers. To confirm the reading frame of the *lacY* gene we sequenced DNA carrying the amber mutation NE4 mapping in a region of the gene specifying the N-terminus of permease[10]. Gels with the respective sequences of NE4 and wild-type DNA are shown in Fig. 4. The guanosine at position 203 is changed to an adenosine, changing a Trp codon (TGG) of the permease

0028-0836/80/060541—05$01.00

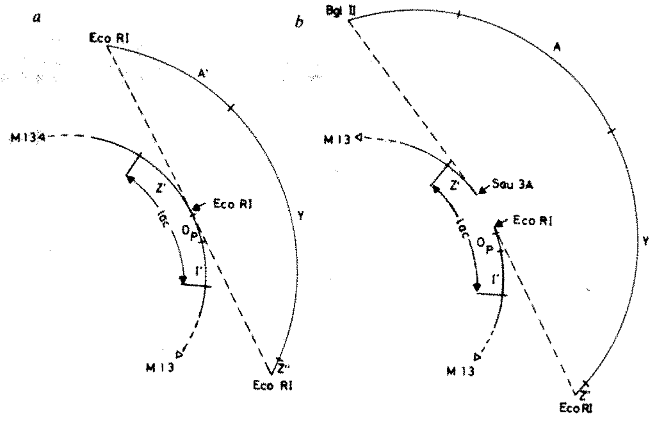

Fig. 1 Cloning of the *lacY* gene. *a*, *Eco*RI restriction endonuclease fragments of the *lac* transducing phage *λh80dlaccI857Ssus7* DNA were ligated with *M13*mp2 RF DNA linearised by *Eco*RI using T_4 DNA ligase according to Bolivar *et al.*[25] The ligation mixture was used to transform strain 75X [*lac, pro*]Δ *thi, strA, ϕ80dlac* [*Y, A, tonB, trp*]Δ 75X (ref. 10) as described by Mandel and Higa[26]. Bacteria were selected for growth at 42 °C in supplemented minimal medium[27] containing 1% melibiose as carbon source. Cells expressing lactose permease activity will grow in these conditions and enrich in the culture. Due to the F^- phenotype of strain, 75X *M13* phages can be extruded from the cells but do not re-infect uninfected bacteria. This prevents an excessive propagation of non-hybrid phage as well as the enrichment of the progeny originating from only a few transducing phage by re-infection. Phage from the supernatant of enriched cultures were used to infect strain MUA2 [*lac, pro*]Δ *thi nalA, F′ lac* $I^Q Y^-$ ΔMUA2 pro^+ (ref. 10) and plated on minimal melibiose plates to grow at 42 °C. Single colonies were assayed for the release of *lacY* transducing *M13* phages in the following way. The supernatants of 1-ml cultures were spotted onto a lawn of indicator strain 50–15 [*lac, pro*]Δ *thi, strA, F′ lac* I^Q Y^- ΔMUA2 pro^+ on minimal melibiose plates containing 0.02% streptomycin to select against the former host. The plates were incubated for about 18 h at 33 °C and then at 42 °C for an additional overnight growth period. In these conditions *M13*mp2 phage give rise to slightly turbid 'plaques' whereas *lacY* transducing phage *M13* cause accelerated growth of the infected cells, resulting in a very turbid plaque with a significant halo of bacterial growth at its borderline. In this kind of plaque test, *M13*mp2 *lacY* tranducing phage can easily be distinguished. In addition, suppression of *lacY* amber mutants and recombination to $lacY^+$ can be monitored directly by the plaque morphology as described below. Two *lacY* transducing *M13* phages from different enrichment cultures were obtained. The length of the inserted DNA was determined to be 5,500 base pairs according to its mobility on 1% agarose gels. As the insert, although already shortened by a large deletion, contained four times more DNA than the approximate length of the *lacY* gene, an additional deletion was selected *in vivo*. This final *lacY* transducing *M13*mp2 derivative contained an insert of 2,100 base pairs (*M13*mp2561). For the sequence analysis according to Sanger *et al.*[12], a *M13 lacY* derivative with the insert in the inverted orientation was constructed by cutting *M13*mp2561 DNA with *Eco*RI and then ligating. After transformation, cells were assayed for plaque-forming centres in the *lacY* transduction test described above. Phages carrying the *Y* gene insert in the inverted orientation gave rise to a mottled plaque morphology due to occasional recombination of the Y^- host to wild type during plaque development (*M13*mp2601). A derivative of *M13*mp2561 carrying the Y^- amber mutation NE4 (ref. 10) was derived by propagating the phage in a strain that carried the mutation on a F′-*lac pro* episome. *lacY*-negative *M13* transucing phages were identified in the plaque test described above. The suppressible character of the mutation was shown by its intermediate phenotype between Y^- and Y^+ using a *supF* host. The correct map position was confirmed by deletion mapping against a set of *lacY* deletions[10] and the failure to recombine with the original NE4 mutation. *b*, To obtain clones in non-expressing conditions a 3,500-base pair *Bgl*II–*Eco*RI fragment was prepared from plasmid pBR322-Y46, a derivative of pBR322 (ref. 25) containing a 12,000-base pair *Eco*RI–*Bam*HI insert of *λh80dlaccI857Ssus7* including the *lacY* gene. *M13*mp2 RF DNA was linearised with *Eco*RI, partially digested with *Sau*3A and ligated to the 3,500-base pair *Eco*RI-*Bgl*II fragment. The cap^- cya^- strain CA7914-3 [*lac, pro*]Δ cap^-cya^-*thi strA F′ lac* I^Q pro^+ was transformed. In induced conditions this strain allows only 2% expression of the *lac* operon[9], in repressed conditions in the I^Q (*lac* repressor overproducing) situation, even less. Hybrid phages were assayed by the plaque morphology test described above; *lacY* transducing *M13* phage showed the typical very turbid plaque (*M13*mp2702). To obtain a phage with the *Eco*RI–*Bgl*II insert an inverted orientation, the fragment was inserted into *M13*mp3 (ref. 7) in the same way as described above. *lacY*-transducing phage of this type give rise to mottled plaques in the described conditions (*M13*mp3110).

Fig. 2 Restriction map of the *lacY* gene. The sequenced part of the 2,100- and the 3,500-base pair fragments is shown. A (*Alu*I), B (*Mbo*II), E (*Hae*III), H (*Hha*I), M (*Msp*I), R (*Eco*RI), S (*Sau*3A) and T (*Taq*I) denote the respective restriction cuts. For the Maxam–Gilbert sequencing technique[11] restriction fragments were labelled at the 5′-end with [γ^{32}–P]ATP (NEN) by polynucleotide kinase or at the 3′-end by filling in with the suitable [α-^{32}P]dNTP (NEN) using the DNA polymerase I Klenow fragment. For the sequencing method with chain-terminating inhibitors[12,13], templates were prepared according to Schreier and Cortese[13], restriction subfragments of the *lacY* insert of pGB2601 were used as primers. The same restriction fragments were hybridised to the templates carrying the inserts in opposite orientation so as to obtain the sequence of both complementary strands. Primers of more than 80 base pairs were reduced in length by treatment with exonuclease III before hybridisation with the template (R. Roberts quoted in ref. 13). This yields sequence information on about half of the length of the primer itself. The beginning, direction and extent of the sequence analysis of different parts are indicated by arrows. Arrows above or below the restriction map represent the sequences of the complementary strands determined (5′-end on left-hand side above the map). Wavy arrows represent sequences of the 2,100-base pair insert obtained according to Maxam and Gilbert, and straight arrows those obtained according to Sanger *et al.* Dashed arrows indicate sequences determined from *M13*mp2701 and *M13*mp3110 by the technique of Sanger *et al.*; the double arrow represents the sequence determined from the phage carrying the *lacY* amber mutation NE4 (*M13*mp2561-NE4) according to Sanger *et al.*

Fig. 3 Nucleotide sequence from the *Eco*RI site at the end of the *lacZ* gene to the beginning of the *lacA* gene and the amino acid sequence deduced for the *lac* permease. Nucleotides are continuously numbered, amino acids according to their position in the protein. Restriction endonuclease sites are also shown. The positions of *Msp*I, *Hha*I, *Hae*III and *Mbo*II cuts were derived from the restriction map; *Sau*3A, *Alu*I and *Taq*I cuts were deduced from the DNA sequence.

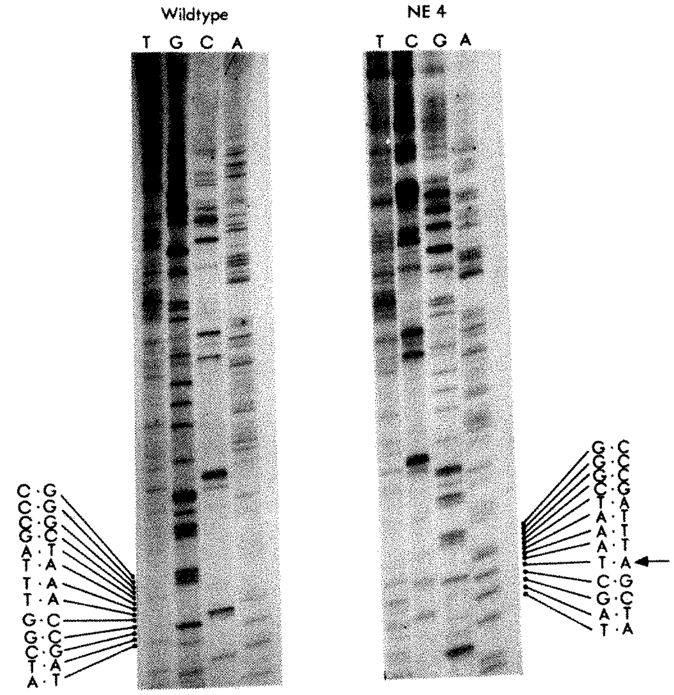

Fig. 4 Autoradiographs of sequencing gels according to Sanger *et al.*[12]. The sequence of the region carrying the NE4 mutation in which the Trp codon TGG no. 33 of the *lac* permease gene is changed into the amber triplet TAG is compared with the wild-type sequence of the same region.

gene into the amber triplet TAG. The sequence analysis of this mutation confirmed the suspected reading frame of the *lacY* gene and limited the possible start points. There are only three ATG and no GTG triplets preceding the NE4 amber codon. Only one of the ATG codons is preceded in a proper distance by a 'Shine–Dalgarno sequence'. Thus, we suspect that the *lacY* gene starts after an intergenic region of 45 nucleotides with an ATG codon and ends 1,251 base pairs later with a single ochre codon. The start codon is preceded at a distance of 8 base pairs by the sequence TAAGGA, which can hybridise to the 3′-end of the 16S ribosomal RNA HO-AUUCCU determined by Shine and Dalgarno[15]. The *lacY* gene recognition site for the 16S rRNA is two nucleotides longer than that of the *lacZ* gene, which is AGGA[16]. The sequences of the end of the *lacZ* gene and the beginning of the *lacY* gene have a high A and T content and show a palindromic symmetry. Figure 5*a* shows a possible secondary structure of the mRNA forming a stem from positions 47–87 and 155–118. The loop of 30 bases contains the 16S ribosomal RNA recognition site and the AUG start codon of the *lacY* gene. Similar secondary structures were proposed by Selker and Yanofsky[17] for *trpB*, *trpE*, *trpG* and *galT* as well as for *lacI*.

The nucleotide sequence from base pair 1,426 to 1,500 (Fig. 3) is compatible with the first 25 amino acids of transacetylase determined by Zabin and Fowler[18]. The start codon for fMet-tRNA cannot be unambiguously deduced from the DNA sequence. An interesting possibility is the TTG codon preceding the AAC asparagine codon. TTG has been reported only as a start codon of a restart fragment of the *lac* repressor[19,20]. A less likely possibility is the GTG codon which lies four triplets upstream of the AAC coding for the N-terminal asparagine. No possible secondary structure of the mRNA could be seen. A ribosomal binding site precedes the UUG in a distance of three bases. The sequence UAACGGAGUGAUC is able to form—with interruptions—of several base pairs with the 3′-end of the 16S ribosomal RNA (Fig. 5*b*).

The sequence of the *lacY* gene as well as the preceding ribosomal binding site carried by the 3,500-base pair *Eco*RI-*Bgl*II fragment cloned without any selection for expression proved to be identical to that of the 2,100-base pair fragment. Thus, we can exclude the possibility that we isolated a *lacY* mutation in our first isolation procedure. We have also cloned the 2,100-base pair fragment in the multicopy plasmid pUR2 (ref. 21). On this plasmid the *lacY* gene is expressed under the control of the *lac* promoter. Strains containing this hybrid plasmid showed at least a fivefold increase in permease activity compared with a strain with the *Y* gene on the F′-*lac pro* episome (P. Betteridge, personal communication). Thus, competition of permease and *M13* coat protein mRNA for a limiting factor or competition of the proteins themselves for space in the bacterial membrane are possible explanations for the low permease activity in strains harbouring the phage *M13*mp2561.

Protein sequence of *lac* permease deduced from the DNA sequence

Ehring *et al.* (see accompanying article)[4] found that *lac* permease synthesised *in vivo* and *in vitro* started with the N-terminal amino acids predicted for native permease from the DNA sequence. The DNA sequence suggests that it consists of 417 amino acids (Fig. 3), resulting in a molecular weight of 46,504. This is higher than the 29,000 reported by Jones and Kennedy[22] and the 30,000 reported by Teather *et al.*[3]. A similar size was found by Ehring *et al.*[4] for permease synthesised *in vivo* and *in vitro*. Thus, either the membrane protein *lac* permease behaves atypically on SDS gels or it is proteolytically degraded at its C-terminus.

lac permease is a strongly basic protein of low polarity (29% polar, 71% unpolar); the high content of phenylalanine residues, 56 out of 417, is remarkable. Of these, 22 are clustered in the N-terminal region, making it highly hydrophobic. The first N-terminal lipophilic part of the protein spans 26 amino acids at positions 9–34 and has a hydrophobicity index of 4.0 determined according to Segrest and Feldmann[23]. It is followed in short distances by three additional hydrophobic sequences at positions 45–66, 76–99 and 108–118, with hydrophobicity values of 2.5, 3.4 and 2.4, respectively. The middle part has a more hydrophilic character, containing charged and less hydrophobic amino acids. This region, from residue 119 to 274, is separated into two parts by a lipophilic sequence of 11 amino acids (177–187), with a hydrophobicity index of 3.3. The C-terminus again contains hydrophobic sequences in clusters: residues 275–283, 291–299, 326–334, 347–357 and 381–395, with corresponding hydrophobicity indices of 3.7, 2.3, 2.7, 3.0 and 2.7.

We conclude that we can divide lactose permease into four structural parts: a hydrophobic N-terminus, two hydrophilic regions in the middle part of the protein, separated by a lipophilic sequence of 11 amino acids, and a hydrophobic C-terminus. We propose that the hydrophobic regions at the N-terminus and the C-terminus function as anchors by which the protein is fixed in the membrane; they could also form pores for galactoside and proton transport. The length of the lipophilic sequence from residue 177 to 187 separating the two hydrophilic parts may be sufficient to penetrate the membrane. Thus, the function of sugar recognition and binding may be carried out by the two hydrophilic domains which could occupy sites inside and outside the membrane. Genetic and biochemical data support the idea that *lac* permease is active as an oligomer, possibly as a dimer[24].

We thank Dr Peter H. Schreier for his introduction in DNA sequencing with chain-terminating inhibitors, Caecilia Rüth for technical assistance, and Constanze Bonifer for construction of *M13*mp2561–NE4. This work was supported by a grant from Deutsche Forschungsgemeinschaft through SFB 74 to B.M.-H.

Structure of the junction between communicating cells

P. N. T. Unwin[*] & G. Zampighi[†]

[*] MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK
[†] Department of Anatomy, Duke University Medical Center, Durham, North Carolina 27710

An 18-Å resolution map of the 'gap junction' has been obtained by electron microscopy. The protein oligomer in the junctional membranes, the 'connexon', is a cylinder composed of six subunits which are tilted around its axis. Analysis of two different subunit configurations suggests how the connexon might regulate the passage of small molecules between cell interiors.

SPECIALISED regions of contact known as gap junctions[1] exist between apposed plasma membranes of communicating cells. These junctions are believed to mediate and regulate the passage of ions and small molecules between the cell interiors[2]. They are composed of units, called connexons[3], which are embedded in the apposed membranes, in register, and linked to each other. The connexon is often organised on a regular hexagonal lattice, as first described in detail by Robertson[4]. Its structure in this lattice has been studied by electron microscopy[5,6] and low angle X-ray diffraction[7,8]. It is thought to be constructed from protein oligomers arranged in the form of an annulus and delineating a narrow channel through the membrane. This channel is presumed to provide the regulated hydrophilic pathway connecting the cytoplasms of adjacent cells.

Experiments with fluorescent tracer molecules (see, for example, refs 9, 10) suggest that the channel can accommodate a wide range of molecular sizes (up to about 800 daltons in mammalian cells[10]). Cytoplasmic free Ca^{2+} concentration[11] and/or pH (ref. 12) may be involved in regulating its permeability. Although electron microscopic and X-ray evidence point to changes in the size[13], shape and packing of the connexon[8,13], it is

0028-0836/80/060545—05$01.00

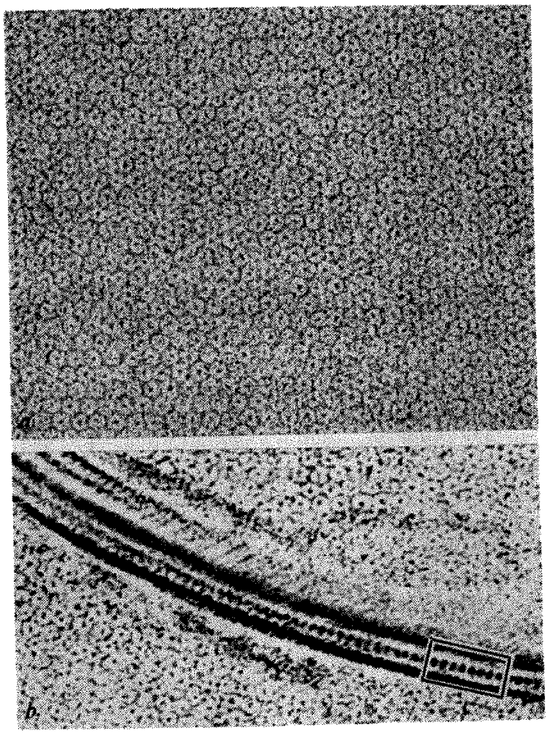

Fig. 1 Electron micrographs of isolated gap junction sheets viewed from a direction perpendicular to the plane of the membranes (*a*) and a direction more nearly parallel to this plane (*b*). In *a* the connexons are seen as annular units organised on a hexagonal lattice, with unit cell dimension 85 Å; in *b* they are seen as bridges connecting the two apposed membranes. The view in *b* arises from a fortuitous curling up of a sheet at its edge; the region outlined (looking along the [1, 1] direction) was used to estimate the average density profile in the direction perpendicular to the plane of the junction, and hence the variation in amplitude and phase along the lattice line through the origin. Uranyl acetate negative stain. ×300,000.

not clear how changes in the structure cause the permeability changes.

We have studied the structure of isolated gap junctions to a resolution of 18 Å by electron microscopy of specimens tilted at various angles to the incident beam. The three-dimensional maps reveal the configuration of the connexon subunits, their relationship to the membrane surfaces and the nature of the region they enclose, within the membrane. The subunits are found to take up two alternative configurations; the differences between them suggest a simple molecular mechanism by which the permeability may be controlled *in vivo*.

Electron microscopy

We used rat hepatocyte junctions, isolated and negatively stained as described previously[14]. *En face* views show the (superimposed) connexons as annuli arranged on a hexagonal lattice of unit cell dimension 85 Å (Fig. 1*a*). Edge-on views show the connexons as links which bridge the extracellular space between the apposed membranes, creating a gap of 30–40 Å (Fig. 1*b*). These junctions seem to be the same as those isolated by others (for example, ref. 15). They can be converted to a second form having the same hexagonal lattice, but in which individual connexons are less distinct, by dialysing them against water at 4° C for several days[14]. We shall describe below how the normal form, as in Fig. 1, and this second form differ in their three-dimensional structure.

We investigated the structure of the normal junctions by Fourier methods[14,16,17]. Specimens were tilted at angles of between 0° and 79° to the incident 100-kV electron beam, and micrographs were recorded using low electron doses to minimise the effects of radiation damage. Densitometry and computer processing were carried out on selected micrographs[14] from several specimens to give the Fourier terms into which the structure can be analysed. The three-dimensional Fourier transform consists of a set of reciprocal lattice lines, perpendicular to the plane of the junction, along which the amplitudes and phases vary continuously. The Fourier terms determined from micrographs taken with different tilts give the values of the amplitudes and phases at different sections through these lattice lines. To map out the continuous variation along each line, the terms were combined, in the first instance, according to the lowest symmetry compatible with the hexagonal projected structure, that of the crystallographic space group, P3. We began with data from specimens recorded with smallest tilt, and only compared values which along any given line lay within 0.0025 Å^{-1} of each other. Twenty-six micrographs were used, each providing up to 30 independent measurements of amplitude and phase. The average phase error, based on comparisons between each new measurement and all previously accumulated phases related by symmetry, was 21°. Smooth curves, then drawn through the combined data, demonstrated that points equidistant from the midpoint along each lattice line had equivalent amplitudes and opposite phases. This result indicated that, at least to the resolution of the analysis, the junction had the higher symmetry of the space group, P6. Therefore, to improve the accuracy, the data were refined a second time according to this latter space group.

The amplitude and phase curves (Fig. 2) show minor departures from the symmetry of the space group, P622, relating the two oppositely facing halves of the junction by dyad axes lying in its central plane. Therefore, the two halves are almost, but not exactly, equivalent. The departures from perfect symmetry were probably produced as the stain dried around the specimen and support film. In favour of this argument, we found that the phase error introduced in combining data from different junctions depended on whether we took the surface next to the support film to be at the top or bottom of the structure. In all cases, the assumption of a consistent location for the support film gave the smallest value for this error.

It was useful, although not critical for an understanding of the structure, to estimate the average density profile in the direction perpendicular to the plane of the junction, and hence the variation in amplitude and phase along the lattice line through the origin (the 0,0 lattice line). Edge-on views of the junction, as seen in Fig. 1*b*, were analysed for this purpose. Fourier transforms calculated from these views gave directly the variations along the 0,0 and 1,1 lattice lines. Correlation with the 1,1 lattice line derived from the combined data then allowed us to select the most accurate 0,0 lattice line and determine the scale for the variation along it. Its peak amplitude was found to be six times that of the 1,1. We assumed that the profile corresponding to this variation was reasonably correct because it could be closely matched to features in a preliminary three-dimensional map obtained without the 0,0 lattice line included in the calculations.

The complete transform consisted of 11 crystallographically independent lattice lines (0,0; 0,1; 0,2; 0,3; 0,4; 1,1; 1,2; 1,3; 2,1; 2,2; 3,1), and extended in all directions to a resolution of about 18 Å. We collected 192 Fourier terms by sampling the smooth curves at intervals of 0.0025 Å^{-1} along these lines.

Three-dimensional map

The map calculated by Fourier synthesis of these terms depicts the membrane surfaces and the hydrophilic surfaces of the connexon subunits, as these are the parts of the structure exposed to the negative stain. In Fig. 3 we consider one half of this map, corresponding to one of the two oppositely facing halves of the junction. There is a rather featureless zone, presumed to be the membrane, with matter on either side

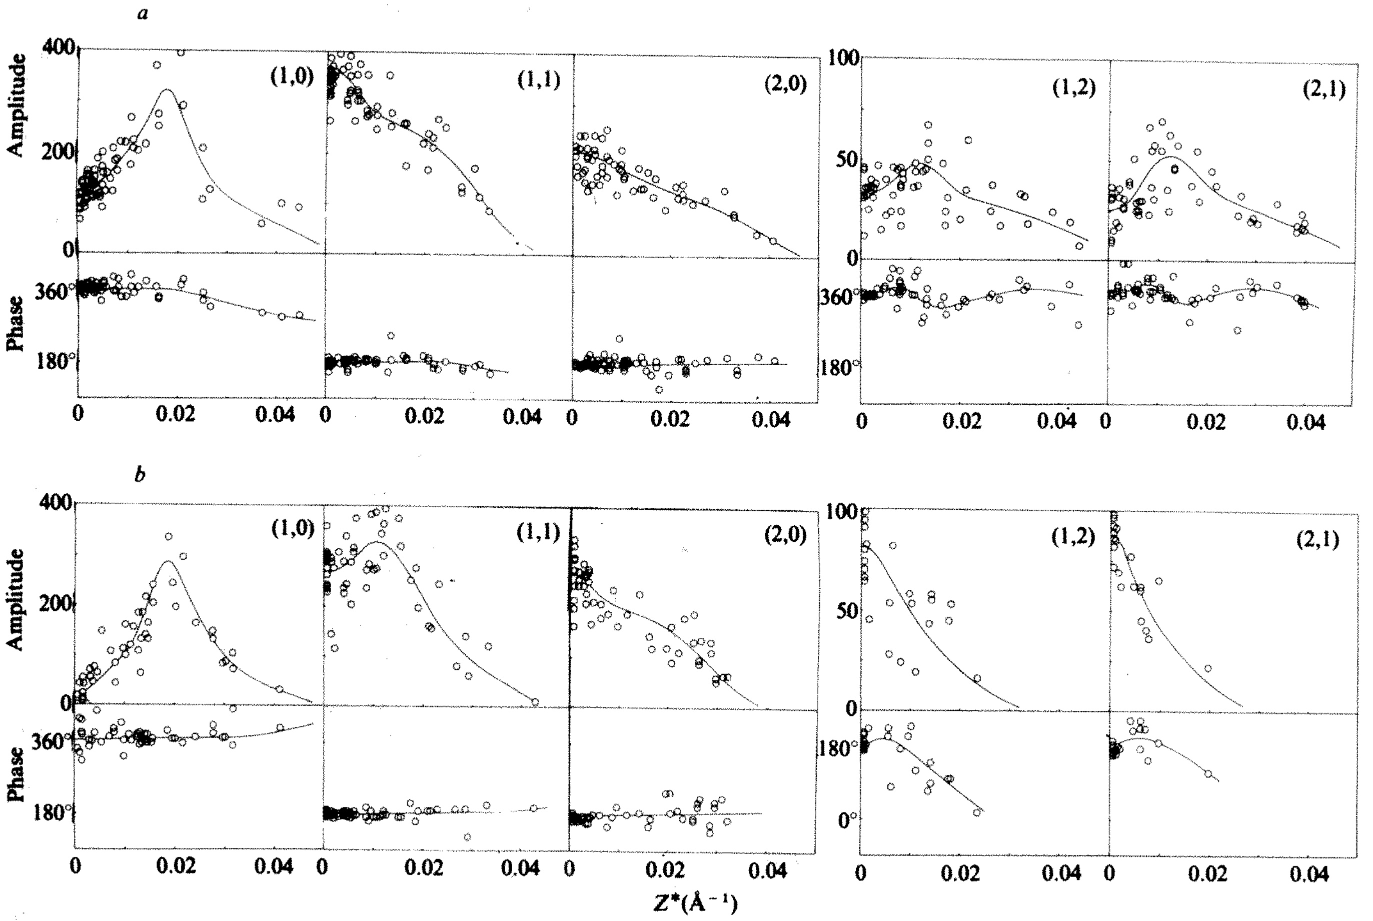

Fig. 2 Values of amplitude and phase determined along reciprocal lattice lines from micrographs of specimens tilted to the incident electron beam by angles up to 79°; *a*, the normal junction (as in Fig. 1); *b*, the form after the transition. Z^* is the distance from the midpoint along the lattice line. The tilt range 0–55° was obtained conventionally, using a goniometer stage; the additional tilt to 79° was achieved by bending the support grids. The data have been combined assuming the space group, P6; thus, the Friedel relationship gives the values for negative Z^*. Smooth curves drawn through the points and sampled at intervals of 0.0025 Å^{-1} gave the Fourier terms from which the maps were calculated. The data extend to the points where the amplitudes became comparable with the local background level, that is, to a resolution of ~18 Å in *a* and ~23 Å in *b*. The high tilt angles (>60°) were required to determine the variation along the 1,0 lattice line at values of $Z^* \geq 0.02\ \text{Å}^{-1}$; only the strong low resolution lattice lines (1,0; 1,1; 2,0) were used in the refinement of these data. The additional lattice lines, obtained for *a*, but not shown, are weak and do not significantly affect the detail in Fig. 4*a*; they improve the definition in Fig. 3, but do not contribute new features.

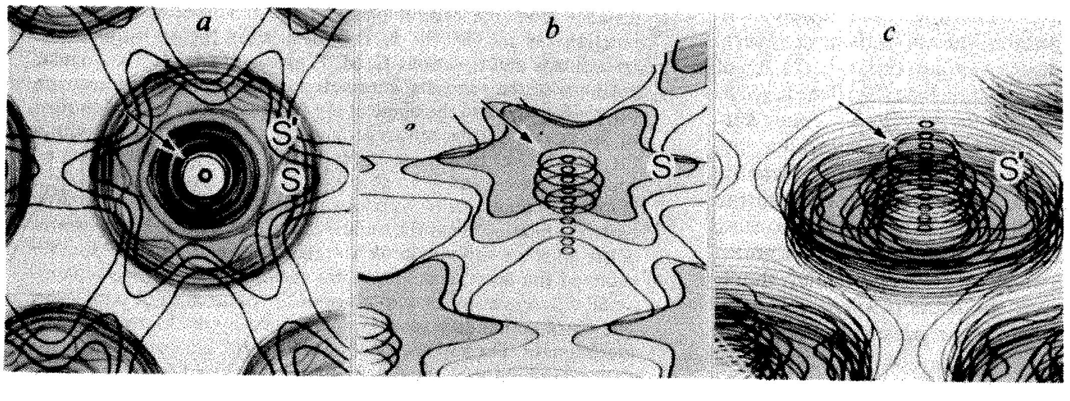

Fig. 3 Map of one half of the gap junction, as seen from the interior of the cell. Sections through the structure were traced onto Perspex sheets, which were then stacked on top of each other; the complete map (*a*) is composed of a portion (*b*) containing the cytoplasmic face, stacked on an equal portion (*c*) containing the extracellular face. The orthogonal view (*a*) emphasises changes in the angular disposition of the subunits; the oblique views (*b*, *c*) emphasise the subunit features in relation to the membrane surfaces. The contours identify the stain-excluding regions formed by the components of the junction (compare Fig. 4*a*); the exact positions of their boundaries are not accurately determined because these are sensitive to small errors in the variation along the 0,0 lattice line. The detail protruding from the membrane is emphasised by shading and by additional contours. The arrow points to the opening surrounded by the connexon subunits, one of which is labelled, S and S'. Hexagons have been drawn at the 6-fold axis of the connexon on each of the Perspex sheets. The half of the junction not shown contains essentially the same detail, but is slightly less well contrasted by the stain.

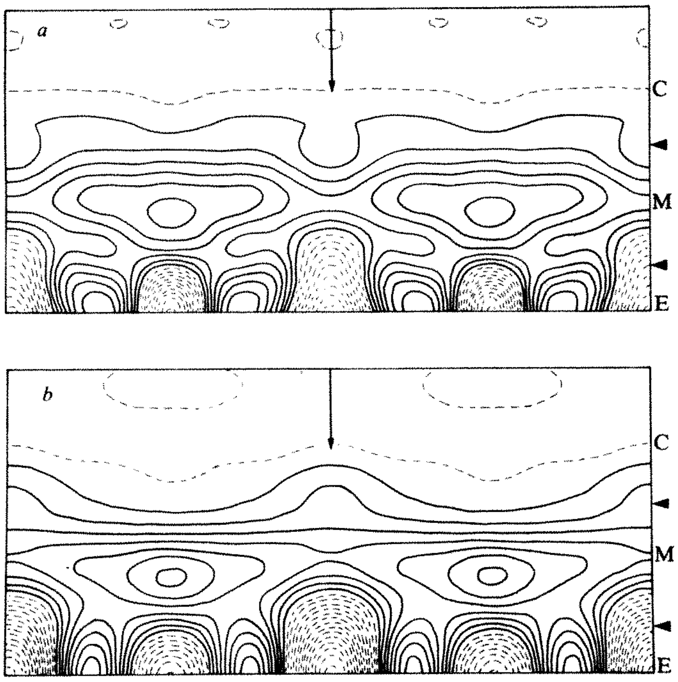

Fig. 4 Sections through the maps perpendicular to the plane of the junction, along a line joining the connexon axes; *a*, the normal junction (as in Fig. 3); *b*, the form after the transition. Arrowheads point to the approximate locations of the cytoplasmic (upper) and extracellular (lower) membrane surfaces. The zones C, M and E refer to the cytoplasm, membrane and extracellular space, respectively. Matter at the cytoplasmic surface moves towards the connexon axis (vertical arrow), closing the opening there, in going from *a* to *b*. This effect is contributed mainly by the change in amplitude along the strong 1,1 lattice line. Contours corresponding to stain-excluding regions (negative contours) are drawn as continuous lines; contours corresponding to stain-filled regions (zero and positive contours) are drawn as broken lines. The same Fourier terms along the 0,0 lattice line were used in the calculations for both maps. The sections contain two unit cells in the horizontal direction and half of the junction in the vertical direction. The absolute scale in the vertical direction is sensitive to flattening effects associated with the stain drying around the specimen[22]. Assuming a total thickness of 50 Å for the membrane[8], the connexon must extend about 75 Å from the central plane of the junction.

(shaded in Fig. 3) clustered around the 6-fold axes. The clusters are hexamers, presumed to be the exposed portions of six connexon subunits protruding from the cytoplasmic and extracellular faces of the membrane. The subunits have several features of interest. Their length is approximately 75 Å, of which less protrudes from the cytoplasmic face (5–10 Å; Fig. 3*b*) than from the extracellular face (15–20 Å; Fig. 3*c*). They surround a narrow opening (arrow) which penetrates the membrane and widens to a diameter of about 20 Å in the extracellular region of the junction. They are centred on the cytoplasmic face at points (such as S) where neighbouring connexons come closest, and on the extracellular face at points (such as S′) in between these locations. The subunits are therefore at different angular positions about the 6-fold axes on the two faces and must be inclined in their passage through the membrane.

The distinct annular appearance of the connexon in the micrograph (Fig. 1*a*) can now be understood to result from summation of annular features on both the cytoplasmic and extracellular faces. The 6-fold modulations around this annulus are weak, because the modulations at the cytoplasmic and extracellular faces (peaked at S and S′) are not in register and to some extent cancel each other out.

Two quaternary states

We investigated the structure of the second form of junction, produced by dialysis. Data were collected and combined from 20 micrographs of specimens tilted through the same range of angles as before; the average phase error, assessed in the same way, was 22°. Figure 2 compares the variations in amplitudes and phases for the two forms. There are large differences along the 1,2 and 2,1 lattice lines where the amplitudes peak at different places and the phases differ by about 180°. There are smaller differences, involving mainly amplitudes, along others. Low angle X-ray diffraction patterns from orientated pellets of isolated gap junctions[7,8] corroborate the curves obtained for the normal junction (Fig. 2*a*). The first four X-ray lattice lines (0,1; 0,2; 1,1; '1,2') are the strongest, and the 1,2 lattice line is peaked away from the equator. The most pronounced changes that the transition should produce in the X-ray pattern are a convergence of the off-axial peaks on the 1,2 lattice line into a single peak on the equator, and a splitting of the equatorial peak on the 1,1 lattice line into two slightly off-axial ones.

The maps of the junctions in the two states show several differences. These were interpreted in terms of two kinds of displacement of the subunits, one radial and the other tangential about the 6-fold axis through the centre of the connexon. The radial displacement is insignificant near the centre of the junction, but is pronounced near the cytoplasmic face (Fig. 4). The opening delineated there by the subunits (arrow in Fig. 4*a*) disappears after the transition (Fig. 4*b*), indicating movement of matter towards the connexon axis. A radial displacement of the order of 5 Å would be consistent with the maps, but we emphasise that the method of visualising the structure, using

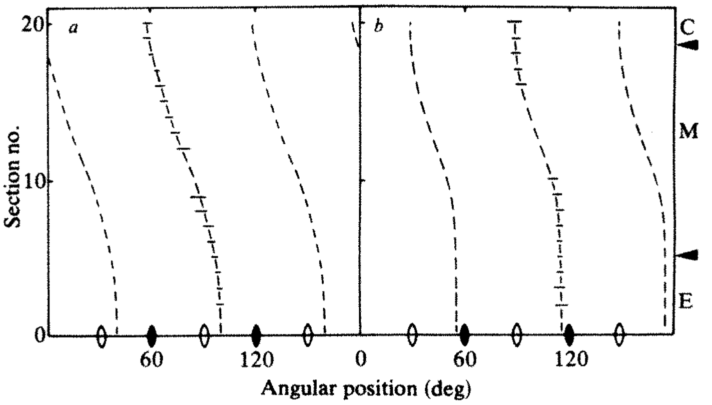

Fig. 5 Two-dimensional net showing the angular positions of the subunits about the 6-fold axis of the connexon in relation to distance from the central plane of the junction; *a*, the normal junction (as in Fig. 3); *b*, the form after the transition. The arrowheads and notations C, M, E are as in Fig. 4. The angular positions of the subunits were determined from sections through the maps parallel to the plane of the junction. They were identified by the peaks in the contours around the connexon axis, or (within the membrane) by the locations where the hexagonally shaped contours came nearest to this axis. An indication of the errors involved in these estimates is given by the lengths of the horizontal bars. Modulations near the middle of the membrane and the centre of the junction were too weak for reliable estimates to be made; we assumed the most direct paths for the subunits in these regions. Small differences in the curvature of the paths are not significant. The absolute handedness was determined by the known sense of specimen tilt. The variations along the 1,2 and 2,1 lattice lines have a strong influence on the details shown. The dyad symbols refer to putative dyad axes lying in the central plane of the junction along the [1,0] (filled symbols) and [1,1] (open symbols) crystallographic directions, and relating the apposed connexons facing each other in the two membranes. Perfect dyads are not present because the two halves of the junction are not quite equally contrasted by the stain. The positions of the subunits in the more poorly stained halves are consistent with the presence of dyads.

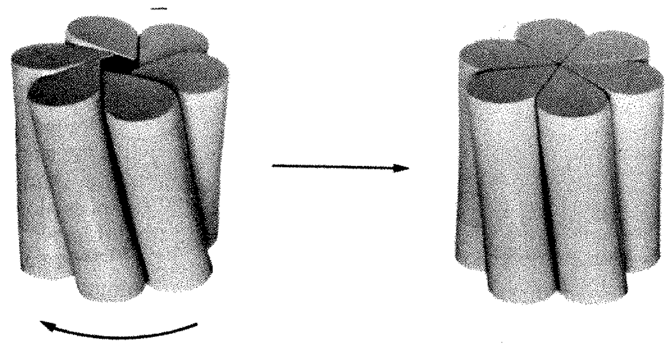

Fig. 6 Wooden model of the connexon, depicting the transition from the 'open' to the 'closed' configuration, as suggested by the maps. It is proposed that the closure on the cytoplasmic face (uppermost) is achieved by the subunits sliding against each other, decreasing their inclination and hence rotating, in a clockwise sense, at the base. The darker shading on the side of the model indicates the portion which would be embedded in the membrane. The subunit inclinations depicted are the average inclinations estimated from the nets (Fig. 5), and the diameter at the base of the connexon, as indicated by our data, is fixed. The radial displacement of each subunit at the cytoplasmic end would be about 6 Å, given the observed inclination change of 5° distributed over its 75-Å length.

negative stain, does not permit an accurate estimate to be made. This redistribution of matter on the cytoplasmic face accounts for the change in contrast of the connexon seen in the micrographs[14]. The annular appearance of the connexon would become less distinct after the transition because the detail on the cytoplasmic face no longer superimposes to reinforce the annular detail on the extracellular face.

The tangential displacement about the connexon axis was measured by tracing the paths followed by the subunits from the two maps. Two-dimensional nets were plotted giving the angular positions of the subunits in relation to distance from the central plane of the junction (Fig. 5). The nets show that the subunits follow fairly straight, slightly sigmoidal, paths which are differently inclined in the two structures. Their average inclination is reduced by the transition (made more nearly perpendicular to the plane of the junction) from 14° (Fig. 5*a*) to 9° (Fig. 5*b*)—a total change of about 5°. In addition to this tilting of the subunits, the connexon itself rotates by about 23° within the crystal lattice. More subtle effects, for example, distortions of the subunits, may be present but are not resolved. It would be difficult to detect small changes in the lengths of the subunits[8] by our technique.

The inclination changes produce rotations between equivalent parts of apposed connexons (that is, connexons facing each other in the two membranes) about their common 6-fold axis. The magnitude of these rotations can be estimated from Fig. 5, as the two halves of the junction are related to each other crystallographically (see Fig. 5 legend). The maximum value, 28°, is in the central plane of the junction, and here the subunits of apposed connexons must slide over each other by a distance of about 11 Å.

Structure of the connexon

The features in the three-dimensional map (Fig. 3) indicate that the connexon is an annular oligomer composed of six protein subunits which span the membrane and protrude from either side. Assuming a value of 25–30,000 daltons (refs 14, 18–20) for the molecular weight of the gap junction protein and 1.3 $Å^3$ per dalton for the partial specific volume (the value obtained for another, well studied, membrane protein[17]), each subunit must occupy a volume of at least 32,500 $Å^3$. To fill this volume, its cross-section inside the membrane would have to be at least equal to that outside. We suppose, then, that the subunits are roughly rod-shaped, about 25 Å in diameter and 75 Å long. A picture similar to this was deduced from a combined study by electron microscopy and low angle X-ray diffraction[8]. In addition, our analysis shows a variation in the dimensions of the central opening delineated by the subunits. It is about 20 Å wide in the extracellular region of the junction, but is narrower within the membrane where it is not fully resolved. The path taken by the subunits is also inclined tangentially with respect to the 6-fold axis of the connexon, giving the whole assembly a left-hand character.

The transition to the second configuration of the connexon is produced by a radial inwards motion of the subunits near their cytoplasmic extremities and a reduction of their inclination tangential to the 6-fold axis. These movements are accompanied by a rotation between the subunits of apposed connexons in the central plane of the junction. A comparable rotational displacement, together with tilting of the subunits, occurs between the two layers of the protein disk of tobacco mosaic virus when it undergoes a transition into the helical assembly found in the virus[21].

We note that radial motion at one end of the connexon could be transmitted through a change of subunit inclination into rotational motion at the other end by a process in which the subunits slide over each other along their lines of contact. The small displacements involved could be accommodated by only very minor distortions of the subunits. Such an action, which is depicted in Fig. 6, seems to describe well the changes in configuration suggested by our maps. The radial displacement of each subunit at the cytoplasmic end should be ~6 Å, given the observed change of inclination of 5°, distributed over its length. Displacement by about this amount is suggested by the details in Fig. 4.

A rearrangement of essentially rigid subunits has not so far been found in oligomeric membrane proteins, but is a common feature of soluble multiple subunit, multi-state assemblies which change their structure and function in response to chemical stimuli. The particular rearrangement in Fig. 6 provides a simple mechanism for opening and closing a narrow channel through a membrane. This mechanism may be the one by which the gap junction regulates the passage of small molecules between living cells. The dimensional changes seem to be of the correct magnitude to account for the observed permeability changes.

IR flashes from the X-ray rapid burster

A. W. Jones, M. J. Selby, C. M. Mountain & R. Wade

We confirm here the report of Kulkarni *et al.*[1] who discovered IR bursts from the X-ray rapid burster, MXB1730−335. We observed two bursts at 2.2 μm, each of energy ~10^{31} J, and a new feature; several bright, brief flashes ($\Delta t < 1$ s) superimposed on the burst continuum. The brevity, luminosity and inferred brightness temperature of the flashes ($T_B \geq 10^{10}$ K) imply a powerful, non-thermal emission mechanism. Simultaneous observations across the whole spectrum with high time resolution would be invaluable in understanding the emission process.

The rapid burster was discovered in 1976 by Lewin *et al.*[2] at MIT and is unique in producing ~10^3 X-ray bursts a day in its active periods. These periods occur about every 6 months and last 2–6 weeks[3]. Liller[4], and Kleinmann *et al.*[5] have shown that the source lies in a compact globular cluster, now called Liller 1, at a distance of 10 kpc. By 1978 it had become clear that the same cluster also produces 'special' bursts[6], similar to those from the more usual X-ray burst sources. They are characterised by a softening of the X-ray spectrum during decay and are now known as Type I bursts. The rapid bursts are classified as Type II. In April 1979 Kulkarni *et al.*[1], observing from Kavalur in India, detected six bursts at 1.6 μm which they attributed to the Type I X-ray bursts.

On 8 August 1979 Type II bursts were seen by the X-ray satellite Hakucho[7], heralding a new period of activity. We attempted IR observations in early September using the 1.5 m IR flux collector at Izaña, Tenerife. The detector was an indium antimonide diode cooled to 75 K. The cooled filter had an effective wavelength of 2.2 μm and a bandwidth of 0.4 μm. We used a two-mirror focal plane sky chopper[8] at 20 Hz, with one beam (20 arc s diameter) centred on Liller 1 and the reference beam 20 arc s to the north. For calibration we used ϕ Ophiuchi ($m_K = 2.27$) taking its flux as $F_\lambda = 4.8 \times 10^{-11}$ W m^{-2} μm^{-1} in accordance with Johnson's[9] absolute flux calibration.

Table 1 lists the dates and times of our observing periods; a total of 5 h 15 min. In this time we saw only two bursts, 1 min apart, on 5 September 1979 (Kulkarni *et al.* saw six in 2.5 h). The chart recording of the bursts is shown in Fig. 1. They appeared at 21 h 04 min 01 s and 21 h 04 min 55 s UT ± 1 s, and lasted 20 s and 10 s respectively. They are similar in shape to the Kavalur bursts, except for the seven sharp spikes accompanying them. Our nominal time resolution, set by the output filter of our phase-sensitive detector (PSD) was 0.3 s, but the widths of two of the spikes (1d and 2c) remain unresolved (see Table 2). The negative-going spike, marked A in Fig. 1, is probably an artefact of the PSD caused by a sudden, rapidly increasing signal. We have been able to reproduce this feature with a laboratory PSD. The other spikes do not seem to be spurious. They appear nowhere else on the chart trace and are closely associated with the structure of the bursts. Assuming they are real, we can properly describe them as flashes.

Table 1 IR observations of the rapid burster

Date (September 1979)	Times (UT) Start (h min)	Finish (h min)	Duration (h min)	No. of bursts
5	20 50	22 10	1 20	2
6	20 20	22 05	1 45	0
11	21 10	21 45	0 35	0
12	20 05	21 40	1 35	0
		Total	5 15	2

In Table 2 we list some observed and derived characteristics of the flashes assuming a distance of 10 kpc and an interstellar absorption of 1.1 mag (ref. 5). With the data from Table 2 and Fig. 1 we can make the following observations.

Why are IR bursts visible at all? The MIT group[10] have measured the spectra of several X-ray bursts, both Type I and Type II, and have fitted them to black-body curves of temperature $T \approx 2 \times 10^7$ K. The inferred radius of the X-ray emitting region is $R \approx 10^4$ m. If we extrapolate the black-body spectrum into the IR we would expect a flux $F_\lambda \sim 10^{-23}$ W m^{-2} μm^{-1} at 2.2 μm; a factor of 10^{11} below our observed value.

Two of the flashes are unresolved at our instrumental time resolution of 0.3 s, putting an upper limit on the size of the emitting region of $R = 10^8$ m. This implies an IR brightness temperature $T_B \geq 4 \times 10^{10}$ K. If we assume that the IR radiation is coming from the same small region as the X rays, T_B rises to an improbable 4×10^{18} K.

If the radiation is isotropic, then the IR burst energies in our 0.4-μm bandwidth are 9×10^{30} J and 6×10^{30} J, and the peak luminosity is 2.2×10^{30} W. This compares with ~10^{32} J and ~10^{31} W for the Type I X-ray bursts[3].

It may be significant that the three flashes in each burst occur at similar times after the initial rise (see Table 2), except

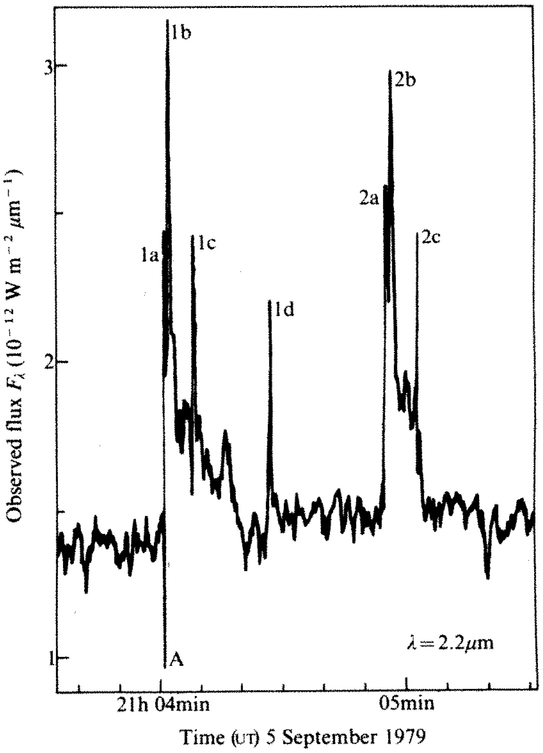

Fig. 1 Two IR bursts from the X-ray rapid burster, accompanied by seven brief flashes. The flux scale is not corrected for interstellar absorption. The feature at A is an artefact of the detection system.

0028–0836/80/060550—02$01.00

Table 2 Details of the IR flashes

Flash no.	Time of peak (s ± 0.1)	Half-peak width (s ± 0.1)	In bandwidth 0.4 μm Luminosity (10^{30} W)	In bandwidth 0.4 μm Energy (10^{30} J)
1a	0.0	0.5	1.3	0.6
1b	1.2	0.9	2.2	1.9
1c	7.0	0.8	1.3	1.0
1d	25.7	0.3	1.0	0.3
2a	54.2	0.6*	1.4	0.8
2b	55.6	1.5	1.9	2.8
2c	61.7	<0.3	1.2	<0.4

The half-peak widths, luminosities and energies were measured with respect to the background on either side of each burst. Isotropic radiation is assumed.

*This is the rise time: the half-peak width cannot be measured.

for the solitary flash 1d, which occurs in the space between the bursts.

Although we observed for 5 h 15 min the bursts appeared in the space of 1 min, suggesting that they may be physically associated. Kulkarni *et al.* noted similar groupings among some, but not all, of their bursts.

There are no clear spikes in the Kavalur bursts, but they did have a lower time resolution (0.6 s) and the signals were 2 or 3 times noisier than ours. It is not clear whether flashes would have been detected if they were there. The difference in wavelength could also be important. If the spectral index of the flashes is different from that of the burst continuum, then the flashes may be apparent at one wavelength but not at another.

We do not intend to go into the details of possible mechanisms, but we conclude: (1) As there have been no simultaneous X-ray/IR observations, we cannot say for certain that our bursts correspond to X-ray bursts; Type I X-ray bursts recur at intervals of hours, while the Type II bursts repeat at intervals of seconds or minutes. The IR bursts observed so far do not fit either category.

(2) If our observations do correspond to X-ray bursts, then the high brightness temperature and unexpectedly intense IR flux strongly suggest a non-thermal emission mechanism. The favoured explanation of the Type I X-ray bursts is a thermonuclear helium flash in accreted material on a neutron star[3,11]. This accounts for the observed X-ray behaviour very well, but does not predict an observable IR flux. Apparao and Chitre[12] propose that the IR bursts are produced by a 'cyclotron maser' operating above the poles of a magnetised neutron star in a close binary system.

Further observations at IR wavelengths should attempt time resolutions of <0.1 s to detect and resolve the flashes. Simultaneous observations at X-ray, optical and several IR wavelengths would be invaluable in understanding the emission process.

We thank Professor P. V. Kulkarni and N. M. Ashok for details of their bursts, and Professor F. Sánchez Martinez of the Cabezon Observatory of the Instituto de Astrofísica de Canarias, La Laguna, for cooperation. A.W.J. and C.M.M. were supported by SRC research studentships and R.W. by an SRC research fellowship.

Semi-empirical estimates of gravitational wave generation by stellar collapse

J. I. Katz

Department of Astronomy and IGPP, University of California,
Los Angeles, California 90024

The problems of the generation and detection of gravitational waves and the difficulty of detecting the burst of gravitational radiation produced by a stellar collapse in our Galaxy, or in neighbouring clusters of galaxies where such collapses are expected to occur frequently, have been reviewed elsewhere[1–3]. As stellar collapses, explosions, or supernovae are poorly understood, the values of the strength of these sources depend on uncertain assumptions. However, it is possible to make some independent estimates on semi-empirical grounds, using observed facts concerning the remnants of stellar evolution. These estimates, reported here, have serious weaknesses. They must involve oversimplified models and very crude standard calculations of the collapse and radiation processes. Also, because they are based on observed properties of stellar remnants, they say nothing about collapses which do not produce observable remnants. Although this selection may introduce a strong bias, these estimates deserve consideration because they are tied to real data.

Consider a simple model for the collapse of a stellar core of mass m into a dense remnant and expelled debris: ignoring the mass and momentum radiated away, the remnant has a mass $(1-\alpha)m$ and a velocity αv; the debris have a total mass αm and their barycentre has a velocity, in the opposite direction to that of the remnant, of $(1-\alpha)v$. If we assume that the debris cloud acts as a point at its barycentre, and that acceleration of remnant and debris occurs over a time t, then it is easy to estimate the emitted power P, energy E, and efficiency ε. The quadrupole moment is given by

$$Q \approx Mv^2t^2\alpha(1-\alpha) \tag{1a}$$

$$|\dddot{Q}| \approx Mv^2\alpha(1-\alpha)/t \tag{1b}$$

The duration of the radiation is also about t. Then

$$E \approx Pt \approx \frac{Gt}{5c^5}|\dddot{Q}|^2 \approx \frac{GM^2v^4}{5c^5t}\alpha^2(1-\alpha)^2 \tag{2a}$$

$$\varepsilon \equiv \frac{E}{Mc^2} \approx \frac{GMv^4\alpha^2(1-\alpha)^2}{5c^7t} \tag{2b}$$

Now we can apply our knowledge of certain classes of collapsed objects. For the X-ray sources in globular clusters a simple argument[4] based on the dynamical properties of the clusters shows that the recoil velocity of the remnant $\alpha v < 10^{-4}c$. For galactic pulsars $\alpha v \approx 10^{-3}c$. Taking $1-\alpha \approx 1$ and, with r the size of the exploding core, $t \approx r/v \approx (c/v)(10GM/c^3) \approx 10GM/vc^2$ gives

$$\varepsilon \approx \frac{1}{50}\left(\frac{v}{c}\right)^5\alpha^2 \tag{3}$$

Although we have an empirical indication of the recoil velocity αv, we must guess at v; take $v = 0.4c$. Then

Table 1 Angular momentum and efficiency of radiation of various objects

Object	l (cm^2 s^{-1})	ε
Neutron star rotating at breakup	10^{16}	10^{-4}
Crab pulsar $P = 0.03$ s	2×10^{14}	10^{-11}
Typical pulsar $P = 1$ s	6×10^{12}	10^{-17}
White dwarf $P = 71$ s	3×10^{16}	10^{-7}
White dwarf $P = 2\times10^3$ s	1×10^{15}	10^{-8}
White dwarf $P = 2$ h	3×10^{14}	10^{-10}

$$\varepsilon < 10^{-11} \quad \text{(globular cluster sources)} \tag{4a}$$

$$\varepsilon \approx 10^{-9} \quad \text{(galactic pulsars)} \tag{4b}$$

These estimates are disappointingly low. They also require very small values of α, in apparent disagreement with the observed masses of supernova debris. The low observed recoil velocities of the compact remnants imply that the core of the explosion is very symmetric; the moderate velocities and high masses of the exploded envelopes imply that the energy released in the core is spread over the massive envelope of the original star, slowing the velocity as a large mass is swept up. Our estimates yield kinetic energies of $<4\times10^{49}$ erg and $\approx4\times10^{50}$ erg from the globular cluster sources and the pulsars respectively, not far from observed supernova energies. The sweeping up of the stellar envelope occurs at much lower densities and on longer time scales than the core collapse, and hence radiates negligible gravitational radiation, despite the greater mass involved. An alternative estimate, assuming massive debris ($\alpha = \frac{1}{2}$), yields even lower values of ε than equation (4) because then the data require small values of v.

The preceding estimates have led to low values of ε because a model for the explosion was chosen in which any gravitational radiation producing asymmetry also produced a net recoil, which is strictly constrained by the data for the observed objects. There are other kinds of varying quadrupole which radiate, but which are not so constrained. Saenz and Shapiro[5] have calculated higher efficiencies from asymmetric core bounces. Another kind of asymmetry, resulting from the flattening of a collapsing rotating object, may be empirically estimated. We have no direct knowledge of the rate of rotation of the cores of ordinary stars before their collapse, but we do know how much angular momentum some of their compact remnants have; the observed spins of white dwarfs and neutron stars may be used as a guide. Accreting compact objects in binaries are observed to rapidly spin up (and, by indirect statistical arguments, must spin down when they are unobservable), so the present spins of neutron stars in X-ray binaries give no information about their spins at birth. The spin of one accreting binary white dwarf (DQ Her) is known to be 71 s. Because of its spin-up, the present period need not reflect the spin of the stellar core before it lost its envelope; nor do we know if the evolution of an accreting white dwarf which undergoes nova outbursts ever leads to collapse. Therefore, we turn to single compact objects for information about the angular momentum of stellar cores at the times of their collapses.

Pulsars are observed with spin periods between 0.03 and several seconds. If the Crab pulsar had been born with a period much faster than its present 0.03 s, the difference in rotational kinetic energy would be much larger than the observed radiated energy, the observed kinetic energy, or the inferred energy of relativistic particles. There is no direct evidence concerning the initial periods of other pulsars. For nonmagnetic DA white dwarfs, well observed objects have spin periods of at least 30 min (ref. 6). There is no evidence for any single nonmagnetic white dwarfs with shorter periods. ZZ Ceti stars may have periods of ~1 d (ref. 7). Magnetic white dwarfs are known[8] with periods of 2 hours and a day; others may have periods >100 yr. Single white dwarfs should not have changed their spin periods appreciably since their formation, unless the periods are many years, in which case interstellar accretion torques may be significant.

For a star flattened by rotation $Q \approx r^5\omega^2/G$, where ω is the spin frequency in rad s^{-1}. During collapse the specific angular momentum l is approximately conserved, and Q changes on the same time scale as the collapse. At neutron star densities where the radiation is produced, $t \approx 20GM/c^3$. Then, using crude conventional estimates as before

$$E \approx Pt \approx \frac{Gt}{5c^5}|\dddot{Q}|^2 \approx \frac{Gt}{5c^5}\left(\frac{rl^2}{Gt^3}\right)^2 \approx \frac{r^2l^4}{5c^5Gt^5} \tag{5}$$

For ordinary stellar cores $t \approx 10^{-4}$ s, $r \approx 10^6$ cm, and the efficiency is given by

$$\varepsilon \equiv \frac{E}{Mc^2} \approx \frac{r^2l^4}{5GMc^7t^5} \approx (10^{-68}\ \text{s}^4\ \text{cm}^{-8})l^4 \tag{6}$$

Table 1 gives the values of l and ε corresponding to various objects. The value for the neutron star rotating at breakup is within an order of magnitude of a detailed calculation[9], indicating the adequacy of our estimates. A white dwarf with a 71-s period would have $l \approx 3\times10^{16}$ cm^2 s^{-1}, exceeding l for a neutron star at breakup. Angular momentum would prevent the dynamic collapse of such an object to neutron star densities, reducing ε far below the value corresponding to the maximally rotating neutron star; ε is not a monotonic function of l. The collapse stops at a radius $r \approx l^2/GM$ on a time scale $t \approx (r^3/GM)^{1/2}$; equation (5) then leads to

$$\varepsilon \approx \frac{1}{5}\left(\frac{GM}{cl}\right)^7 \approx (5\times10^{108}\ \text{s}^{-7}\ \text{cm}^{14})l^{-7} \tag{7}$$

The further collapse of such an object is slow, because it depends on processes of angular momentum transport. Equation (7) is used on the fourth line of Table 1. Only for a narrow range of l can ε approach the value for a neutron star rotating at breakup.

The values of ε in Table 1 are again disappointingly small, especially when one recalls that both the neutron star rotating at breakup and the 2,000-s white dwarf are hypothetical objects, and that the 71-s white dwarf is the product of unusual circumstances.

It is possible that stellar collapse is an efficient ($\varepsilon \approx 10^{-3}$) source of gravitational radiation, but this is not implied by any existing data. If we try to set a semi-empirical lower limit we find $\varepsilon \approx 10^{-11}$ from the rotation of the Crab pulsar, or $\varepsilon \approx 10^{-10}$ from that of the white dwarf with a 2-h period. The recoil velocity of pulsars may suggest $\varepsilon \approx 10^{-9}$. As pointed out by Smarr[10] it is important to obtain further data on the rotation of white dwarfs and the initial spins of neutron stars.

This work was supported in part by NASA and the NSF. I thank Rueben Epstein and Jesse Greenstein for discussions, and the Dominion Astrophysical Observatory, Victoria, B.C. for hospitality. I am an Alfred P. Sloan Fellow.

North Atlantic Deep Water formed by the later middle Miocene

There is evidence that in Mesozoic and Palaeogene times both north and south subpolar areas had a mild climate[1,2]. Unlike the present day climatic symmetry, with warm equatorial regions and ice-covered polar regions, a strong planetary asymmetry developed in the middle Miocene, when the Antarctic ice cap was established while the northern high latitudes remained unglaciated[3]. The symmetry was restored when a Northern Hemisphere continental ice cover was established ~3 Myr ago in the middle Pliocene[4]. These changes influenced the formation of deep water in the ocean. At present the cold, dense bottom waters originate in only two high latitude areas—the Weddell Sea producing Antarctic Bottom Water, and the Norwegian Sea, producing Norwegian Sea Overflow Water which after mixing is a major component of the North Atlantic Deep Water. The production of cold deep water in the Southern Ocean started at the Eocene–Oligocene boundary[3]. We present here new evidence from isotope analyses of benthic Foraminifera from DSDP site 116 indicating that the production of oxygenated deep water in the North Atlantic Ocean started in the late middle-Miocene, ~12 Myr ago.

Site 116 (57°29′ N–15°55′ W) is on the Rockall Plateau, a shoal area at a depth of ~1,000 m. It is separated from Ireland and the Porcupine Bank by the Rockall trough and is on the present path of Norwegian Sea Overflow Water which spills through the Faeroe sill into the North Atlantic[5]. The Rockall Plateau has a continental basement and had already subsided to a depth of >1,000 m by the end of the Oligocene. The physiography of the area has not changed during the whole Neogene[5]. It is thus an ideal place to investigate the initiation of the production of cold deep water in the Northern Hemisphere.

Isotopic analyses have been performed on benthic Foraminifera from almost every section of cores 2–18, hole 116 and cores 8–11, hole 116A. Our analytical procedures[6] are identical to those described by Shackleton[7,8]. Results are expressed as

$$\delta = \left[\frac{R\text{ sample}}{R\text{ standard}} - 1\right] \times 10^3$$

where R is the isotopic ratio $^{18}O/^{16}O$ or $^{13}C/^{12}C$ and the standard used is the PDB standard.

In 71 samples, down to core 116–12, only aliquots composed entirely of *Cibicides* were analysed. In 22 samples, from core 116–15 to 18, mixed benthics have been used but the $\delta^{18}O$ results have been corrected by −0.23‰ and the $\delta^{13}C$ by +0.66‰ to make up for the mean difference observed in cores 116–11 and 12, where both *Cibicides* and mixed benthics have been analysed for calibration. Values will be tabulated elsewhere.

The $\delta^{18}O$ results are displayed in Fig. 1*a* together with those from sites 281 and 279, which are representative of the Southern Ocean, near the Antarctic Bottom Water source[3]. Only stratigraphic correlations[3,5] which are independent of the isotopic record have been used. These data indicate that the main $\delta^{18}O$ events (the late early-Miocene isotopically light peak, followed by an increase throughout the middle Miocene) are synchronous at these sites. We therefore consider that the stratigraphic correlations are satisfactory down to the late early-Miocene. The analyses at sites 279 and 281 were performed on *Uvigerina* or mixed benthics, while our site 116 analyses have been done on *Cibicides*, or corrected for departure from *Cibicides* when mixed benthics have been used. *Cibicides* has been shown[9,10] to be isotopically lighter than *Uvigerina* when taken from the same sediment. Moreover, site 279 is >2,000 m deeper than site 116 and is at present ~2 °C cooler. These effects combine to make the $\delta^{18}O$ values at site 116 consistently ~1% lighter than those for the southern sites. Nevertheless, data from both regions show trends similar to those already observed in other oceans[11–13]. We find generally low $\delta^{18}O$ values in the early Miocene sediments, up to core 116–10 (foraminiferal zones N8 and N9, ~16 Myr BP) followed by a general increase. This shift has been interpreted as corresponding to the establishment of the Antarctic ice cap[3,14]. This increase is not monotonic; oscillations of an amplitude of as much as 1‰ occur in $<10^5$ yr according to the published sedimentation rate of 2.4 cm kyr^{-1}. The values remain more stable, with a noise reduced to 0.5‰, during the late Miocene and early Pliocene (cores 116–6 to 2, 116A–11 and 10). A second much smaller increase in $\delta^{18}O$ is then registered, probably reflecting the inception of continental ice sheets in the Northern Hemisphere at ~3 Myr BP (core 116A–9). The oscillations above this level mark the Quaternary glaciations. The similarity of the $\delta^{18}O$ records at site 116 and in the other oceans during the Miocene and the early Pliocene time shows that the thermal history of the deep North Atlantic has been the same as that of the other deep water masses.

We also measured the $\delta^{13}C$ of benthic Foraminifera, which primarily reflects the $^{13}C/^{12}C$ ratio of the CO_2 dissolved in the deep water. $\delta^{13}C$ values will be modified if the rate of cycling through the exchangeable CO_2 reservoir changes. The two main causes of such a change are: (1) a modification of the volume of one part of the exchangeable CO_2 reservoir, for instance, an increase or a decrease in the continental biomass[9]. Such a modification, being extra-oceanic, must be felt equally in all oceans and the $\delta^{13}C$ must change everywhere in the same way; (2) a change in the residence time of the deep water masses: a longer residence time favours the conversion through oxidation of ^{13}C-depleted carbon from marine organic matter to dissolved bicarbonate. The longer the residence time, the lower the $\delta^{13}C$ (refs 15–17). This cannot explain a change in the $\delta^{13}C$ of the world ocean as a whole: the rate of cycling of carbon through the ocean can only be changed through a change in the turnover of the deep water masses. This in turn must have local causes, such as a change in the ratio of production of cold, dense bottom water, but such causes would have different effects on the $\delta^{13}C$ of the various ocean basins according to their distance and accessibility from the source.

Figure 1*b* compares the $\delta^{13}C$ for site 116 and for sites 279 and 281. Both curves begin with rather low values in the lowermost Miocene section. Towards the end of the early Miocene there is a fairly sharp increase in $\delta^{13}C$; this increase is of similar magnitude at both sites: 1.1‰ at site 279 and 1.2‰ at site 116. High values seem to persist longer in the Southern Ocean than in the North Atlantic, but this may be due to stratigraphic error in the comparison of the curves. During the middle Miocene the $\delta^{13}C$ values decrease to the previous early Miocene average at both sites.

So between the early and middle Miocene the parallelism in the trends of the $\delta^{13}C$ at both sites shows that the causes for the $\delta^{13}C$ changes were extra-oceanic. In contrast, we have no indication of a modification of the chemistry of CO_2 in the oceans, an indication that the residence time of the deep water masses remained constant.

After the late middle-Miocene (core 116–7, ~12 Myr BP) the carbon isotopic record in the North Atlantic acquires a character different from that of the South Pacific. While the $\delta^{13}C$ at site 281 continues to decrease, at site 116 there is a new increase in $\delta^{13}C$ of *Cibicides* of as much as 0.7‰ when measured on peak values. This is followed by stabilisation at values on average 0.3‰ above those of the earliest Miocene. These late Miocene $\delta^{13}C$ values are the same as those of Holocene *Cibicides* from

0028–0836/80/060553—03$01.00

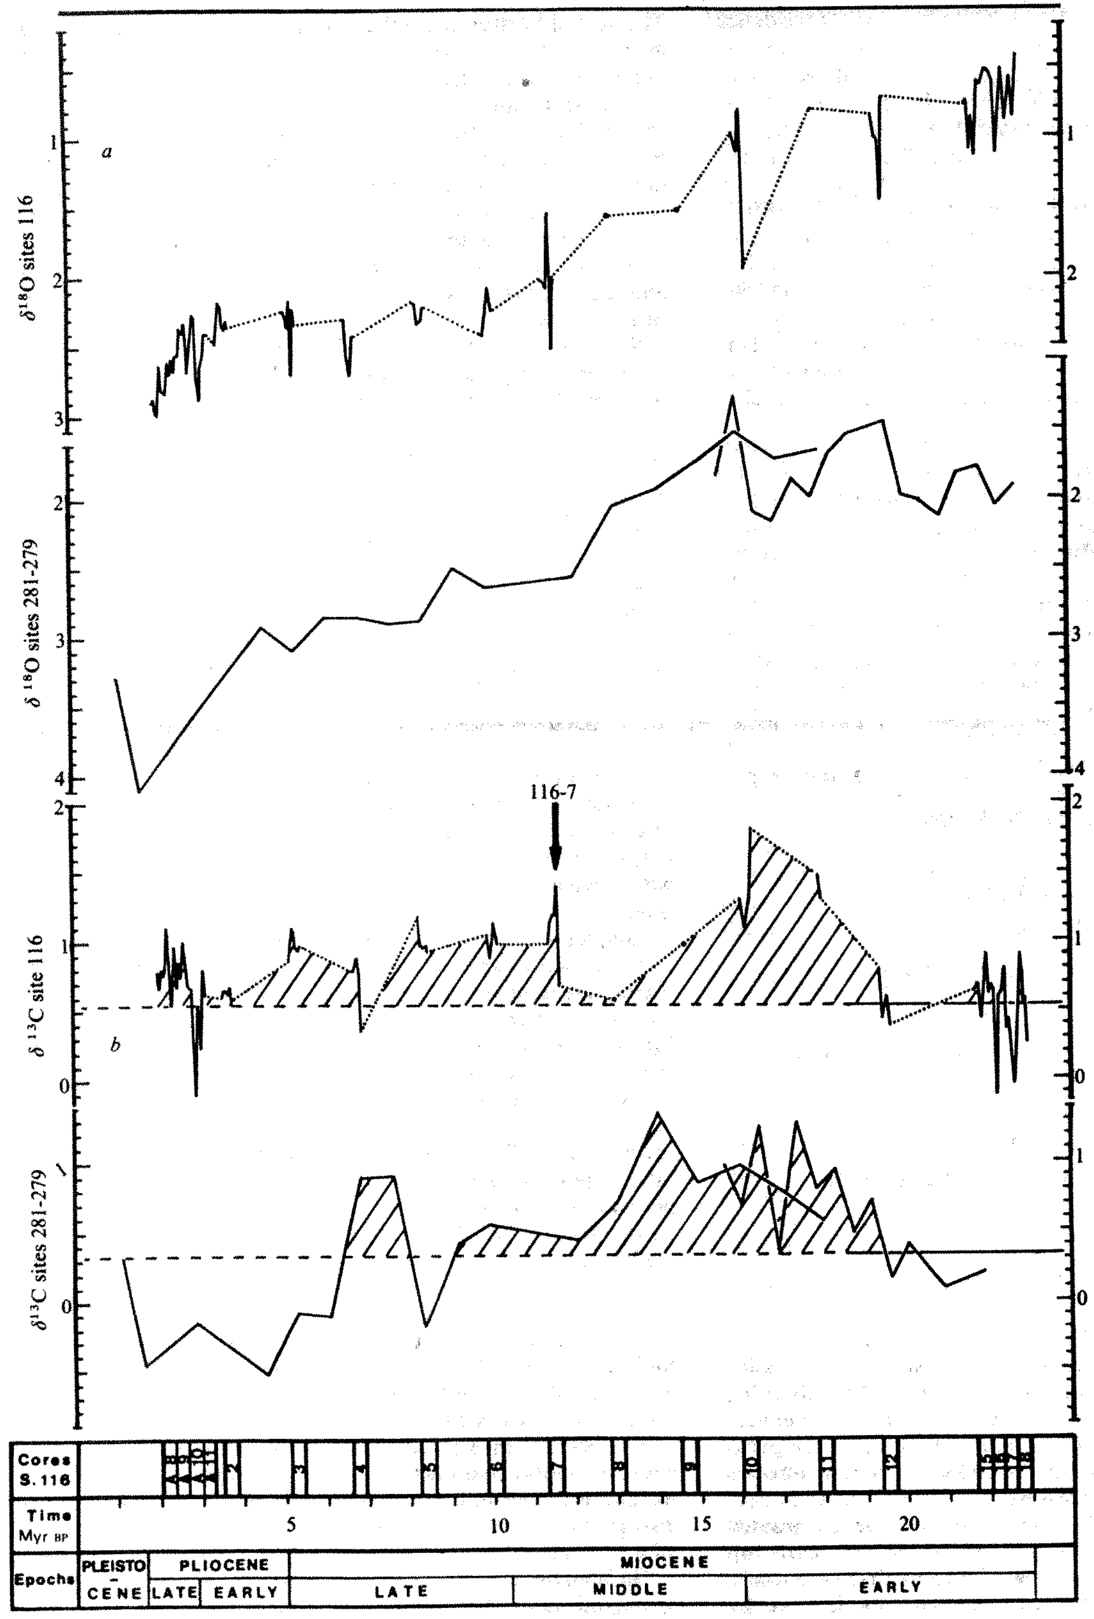

Fig. 1 Oxygen and carbon isotopic composition of benthic Foraminifera at DSDP site 116 (North Atlantic) compared to DSDP sites 279 and 281 (Southern Ocean). For comparison, a dashed line showing the average $\delta^{13}C$ for the early Miocene has been drawn throughout each ^{13}C curve and the area above this line has been shaded.

piston core CH 73139 C taken on the Feni ridge (J.-C.D., unpublished results). In the same way, at equatorial Atlantic site 366, the benthic Foraminifera, which also lived in the North Atlantic Deep Water, show $\delta^{13}C$ values similar to the present day values down to the late- to middle-Miocene boundary. Those values are ~0.8‰ below the late early-Miocene peak values, in comparison with 0.9‰ difference at site 116. The records are thus similar at both sites, but at site 366 a condensed sequence encompassing most of the middle Miocene precludes any accurate observations of the carbon shift[18].

Thus, at ~12 Myr BP the deep water in the North Atlantic Ocean became significantly richer in ^{13}C than before. No such enrichment is found in the Southern Ocean which indicates that it is a local North-Atlantic event. The present residence time of the North Atlantic Deep Water is short, and as the $\delta^{13}C$ of *Cibicides* has been of the same order during the past 12 Myr then this residence time must have been short during that period. Although the amplitude of the ^{13}C-shift in core 116–7 is difficult to estimate accurately, it is of the same order as the difference presently observed between the North and South

Pacific deep waters[15-17]. This shows that the previous residence time of the North Atlantic Deep Water was high, reflecting its great distance from the Deep Water source. No cold deep water was produced in this area as the coasts of the North Atlantic Ocean, which did not yet communicate with the Norwegian–Greenland sea, still enjoyed mild climates. The southern high latitudes were then the only sources of cold bottom water. The present influence of Antarctic Bottom Water is felt as far as 40° N in the Atlantic Ocean. Until the middle Miocene, it must have been felt even further north, as it now does in the North Pacific.

We have assumed that the late middle-Miocene age for the initiation of North Atlantic Deep Water depends on the stratigraphic interpretation of the fossil record at site 116. This interpretation was made difficult by the discontinuous coring, the severe drilling disturbance and the high latitude of the site. The date of 12 Myr BP for the same event is even more tentative, as it also relies on correlations between biostratigraphic events and radiometric dates.

Still, this date is in remarkable agreement with the age assumed for the subsidence of the main platform of the Iceland–Faeroe ridge below sea level[19,20]. The area of production of cold dense water must thus have been north of the ridge, either in the Norwegian Sea as it is today or further north in the Arctic Ocean. The appearance of this water south of the ridge is mainly a consequence of a tectonic process, and not of a climatic event, although cold winters are necessary to initiate the sinking of the surface water.

We thank the NSF for DSDP samples, also B. Le Coat and J. Antignac for help in the isotope analyses, and S. M. Savin and R. K. Matthews for useful comments.

Late Miocene palaeo-oceanography of the Atlantic: oxygen isotope data on planktonic and benthic Foraminifera

R. K. Matthews, W. B. Curry, K. C. Lohmann & M. A. Sommer

CENOP, Department of Geological Sciences, Brown University, Providence, Rhode Island 02912

R. Z. Poore

CENOP, US Geological Survey, Menlo Park, California 94025

The oxygen isotopic compositions of tests of Foraminifera are quantitatively related to global ice volume[1,2] and local temperature and salinity conditions in which the Foraminifera grew[3-8]. Thus, a well-preserved sample of deep-sea core contains information about sea-surface temperature (shallow-dwelling planktonic Foraminifera), structure of the thermocline (deeper-dwelling planktonic Foraminifera), and bottom water temperature (benthic Foraminifera), and the global ice volume effect is also superimposed. The progress which has been made in calibration of core–top isotopic data to modern oceanographic data[5,7,8], has led us to test state-of-the-art core–top methodology and calibration on a late Miocene time slice (6.0 ± 0.5 Myr BP) of the Atlantic Ocean. Samples studied can be related to either uppermost Zone NN11 or lowermost NN12 of Martini[9] and uppermost Zone N17 of Blow[10].

Our experimental design was as follows. We selected core samples representing a wide range of latitude because simultaneous consideration of bottom water conditions and high-latitude and low-latitude surface conditions imposes important constraints on interpretation of isotopic data. Then we sampled tightly controlled size fractions of numerous species of both planktonic and benthic Foraminifera from each sample. By sampling numerous species, our data should include the isotopically lightest and heaviest of the planktonic Foraminifera. We evaluated possible diagenetic alteration of Foraminifera wall structure using cathodoluminescence and scanning electron microscopy. Recrystallisation and/or precipitation of calcite after sediment deposition can seriously affect palaeo-oceanographic information. Finally, we compared analytical results with calculated values for the modern ocean and other explicit models.

Samples selected for study were washed, picked, and ultrasonically cleaned at the US Geological Survey, Menlo Park, taking care not to expose materials to high temperature or harsh chemicals. (Taxonomic identifications were done by R.Z.P.). Machine-ready Foraminifera samples were then shipped to Brown University where they were roasted *in vacuo* at 380 °C for ~1 h, reacted *in vacuo* with water-free polyphosphoric acid at 50 °C, and analysed on an on-line VG Micromass 602D mass spectrometer. PDB calibration via calcite standards from three other laboratories is within ±0.2‰ of these laboratories. Ten percent of all data were randomly duplicated with an average $\frac{1}{2}\Delta \pm 0.06$‰ for $\delta^{18}O$ and ±0.08‰ for $\delta^{13}C$. Our results are presented in Table 1 and Fig. 1. (Analytical details are available from the authors.)

Species lists in Table 1 are ranked on the basis of oxygen isotopic composition of the largest size fraction analysed, isotopically lightest (shallowest-dwelling planktonic Foraminifera) to isotopically heaviest (benthic Foraminifera closest to equilibrium). Note that although benthic $\delta^{18}O$ values in DSDP 116, 5/5, 119–121 cm are extremely light, we report these data because there is no objective reason to reject these analyses. As we did not have sufficient material to repeat the analyses we disregard all data from this sample in favour of data on 116, 5/5 143–145 cm.

The similarity between $\delta^{18}O$ species ranking in Table 1 and analogous core–top data is encouraging. High latitude sites (408 and 116) exhibit <1‰ variation among planktonic species whereas low latitude sites (98 and 366A) exhibit approximately 3‰ variation from isotopically lightest to isotopically heaviest planktonic Foraminifera. These relationships are quite similar to core–top studies[5,8]. Further, *G. sacculifera, G. triloba, O. universa, G. cultrata* (s. 1.), and *G. scitula* are all well known from plankton tow and core–top[5,7,11,12,13] and display generally similar rankings in most of our late Miocene samples.

Figure 1 compares late Miocene and modern $\delta^{18}O$ values with latitude. Late Miocene palaeo-oceanographic conditions are deduced by comparing the Miocene data with the appropriate values calculated from modern conditions[8].

Planktonic species lists are ranked on the basis of $\delta^{18}O$ of the largest size fraction.

* We disregard data on this sample in favour of data on 116, 5/5, 143–145 cm.

† We disregard data on this sample in favour of data on 554 cm; diagenesis apparent.

Four features of Fig. 1 are important for interpreting our late Miocene data. First, late Miocene $\delta^{18}O$ benthic data values for *P. wuellerstorfi* and *G. subglobosa* differ from calculated modern benthic equilibrium values by −1.0‰ and −0.5‰, respectively. These values match observed Holocene departures of these species from equilibrium. Second, the isotopically lightest late Miocene values at each of the three North Atlantic sites (408, 116, and 335) are in remarkable agreement with calculated values for the modern summer. A similar correlation of isotopic data to summer conditions has been noted in core-top studies[8]. Third, consider the relation of isotopically heaviest planktonic Foraminifera species to the value calculated for the modern equal density surface, $\sigma_T = 26.8$. Curry has shown this surface to be the habitat of deepest-dwelling *Globorotalia* in core-top and 18,000 yr BP materials from the Indian Ocean[8,14]. Note the outstanding agreement in Fig. 1 between isotopically heaviest late Miocene planktonic Foraminifera and the calculated $\delta^{18}O$ values for the modern $\sigma_T = 26.8$ surface. Finally, there is a general discrepancy between isotopically lightest values at Sites 98, 366A, and CH115-86 and the calculated values for modern

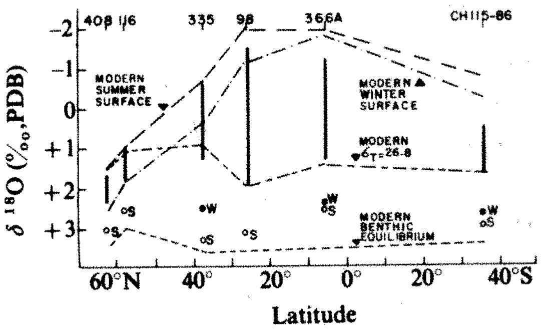

Fig. 1 Transect of the Atlantic Ocean depicting late Miocene observed and modern expected δ^{18}O values on planktonic and benthic Foraminifera plotted versus latitude. Numbers across the top are sample sites. Late Miocene δ^{18}O data on planktonic Foraminifera (bars) and benthic Foraminifera (○, *G. subglobosa*; ●, *P. wuellerstorfi*). Dashed lines represent modern expected δ^{18}O values for equilibrium with summer and winter sea-surface conditions, the 26.8 σ_T surface and bottom water. Observed late Miocene data agree well with modern expected values except for anomalously heavy surface isotopic values for Sites 98, 366A, and CH115-86. The discrepancy at CH115-86 is beyond the error of measurements and calculations and, therefore, requires explanation. See text for the three alternative hypotheses.

surface conditions. In particular the discrepancy between the data for CH115-86 and the calculated values demands an explanation.

Although three of these comparisons suggest the late Miocene Atlantic was indistinguishable from the modern, the final one contradicts this conclusion. To bring these comparisons into agreement over similarities and differences between late Miocene Atlantic and the modern, we consider three hypotheses: (1) late Miocene ice volume was larger than today; (2) site CH115-86 was significantly colder in late Miocene than it is today; and (3) the surface-dwelling Foraminifera at CH115-86 yield heavy δ^{18}O values because they have undergone significant shallow burial diagenesis.

(1) If the discrepancy between late Miocene and modern at CH115-86 is attributed to greater ice volume in late Miocene, then this effect must also be superimposed on sea-surface and benthic data for all other sites[1,2]. The agreement between benthic data and high latitude North Atlantic surface data, and modern conditions, means that any proposal for an increased ice volume must be accompanied by a proposal of increased water temperature in those sectors. While such a proposal is not out of the question, we suggest that global ice volume, Atlantic bottom water temperatures, and North Atlantic sea surface temperatures in late Miocene were similar to modern and seek some other explanation for the discrepancy at CH115-86.

(2) If one considers that site CH115-86 really was four or five degrees colder in late Miocene than it is today, one plausible palaeo-oceanographic cause of this cooling is that surface gyre circulation was less intense in the late Miocene. This would reduce the zonal anomaly at Sites 98 and CH115-86, making both sites cooler than today. However, faunal evidence that argues against this interpretation. Planktonic Foraminifera assemblages (>149 μm size fraction) in modern sediments from the vicinity of CH115-86 contain ~5% of the tropical Foraminifera, *G. sacculifera*[15]. Counts of the >177 μm size fraction of CH115-86 samples show that *G. sacculifera* is at least 10% and sometimes as much as 20% of late Miocene faunal assemblages. Therefore, we assume sea surface temperatures in the vicinity of CH115-86 were not significantly cooler during the late Miocene than they are today.

(3) There is good reason to believe that the samples at CH115-86 (and those at Site 98) have undergone some shallow burial diagenesis. Both sites are situated above the modern aragonite compensation depth. If aragonite is buried with the sediment, the greater solubility of aragonite surely drives a dissolution/reprecipitation process through which calcite is precipitated onto pre-existing calcite nuclei such as planktonic Foraminifera. In the simplest situation, this new calcite grows from pore fluid with oxygen isotopic composition similar to bottom water and at bottom water temperatures. Precipitation of such calcite would bring isotopic values for surface-dwelling planktonic Foraminifera closer to those observed for benthic Foraminifera. The isotopic data for sample CH115-86, 702 cm, is consistent with this hypothesis. Isotopic values for benthic Foraminifera in this sample are consistent with values obtained on CH115-86, 554 cm, yet all values of *G. triloba* in the 702 cm are significantly heavier than the values for *G. sacculifera* in the 554 cm sample, and the fine fraction *G. triloba* and *G. dehiscens* in the 702 cm sample have isotopic values approaching those of benthic Foraminifera. Examination of the *G. sacculifera* material from the CH115-86 samples gives a clear indication of precipitation of calcite cement onto the interior wall of the foraminiferal tests as well as partial dissolution of original wall material.

Three out of four important comparisons between modern Atlantic and late Miocene Atlantic, yield indistinguishable δ^{18}O values for the two oceans. We are optimistic that stable isotope data can be used to quantify several important aspects of palaeo-oceans and to place extinct species within their three-dimensional ecological context in still older palaeo-oceans. We are convinced that diagenesis can seriously compromise the palaeo-oceanographic integrity of foraminiferal isotopic data, but that it can be recognised and avoided. Care should be taken in future studies on samples which may have been deposited above the aragonite compensation depth, and scanning electron microscopy and chemical studies should be used to demonstrate the palaeo-oceanographic integrity of materials submitted to isotopic analysis.

Isotopic data for scleractinian corals explain their palaeotemperature uncertainties

New data on the variability of the oxygen isotope composition of water on a coral reef reveal that there are large changes in δ^{18}O linked to high evaporation rates and precipitation. This together with variation in growth rate is sufficient to mask large water temperature variations, which otherwise would be reflected in

the skeletal oxygen isotope ratio. The carbon isotope ratio in the skeleton, however, does vary probably as a result of growth rate. In contrast to previous studies only the most recently formed part of the skeleton was used to reduce the possibility of diagenetic additions which would distort the results.

Calcium carbonate precipitated from water by marine organisms has an oxygen isotope composition which is temperature dependent[1,2]. This has been used for Foraminifera which secrete carbonate in equilibrium with seawater to map palaeotemperature variations through the Pleistocene[3]. Weber and Woodhead[4] have shown that although corals fractionate both the carbon and oxygen isotopes, the slope of the temperature relationship is similar to that determined by Epstein *et al.*[2]. Most corals are characterised by alternating bands of dense and less dense skeleton. The denser layer is believed to be a result of thickening of the skeletal components and a closer bundling of the aragonite crystals. Attempts to use the temperature dependence of the ^{18}O ratio to determine in which part of the year the denser bands were formed have led to conflicting conclusions[5–7]. From isotopic evidence Weber *et al.*[5] concluded that the bands were formed during the warmer part of the year and although similar trends were noticed by Goreau[6] he discounted the trend as the corals which he examined formed their dense bands in the winter when the temperature is low. Emiliani *et al.*[7] suggested that the denser bands could be produced in both summer and winter, however, they also noted a broad inverse correlation between $\delta^{13}C$ and $\delta^{18}O$ in contrast to other researchers who found positive correlations[8–10] and Goreau who found no correlation at all[6]. In contrast to oxygen, the carbon isotope ratio may be related to growth rate. Emiliani *et al.*[7] concluded that during the slower growth of the coral less fractionation occurred and therefore $\delta^{13}C$ approached that of seawater. However, considering other reports[8,11] that corals growing at depth are depleted in ^{13}C with respect to corals growing near the surface, this explanation apparently is not plausible, as surface corals generally have much higher growth rates[12].

The palaeotemperature equation developed by Epstein *et al.*[2] and modified by Craig[13]

$$T = 16.9 - 4.21(\delta c - \delta w) + 0.14(\delta c - \delta w)^2$$

shows that the oxygen isotope composition of a carbonate is not only a function of temperature but also depends on the isotope composition of the water; $\delta c - \delta w$ is the measured difference between the carbonate and water. For seawater, variations in $\delta^{18}O$ are related to changes in salinity[14], but previously, local and short-term variations were considered to have a negligible effect on the $\delta^{18}O$ of skeletal carbonates. In an attempt to examine these effects on the aragonite skeletons of a scleractinian reef coral, samples of water and specimens of *Acropora cuneata* were collected in January 1978 from three sites across the reef profile at Heron Island, Australia.

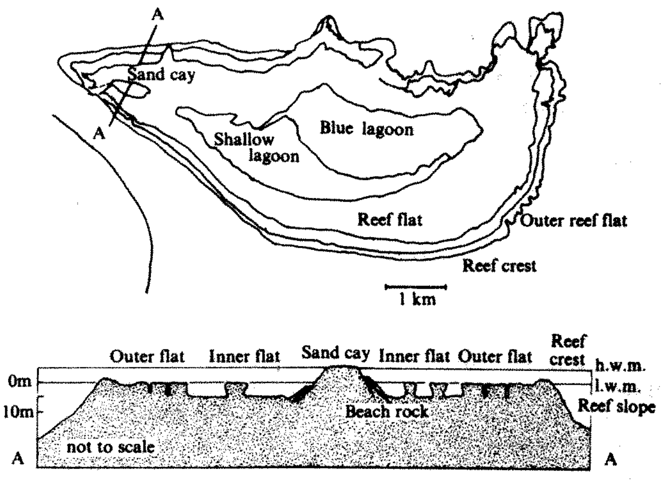

Fig. 1 The physiographic zonation and cross-section of Heron Island Reef.

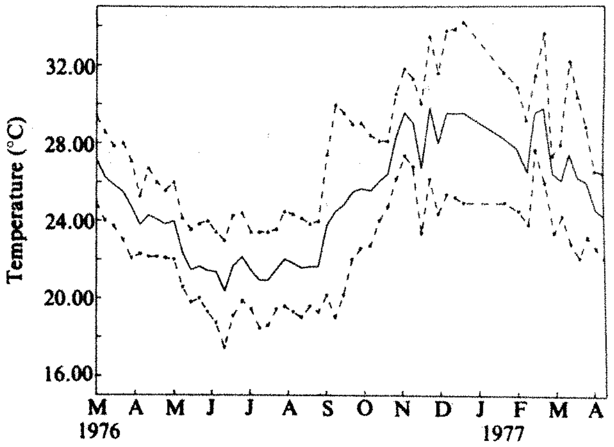

Fig. 2 Average weekly seawater temperatures on the reef flat at Heron Island, March 1976–April 1977 (unpublished data from D. Potts). The maximum and minimum temperatures are shown by the dashed lines.

Heron Island is a typical lagoonal platform reef[15], near the southern end of the Great Barrier Reef, showing standard reef zonation (see Fig. 1). The reef flat has been shown to experience diurnal temperature variations as high as 12 °C (ref. 16) (Fig. 2), whereas off the reef temperature ranges are small. These variations arise at low tide, during which there may be several hours of slack water. At this time, the semi-isolated pools on the reef flat may become subjected to intense heating resulting in changes in temperature and salinity. However, changes in salinity also result from evaporation caused through high wind speeds and dilution due to rainfall. Water samples were collected over a 3-month period, mainly from the reef flat, to determine the range of salinity and $\delta^{18}O$ variation. These results are shown together with the data of Lowenstam and Epstein[14] in Fig. 3.

For the carbonate isotope analysis only the terminal growth portion of each specimen was used to avoid the possibility of any diagenetic carbonate being present. Diagenetic additions occur very shortly after initial growth and their presence would distort the result. Before analysis, the organic material known to be intimately associated with the skeleton must be removed, as the organic molecules in the extracted gas interfere with the analysis: (the effects of the organic material has been summarised elsewhere[11]). As removal of organic material with sodium hypochlorite solution or roasting in a helium atmosphere may alter the isotope ratio, the organic material was removed in a low temperature oxygen plasma furnace. Periods of up to 12 h had no affect on the isotopic composition of either control samples or the laboratory standard.

For isotopic analysis, carbon dioxide was extracted from the carbonate by the normal method, reaction with phosphoric acid[17]. This process involves an isotopic fractionation of oxygen which is different for calcite and aragonite (1.01025 and 1.01034, respectively[18]). As the samples were analysed with reference to a calcite standard, the $\delta^{18}O$ values shown in Fig. 4 were corrected for this effect (as well as the usual isobaric interferences and instrumental effects[19,20]). Similarly, calcite and aragonite precipitated at the same temperature have different isotopic compositions[21,22] for which a correction must be made if attempting to calculate temperature, or isotopic composition of the water. Previous papers on corals[5–11] have not stated whether any of these correction factors were applied.

Corals growing on the reef flat (Fig. 1) might be expected to reflect the large temperature variations as well as the changes in the $\delta^{18}O$ content of the water in their skeletons. Corals growing on the reef slope which is a much more stable environment should be isotopically more uniform. However, Fig. 4 shows that there are no discernable differences in the $\delta^{18}O$ between the three environments even though the heaviest oxygen values occur off the reef flat as one might expect if there were a temperature relationship. As far as the $\delta^{13}C$ value is concerned, there is a statistically lower value on the reef slope, thereby confirming previous results[8,11]. Woodhead's[12] statement that corals at Heron Island on the reef slope have a much lower growth rate than those on the reef flat supports the idea of Goreau[6] that faster growing corals utilise more inorganic carbon relative to metabolic carbon which has more negative values.
